Medicine

Davidson's

Principles and Practice of

Medicine

21st Edition

Sir Stanley Davidson (1894–1981)

This famous textbook was the brainchild of one of the great Professors of Medicine of the 20th century. Stanley Davidson was born in Sri Lanka and began his medical undergraduate training at Trinity College, Cambridge; this was interrupted by World War I and later resumed in Edinburgh. He was seriously wounded in battle, and the carnage and shocking waste of young life that he encountered at that time had a profound effect on his subsequent attitudes and values.

In 1930 Stanley Davidson was appointed Professor of Medicine at the University of Aberdeen, one of the first full-time Chairs of Medicine anywhere and the first in Scotland. In 1938 he took up the Chair of Medicine at Edinburgh and was to remain in this post until retirement in 1959. He was a renowned educator and a particularly gifted teacher at the bedside, where he taught that everything had to be questioned and explained. He himself gave most of the systematic lectures in Medicine, which were made available as typewritten notes that emphasised the essentials and far surpassed any textbook available at the time.

Principles and Practice of Medicine was conceived in the late 1940s with its origins in those lecture notes. The first edition, published in 1952, was a masterpiece of clarity and uniformity of style. It was of modest size and price, but sufficiently comprehensive and up to date to provide students with the main elements of sound medical practice. Although the format and presentation have seen many changes in 20 subsequent editions, Sir Stanley's original vision and objectives remain. More than half a century after its first publication, his book continues to inform and educate students, doctors and health professionals all over the world.

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

Preface

Since *Davidson's Principles and Practice of Medicine* was first published in 1952, over two million copies have been sold and the book has acquired a large following of medical students, doctors and other health professionals all over the world. It has been translated into many languages, most recently Russian and Polish, and has won numerous prizes, the last edition receiving an award from the Society of Authors and the Royal Society of Medicine. *Davidson's* has endured because with each new edition it has evolved to provide comprehensive updated information in a format suitable for its contemporary readership, and yet it has remained concise and easy to read. This 21st Edition has been extensively updated and revised, but has not increased in length or size.

Since its beginnings, *Davidson's* has sought to explain the basis for medical practice. The integration of 'pre-clinical' science with clinical practice is now a feature of many undergraduate medical curricula, and many students use *Davidson's* from the outset of their medical course. In recognition of this, the first part of the book, 'Principles of Medicine', highlights the mechanisms of health and disease, along with the professional and ethical principles underlying medical practice. Many examples of clinical problems are included to bring the medical sciences to life for the new student and to rejuvenate the interest of the experienced clinician. The second part of the book, 'Practice of Medicine', covers the major medical specialties. Every chapter has been rewritten for this edition to ensure that it reflects the 'cutting edge' of medical knowledge and practice, pitched at a level of detail to meet the needs of candidates preparing for examination for Membership of the Royal College of Physicians or its equivalent.

Many of the innovations introduced in recent editions have been warmly received. We have retained the ever-popular 'Clinical Examination' overview pages and the patient-orientated approach in the 'Presenting Problems' sections, while enhancing the book's practical content with a new series of 'Emergency' and 'Practice Point' boxes. Embedding horizontal themes within the book—for example, with the 'In Old Age' boxes—has been applauded, and we have extended this approach by adding 'In Pregnancy' boxes in relevant chapters. The inclusion of both SI and non-SI units in the last edition proved popular and has been maintained.

We are proud of *Davidson's* international heritage. As well as recruiting authors from around the globe, particularly for topics such as Infectious Diseases and Envenoming, we have welcomed new members on to our International Advisory Board. These leading experts provide detailed comments that, along with the feedback received from our global readership, are crucial to our planning of every chapter in each new edition. In 2006, we had the privilege of visiting several medical schools on the Indian subcontinent and were delighted with the enthusiasm of the students and teachers that we met, and the very useful criticisms and feedback they provided. We have tried to address as many of these as possible in this edition.

Education is achieved by assimilating information from many sources and we are delighted that readers of this book can enhance their learning experience using complementary resources. The StudentConsult platform continues to provide online access to the text and illustrations of the main edition. *Davidson's* has had a long-standing association with its sister books, *Macleod's Clinical Examination* (now in its 12th Edition) and *Principles and Practice of Surgery* (now in its 5th Edition). The *Davidson's* 'family' has now expanded with the publication of *Essential Davidson's*, a long-requested pocket-size version of the main text; *Davidson's Foundations of Clinical Practice*, an indispensable guide to starting work as a junior doctor; and *Davidson's Clinical Cases*, which contains over 90 cases based on the 'Presenting Problems' in the main text. We congratulate the editors and authors of these books for continuing the tradition of concise, easily read and beautifully illustrated text.

The regular introduction of new authors and editors to *Davidson's* is important to maintain the freshness of each new edition. On this occasion, Professor Stuart Ralston has joined the editorial team and 14 new authors have contributed material. We all take immense pride in producing an outstanding book for the next generation of doctors, and in continuing the great tradition first established by Sir Stanley Davidson and passed on by all the previous editors and authors, for what remains one of the world's leading textbooks of medicine.

NRC, BRW, SHR
Edinburgh 2010

The *Davidson* family of textbooks

Medical learning is a life-long process that is facilitated by many different tools. *Davidson's Principles and Practice of Medicine* has stood the test of time because it provides an overview that is both comprehensive and concise. Its long-standing partner textbooks, *Macleod's Clinical Examination* and *Principles and Practice of Surgery*, share a similar ethos. To add value for readers of *Davidson's*, its highly successful style has now been employed in a 'family' of new companion books. These complement the main textbook, both by presenting its material in different formats to enhance learning, and by including supplementary material that could not be accommodated in the main edition.

Davidson's Essentials of Medicine is a 'handbook' version of *Davidson's Principles and Practice of Medicine*, helping those who need portable information to study while on the move – whether commuting between training sites, or during remote attachments and electives. It also serves as a condensed revision aid.

Every effort has been made to maximise readability and avoid dry and unmemorable lists. The text presents the essential elements in a structured format, key *Davidson's* illustrations are adapted and retained, and several new 'added value' sections have been included: Major Investigations describes key diagnostic tests; Therapeutics describes the clinical use of common drugs; and typical OSCE scenarios are included to help the reader to prepare for this examination format.

In the real world, patients do not present with a specific disease; instead they come with problems that might involve many systems, and the primary pathology may not be at all clear. In recognition of this, *Davidson's Clinical Cases* has been written by an impressive international group of physicians with wide clinical experience. This book guides the reader step by step to find the correct path in the maze between a patient's presenting complaint and the final diagnosis. The selection of cases is closely based on the 'Presenting Problems' of *Davidson's Principles and Practice of Medicine* and includes illnesses that reflect an international outlook.

For those just qualified and starting out on their initial years of hospital training, *Davidson's Foundations of Clinical Practice* provides key guidance on how to manage the practicalities of working life. The emphasis is on acute rather than chronic symptom presentation and management in a wide range of disci-

plines. It also provides an invaluable step-by-step guide to undertaking a range of core clinical procedures, along with an insight into the non-clinical aspects of managing a medical career. Much of the text is written by junior doctors, and so provides a real view of what it is like to work as a trainee hospital doctor today.

Davidson's is also closely linked to its two sister titles, *Macleod's Clinical Examination* and *Principles and Practice of Surgery*.

Also available on StudentCONSULT

Davidson's 500 'Best of Five' self-testing questions

Single best answer questions are now widely used for examination purposes as a reliable and discriminatory test of the factual knowledge necessary for good medical practice. To help to consolidate this knowledge, 500 questions based on the content of this edition of *Davidson's* are available at:

www.studentconsult.com/Gopaperless/davidsonsquestionbank.cfm

The questions concentrate on those topics which are of greatest importance in passing examinations, especially evidence-based medicine. The detailed answers help clarify why a particular answer is right or wrong and are linked to selected portions of the main textbook for in-depth exploration of a specific topic. The questions are suitable for all levels, and range in difficulty from core knowledge to more advanced topics.

Introduction

The first section of the book, 'Principles of Medicine', describes the basis on which medicine is practised and the fundamental mechanisms determining health and disease which are relevant to all medical specialties. The second section, 'Practice of Medicine', is devoted to individual medical specialties. Each chapter has been written by experts in the field to provide the level of detail expected of young trainees in their discipline. However, to maintain the book's virtue of being concise, care has been taken to avoid unnecessary duplication between chapters.

The system-based chapters follow a standard format, beginning with an overview of relevant clinical examination, followed by an account of functional anatomy, physiology and investigations, then the common presentations of disease, and finishing with details of the individual diseases and treatments of that system. Where appropriate, the chapters in the first section follow a similar format; the introduction of a problem-based approach in chapters which describe the immunological, cellular and molecular basis of disease brings the close links between modern medical science and clinical practice into sharp focus.

The methods used to present information throughout the book are described below.

Clinical examination overviews

The value of good clinical skills is highlighted by a two-page overview of the important elements of the clinical examination at the beginning of most chapters. The left-hand page of these sections includes a manikin to illustrate the key steps in the examination of the relevant system, beginning with simple observations and progressing in a logical sequence around the body. The right-hand page expands on selected themes and includes tips on examination technique and the interpretation of physical signs. These overviews are intended to act as an aide-mémoire and not as a replacement for a detailed text on clinical examination, as provided in our sister title, *Macleod's Clinical Examination*.

Presenting problems

Medical students and junior doctors must not only learn a great many facts about various disorders, but also develop an analytical approach to formulating a differential diagnosis and a plan of investigation for patients who present with particular symptoms or signs. In *Davidson's* this is addressed by incorporating

a 'Presenting Problems' section into all system-based chapters. Over 200 presentations are included, which represent the most common reasons for referral to each medical specialty. The same approach has been used in several of the chapters in the 'Principles of Medicine' section, to reinforce the close connection between clinical problems and fundamental mechanisms of disease. Many patients present with symptoms such as weight loss, dizziness or breathlessness, which are not specific to a particular system; these are described in the most relevant chapter and cross-referenced elsewhere. An index of presenting problems may be found on the inside back cover.

Boxes and tables

Boxes and tables are a popular way of presenting information and are particularly useful for revision. They are classified by the type of information they contain using the following symbols:

Causes

Clinical Features

Investigations

Treatment

In Old Age

Evidence-based Medicine

In Pregnancy

Practice Point

Emergency

Other Information

In Old Age

In most developed countries, older people comprise 20% of the population and are the chief users of health care. While they contract the same diseases as those who are younger, there are often important differences in the way they present and how they are best managed.

Chapter 7, 'Ageing and Disease', concentrates on the principles of managing the frailest group who suffer from multiple pathology and disability, and who tend to present with non-specific problems such as falls or delirium. However, many older people suffer from specific single-organ pathology. 'In Old Age' boxes are thus included in each chapter, and describe common presentations, implications of physiological changes of ageing, effects of age on investigations, problems of treatment in old age, and the benefits and risks of intervention in older people.

Evidence-based Medicine

Clinicians must base their practice on the best available evidence, which needs to be up to date, relevant, authoritative and easily accessible. Over 150 evidence-based medicine (EBM) boxes are included in this edition. They contain recommendations that are supported by evidence obtained from meta-analysis of several randomised controlled trials (RCTs) or one (or more) high-quality RCT, as described in Chapter 2 (p. 22). Recommendations conform to 'Grade A' criteria, as described in Chapter 1 (pp. 7–8).

In Pregnancy

Many conditions, both acute and chronic, are different in the context of pregnancy, while some arise only during or shortly after pregnancy. Particular care must be taken with investigations (to avoid, for example, radiation exposure to the fetus) and treatment (to avoid the use of drugs which harm the fetus). These issues are highlighted in new 'In Pregnancy' boxes distributed throughout the book.

Practice Point

There are many practical skills that students must learn in order to become effective junior doctors. These vary from inserting a nasogastric tube to reading an ECG or X-ray, or interpreting investigations such as arterial blood gases or thyroid function tests. 'Practice Point' boxes have been introduced in this edition to provide straightforward guidance on how these and many other skills can be acquired and applied.

Emergency

New in the 21st edition, these boxes describe management of many of the most common emergencies in medicine.

Terminology

Recommended International Non-proprietary Names (rINNs) are used for all drugs, with the exception of adrenaline and noradrenaline. However, British spellings have been retained for drug classes and groups (e.g. amphetamines not amfetamines).

Units of measurement

The International System of Units (SI units) is the recommended means of presentation for laboratory data and has been used throughout *Davidson's*. However, we recognise that many laboratories around the world continue to provide data in non-SI units, so these have been included in the text for the commonly measured analytes. Both SI and non-SI units are also given in Chapter 28, which describes the reference ranges used in Edinburgh's laboratories. It should be appreciated that these reference ranges may vary from those used in other laboratories.

Finding what you are looking for

A detailed contents list is given on the opening page of each chapter. In addition, the book contains numerous cross-references to help readers find their way around, along with an extensive index of over 10 000 subject entries. The online text available on StudentConsult (www.studentconsult.com) allows for detailed searches of the content by keyword. A list of up-to-date reviews and useful websites with links to management guidelines appears at the end of each chapter.

Acknowledgements

Following the publication of the 20th Edition of *Davidson's Principles and Practice of Medicine*, Dr Nick Boon and Professor John Hunter retired as Editors. We would like to express our gratitude for the immense contribution they made. We are also indebted to former authors who have stepped down from this edition. They include Dr P. Bloomfield, Dr D.A. Cameron, Dr R.W. Chapman, Professor P.C. Hayes, Dr G.C.W. Howard, Professor G. John, Dr A.L. Jones, Dr L. Karalliedde, Dr P. Lanyon, Dr D.N.J. Lockwood, Professor C.A. Ludlam, Dr S. Paterson-Brown, Dr S.G. Potts, Dr R. Sandford, Dr C. Summerton, Dr W.T.A. Todd and Dr D.F. Treacher.

We are grateful to members of the International Advisory Board, all of whom provided detailed suggestions which have improved the book. Several members have stepped down and we are grateful for their support during the preparation of previous editions. They include Dr S. Aaron, Dr S.K. Agarwal, Professor V. Diehl, Professor K.V. Johnny, Professor J.A. Ker, Professor C.-L. Lai, Professor S.K. Rajan and Dr P.S. Shankar.

Detailed chapter reviews were commissioned to help plan this new edition and we are grateful to all those who assisted, including Dr Alison Avenell, Professor Pradeep Bambray, Dr Richard Davenport, Dr David Eedy, Dr John English, Professor John Iredale, Professor Alan Jardine, Dr Dilip Nathwani, Dr Marianne Nicholson, Dr Denis O'Reilly, Professor John Pettifor, Dr John Saunders, Professor Tom Strachan and Dr Andrew Ustianowski.

As part of the publishers' review, students from several medical schools supplied many innovative ideas on how to enhance the book. We are indebted to the following for their enthusiastic support: Jonathan Beavers, Sarah Edwards, Gulnaz Gill, Akhil D. Goel, Reiyal Goveas, Amanda Jewison, Rohit Kumar, Richard McGregor, Chris McLure, Puja Mehta, David Miller, Aparajita Mitra, Eliza Mohammed, Talha Patel, Jason Reynolds, Kar Teoh, Michael Wilson and Danny Wong.

The authors of Chapter 21 would like to acknowledge Professor Paul Dodson, Dr Robert Lindsay and Dr Ewan Pearson for their specialist advice.

We would like to extend our thanks to the many readers who have used the email feedback address to contact us with suggestions for improvements. Their input has been invaluable and is much appreciated; they are unfortunately too numerous to mention individually.

We are grateful to colleagues who have generously provided many of the illustrations that appear in this edition. They are acknowledged on pages 1299–1300.

We are especially grateful to all those working for Churchill Livingstone, in particular Laurence Hunter, Wendy Lee and Robert Britton, for their endless support and expertise in the shaping, collation and illustration of this edition. We would also like to thank Susan Boobis for her labours in compiling the extensive index and Ruth Noble for expert proofreading.

Medical ethics 9

Personal and professional development 13

Complementary and alternative medicine 14

Since the time of Hippocrates, the role of the doctor has extended beyond the narrow remit of curing patients of their ailments. Good medical practice, or the art of medicine, hinges on recognising and respecting the breadth of physical, cultural, spiritual, experiential and psychosocial characteristics of each patient, and understanding their impact on the patient's beliefs, attitudes and expectations. Doctors must deliver appropriate care which considers the technical complexities of modern treatment, and at the same time deals with the communication and interpersonal needs of the patient, at a time when he or she may feel most vulnerable. In addition to the diagnosis and treatment of illness, the scope of medicine has expanded to preventing disease through measures such as screening, vaccination and health promotion. Doctors are centrally involved in tackling lifestyle-related issues of the modern world such as obesity, alcohol excess, cigarette smoking and sexual health.

Medical professionalism has been described by a Royal College of Physicians working party (2005) as 'a set of values, behaviours and relationships that underpin the trust the public has in doctors'. They stated that, in their day-to-day practice, doctors should be committed to integrity, compassion, altruism, continuous improvement, excellence, and working in partnership with members of the wider health-care team. They perceived that medical professionalism was relevant to leadership, education, career pathways, appraisal and research.

This chapter outlines how doctors must provide patients and their families with relevant but complex information, discuss management options, and reach appropriate clinical decisions that are commensurate with the available resources. It also describes pathways and processes to develop, maintain and assure medical professionalism.

MEDICAL PRACTICE

The doctor-patient relationship

The contents of this book are not all based on indisputable contemporary evidence; many reflect wisdom and understanding distilled over hundreds of years and passed from generation to generation of doctors. This perceived wisdom lies at the heart of the way that doctors and patients interact; it demands respect, and if the doctor also displays compassion, sets the scene for the development of trust.

Due to the complexities of many chronic diseases and treatments, and the multifaceted impact of illness on a patient, there is an increasing role for health care to be delivered by a multidisciplinary team (Box 1.1). This model of care recognises the different skills of each allied health professional and focuses patient care beyond surgical procedures or pharmacological manipulation. The doctor usually takes the lead in determining the overall direction of care but must also:

- guide the patient through the unfamiliar landscape, language and customs of clinical care
- interpret, synthesise and convey complex information
- help patients and families to participate fully in thinking about their care and in the decision-making process.

1.1 Members and roles of a multidisciplinary team

Professional	Roles
Doctor	Diagnosis and treatment Overall coordination of care
Specialist nurse	Patient and family support Information-giving
Physiotherapist	Improving physical function Physical rehabilitation
Occupational therapist	Maximising skills and abilities Complex re-enablement
Speech and language therapist	Optimising communication Swallowing assessment
Dietitian	Nutritional advice Parenteral feeding support
Pharmacist	Safe prescribing Complex medicines delivery
Social worker	Coordination of home care Financial advice
Clinical psychologist	Cognitive interventions Psychological support
Pastoral care	Psychological support Spiritual support

1.2 The duties of a doctor registered with the UK General Medical Council

Patients must be able to trust doctors with their lives and health. To justify that trust you must show respect for human life and you must:

- Make the care of your patient your first concern
- Protect and promote the health of patients and the public
- Provide a good standard of practice and care
 - Keep your professional knowledge and skills up to date
 - Recognise and work within the limits of your competence
 - Work with colleagues in the ways that best serve patients' interests
- Treat patients as individuals and respect their dignity
 - Treat patients politely and considerately
 - Respect patients' right to confidentiality
- Work in partnership with patients
 - Listen to patients and respond to their concerns and preferences
 - Give patients the information they want or need in a way they can understand
 - Respect patients' right to reach decisions with you about their treatment and care
 - Support patients in caring for themselves to improve and maintain their health
- Be honest and open, and act with integrity
 - Act without delay if you have good reason to believe that you or a colleague may be putting patients at risk
 - Never discriminate unfairly against patients or colleagues
 - Never abuse your patients' trust in you or the public's trust in the profession.

You are personally accountable for your professional practice and must always be prepared to justify your decisions and actions.

Fig. 1.1 Some aspects of the doctor–patient relationship.

In many clinical disciplines, doctors from several specialties form a multidisciplinary team in order to formulate a treatment plan. In oncology, for example, this ensures that various modalities of treatment (surgical, oncological and palliative) are considered.

The doctor–patient relationship is in itself therapeutic; a successful consultation with a trusted and respected practitioner will therefore have beneficial effects irrespective of any other therapy given. The doctor–patient relationship is also multilayered, dynamic and bilateral. Figure 1.1 illustrates how it may be influenced by differences in attitudes or beliefs, and behaviours or roles.

Regulatory bodies such as the UK General Medical Council seek to define the medical side of the doctor–patient relationship in terms of the duties of a doctor (Box 1.2). It is common for medical schools to require undergraduate students to sign an ethical code of conduct based on statements like this.

Clinical and communication skills

Communication lies at the heart of good medical practice. The most technically capable clinician will fail in the duty of care if he or she is unable to communicate effectively with patients or relatives, since this is essential for accurate history-taking, information-giving and decision-making. Likewise, the delivery of holistic care requires effective communication with other doctors and members of the multidisciplinary team, failure of which may lead to clinical errors. Clear and appropriately detailed clinical note-keeping is essential, as are timely and accurate written communications between professionals.

Failures in communication may also lead to poor health outcomes, strained working relations, widespread dissatisfaction among patients, their families and health professionals, anger and litigation. The

1.3 Some barriers to good communication in health care

The clinician

- Authoritarian or dismissive attitude
- Hurried approach
- Use of jargon
- Inability to speak first language of patient
- No experience of patient's cultural background

The patient

- Anxiety
- Reluctance to discuss sensitive or seemingly trivial issues
- Misconceptions
- Conflicting sources of information
- Cognitive impairment
- Hearing/speech/visual impediment

majority of complaints received by health-care professionals could have been avoided by effective communication. Some common barriers to good communication are listed in Box 1.3.

The development of communication skills to facilitate accurate history-taking and information-giving takes many years and requires frequent opportunities for personal reflection on previous consultations. A detailed account of history-taking, clinical examination and communication skills is beyond the scope of this chapter but is provided in Davidson's sister title, *MacLeod's Clinical Examination*. However, some basic communication principles are discussed below and these can be applied to most consultations.

The main aim of a medical interview is to establish a factual account of the patient's illness. The clinician must allow the patient to describe the problems without overbearing questioning, but should try to facilitate the process with appropriate questions (Box 1.4). Techniques such as an unhurried approach, checking prior understanding, making it clear that the interviewer is listening, the use of silence when appropriate, recapping on what has been said, and reflection of key points back to the patient are all important. A major requirement is to express complex information and concepts in language

1.4 Communication skills in the medical interview

- **Open questions** allow patients to express their own thoughts and feelings, e.g. 'How have you been since we last saw you?', 'Is there anything else that you want to mention?'
- **Closed questions** are requests for factual information, e.g. 'When did this pain start?'
- **Leading questions** invite specific responses and suggest options, e.g. 'You'll be glad when this treatment is over, won't you?'
- **Reflecting questions** help to develop or expand topics, e.g. 'Can you tell me more about your family?'
- **Active listening** encourages further dialogue, e.g. 'Go on,' 'I see,' 'Hmm' etc.
- **Requesting clarification** encourages further detail, e.g. 'How do mean?', 'In what way?' etc.
- **Summarising** ensures accurate understanding, e.g. 'Tell me if I've got this right.'

with which the patient can readily engage. Non-verbal communication is equally important. The patient's facial expressions and body language may betray hidden fears. The clinician can help the patient to talk more freely by smiling or nodding appropriately.

Beyond the factual account of symptoms, the clinician should also explore patients' feelings, determine how they interpret their symptoms, unearth their concerns and fears, and explore their expectations before suggesting and agreeing a plan of management. Clinicians should demonstrate understanding, sensitivity and empathy (i.e. imagine themselves in the patient's position). Most patients have more than one concern and will be reluctant to discuss potentially important issues if they feel that the clinician is not interested or is likely to dismiss their complaints as irrational or trivial.

Specific communication scenarios such as breaking bad news or dealing with aggression require additional targeted strategies (see *MacLeod's Clinical Examination*).

Using investigations

Modern medical practice has become dominated by sophisticated and often expensive investigations. It is easy to forget that the judicious use of these tools, and the interpretation of the data that they provide, are crucially dependent on good basic clinical skills. Indeed, a test should only be ordered if it is clear that the result will influence the patient's management and the perceived value of the resulting information exceeds the anticipated discomfort, risk and cost of the procedure. Clinicians should therefore analyse their patient's condition carefully and draw up a provisional management plan before requesting any investigations.

The 'normal' (or reference) range

Although some tests provide qualitative results (present or absent, e.g. faecal occult blood testing, p. 856), most provide quantitative results (i.e. a value on a continuous numeric scale). In order to classify quantitative results as normal or abnormal, it is necessary to define a 'normal range'. Many quantitative measurements in populations exhibit a bell-shaped, or Gaussian, frequency distribution (Fig. 1.2); this is called a 'normal distribution' and is characteristic of biological variables determined by a complex mixture of genetic and environmental factors (e.g. height) and of test results (e.g. plasma sodium concentration). A normal distribution can be described by the mean value (which places the centre of the bell-shaped curve on the x axis) and the standard deviation (SD, which describes the width of the bell-shaped curve). Within each SD away from the mean there is a fixed percentage of the population. By convention, the 'normal range' is usually defined as those values which encompass 95% of the population, i.e. the values within 2 SDs above and below the mean. If this convention is used, however, 2.5% of the normal population will have values above, and 2.5% will have values below, the normal range; for this reason, it is more precise to describe 'reference' rather than 'normal' ranges.

'Abnormal' results, i.e. those lying beyond 2 SDs from the mean, may occur either because the person is one of the 2.5% of the normal population whose test result is outside the reference range, or because he or she has

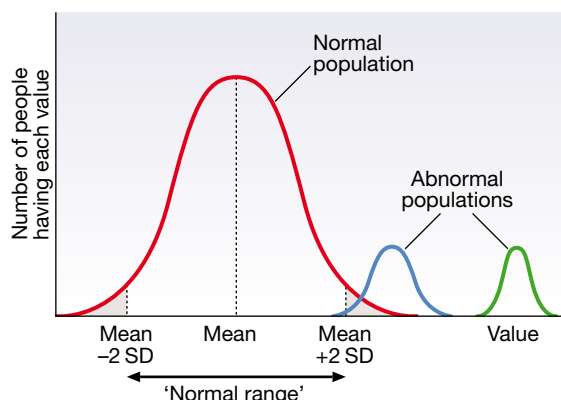

Fig. 1.2 Normal distribution and 'normal' (reference) range. For many tests, the frequency distribution of results in the normal healthy population (red line) is a symmetrical bell-shaped curve. The mean \pm 2 standard deviations (SD) encompasses 95% of the normal population and usually defines the 'normal range' (or 'reference range'); 2.5% of the normal population have values above, and 2.5% below, the reference range (shaded areas). For some diseases (blue line), test results overlap with the normal population or even with the reference range. For other diseases (green line), tests may be more reliable because there is no overlap between the normal and abnormal population.

a disease characterised by a different result from the test. Test results in 'abnormal' populations also have a bell-shaped distribution with a different mean and SD (see Fig. 1.2). In some diseases, there is typically no overlap between results from the normal and abnormal population (e.g. elevated serum creatinine in renal failure, p. 465). In many diseases, however, there is overlap, sometimes extending into the reference range (e.g. elevated serum thyroxine in toxic multinodular goitre, p. 750). In these circumstances, the greater the difference between the test result and the limits of the reference range, the higher the chance that the person has a disease, but there is a risk that results within the reference range may be 'false negatives' and results outside the reference range may be 'false positives'.

Each time a test is performed in a member of the normal population there is a 5% (1 in 20) chance that the result will be outside the reference range. If two tests are performed, the chance that one of them will be 'abnormal' is 10% (2 in 20), and so on; the chance of detecting an 'abnormal' result increases as more tests are performed, so multiple indiscriminate testing should be avoided.

In practice, reference ranges are usually established by performing the test in a number of healthy volunteers who are assumed to be a random sample of the normal population. Not all populations are the same, however, and while it is common to have different reference ranges for tests in men and women, or in children and adults, clinicians need to be aware that reference ranges defined either by test manufacturers or even within the local laboratory may have been established in small numbers of healthy young people who are not necessarily representative of their patient population. This is another reason to recognise that reference ranges do not discriminate perfectly between health and disease.

For some tests, the clinical decision does not depend on whether or not the patient is a member of the normal population. This commonly applies to quantitative risk factors for future disease. For example, higher plasma total cholesterol levels are associated with a higher risk

of future myocardial infarction (p. 579) within the normal population. Although a reference range for cholesterol can be calculated, cholesterol-lowering therapy is commonly recommended for people with values within the reference range; the 'cutoff' value at which therapy is recommended depends upon the presence of other risk factors for cardiovascular disease. The reference range for plasma cholesterol is therefore redundant and the phrase 'normal plasma cholesterol level' is unhelpful. Similar arguments apply for interpretation of values of blood pressure (p. 579), blood glucose (p. 805), bone mineral density (p. 1118) and so on.

Some quantitative test results are not normally distributed, usually because a substantial proportion of the normal population will have an unrecordably low result (e.g. serum prostate-specific antigen, p. 513, and serum troponin, p. 531), and the distribution cannot be described by mean and SDs. Alternative statistical procedures can be used to calculate 95th centiles, but it is common in these circumstances to use information from normal and abnormal people to identify 'cutoff' values which are associated with a certain risk of disease, as described below.

Sensitivity and specificity

Many tests are potentially hazardous and none is completely reliable. All diagnostic tests can produce false positives (an abnormal result in the absence of disease) and false negatives (a normal result in a patient with disease). The diagnostic accuracy of a test can be expressed in terms of its sensitivity and its specificity (Box 1.5).

Sensitivity is defined as the percentage of the test population who are affected by the index condition and test positive for it. In contrast, specificity is defined as the percentage of the test population who are healthy and test negative. A very sensitive test will detect most disease but may generate abnormal findings in healthy people. A negative result will therefore reliably exclude disease but a positive test is likely to require further evaluation. On the other hand, a very specific test may miss significant pathology but is likely to establish the diagnosis, beyond doubt, when the result is positive.

In choosing how a test is used to guide decision-making there is an inevitable trade-off between emphasising sensitivity as opposed to specificity. For example, defining an exercise electrocardiogram (p. 530) as abnormal if there is ≥ 0.5 mm ST depression will ensure that very few cases of coronary artery disease are missed but will generate a lot of false positive tests (high sensitivity, low specificity). On

1.5 The accuracy of diagnostic tests

	Affected	Unaffected
Positive test	True +ve (a)	False +ve (b)
Negative test	False -ve (c)	True -ve (d)
Sensitivity (%) = $[a/(a + c)] \times 100$ Specificity (%) = $[d/(b + d)] \times 100$		
Positive predictive value = $a/(a + b)$ Negative predictive value = $d/(c + d)$		
Likelihood ratio: positive test = sensitivity/(1 - specificity) negative test = (1 - sensitivity)/specificity		

Fig. 1.3 Receiver operating characteristic graphs illustrating the trade-off between sensitivity and specificity for a given test. The curve is generated by 'adjusting' the cutoff values defining normal and abnormal results, calculating the effect on sensitivity and specificity, then plotting these against each other. The closer the curve lies to the top left-hand corner, the more useful the test. The red line illustrates a test with useful discriminant value and the green line illustrates a less useful poorly discriminant test.

the other hand, using a cutoff point of ≥ 2.0 mm ST depression will detect most cases of important coronary disease with far fewer false positive results. This trade-off can be illustrated by the receiver operating characteristic curve of the test (Fig. 1.3).

Predictive value

The predictive value of a test is determined by its sensitivity and specificity, and can be expressed in several ways. The positive predictive value is the probability that a patient with a positive test has the index condition, whilst the negative predictive value is the probability that a patient with a negative test does not have the condition (see Box 1.5). The likelihood ratio expresses the odds that a given finding would occur in a patient with, as opposed to a patient without, the index condition (see Box 1.5) (as the odds rise above 1 the probability that disease is present rises).

The interpretation, and therefore the utility, of a test are critically dependent on the circumstances in which it is used. Bayes' theorem dictates that the value of a diagnostic test is determined by the prevalence of the condition in the test population. The probability that a subject has a particular condition (the post-test probability) can be calculated if the pre-test probability and the sensitivity and specificity of the test are known (Box 1.6). Thus, a test is most valuable when there is an intermediate pre-test probability of disease. Clinicians seldom have access to such precise information but must appreciate the importance of integrating clinical and laboratory data.

Screening

Many health-care systems run screening programmes to detect important (and treatable) disease in apparently healthy but at-risk individuals. These initiatives may be directed towards a single pathology (e.g. mammography for breast cancer, p. 274) or may comprise a battery of tests for a wide range of conditions. Screening inevitably generates a number of false-positive results that

1.6 Bayes' theorem: post-test likelihood of disease

Positive test

$$\text{Post-test probability of disease} = \frac{\text{pre} \times \text{sens}}{(\text{pre} \times \text{sens}) + ((1 - \text{sens}) \times (1 - \text{spec}))}$$

Negative test

$$\text{Post-test probability of disease} = \frac{\text{pre} \times (1 - \text{sens})}{(\text{pre} \times (1 - \text{sens})) + ((1 - \text{pre}) \times \text{spec})}$$

(pre = pre-test probability of disease; sens = sensitivity; spec = specificity)

Example

Assume: Exercise tolerance testing for the diagnosis of coronary artery disease (CAD) (using cutoff of 2 mm ST depression) has 70% sensitivity (0.7) and 90% specificity (0.9). The pre-test odds of significant CAD in a 65-yr-old woman with atypical angina on effort are 50% (0.5).

Post-test odds of significant CAD will be:

$$\text{Positive test} \quad \frac{0.5 \times 0.7}{(0.5 \times 0.7) + (0.3 \times 0.1)} = 92\%$$

$$\text{Negative test} \quad \frac{0.5 \times 0.3}{(0.5 \times 0.3) + (0.5 \times 0.9)} = 25\%$$

In contrast, the pre-test probability of significant coronary disease in a 45-yr-old man with typical angina on effort would be 90%, with post-test odds of 95% in the event of a positive exercise test and 75% in the event of a negative test.

1.7 Factors that influence the cost-effectiveness of health screening

- The prevalence of the index condition in the target population
- The cost of the screening test
- The sensitivity and specificity of the screening test
- The availability and effectiveness of treatment for the index condition
- The cost of not detecting and treating the condition

require further, potentially expensive and sometimes risky, investigation. This may engender a good deal of anxiety for the patient and create dilemmas for the clinician; for example, it may be difficult to determine how to evaluate minor abnormalities of the liver function tests in an otherwise healthy person (p. 930).

Some of the criteria that must be considered before deciding if the wider costs of a screening programme can be justified are listed in Box 1.7.

Estimating and communicating risk

Medical management decisions are usually made by weighing up the anticipated benefits of a particular procedure or treatment against the potential risks. To allow patients to contribute to the decision-making process, health professionals must be able to explain risk in an accurate and understandable way.

Providing the relevant biomedical facts is seldom sufficient to guide decision-making because a patient's perception of risk is often coloured by emotional, and

sometimes irrational, factors. Most patients will have access to information from a wide variety of sometimes conflicting sources, including the Internet, books, magazines, self-help groups, other health-care professionals, friends and family. The clinician must be aware of and sensitive to the way in which these resources influence the individual, while building trust with the patient, clarifying the problem and conveying the key facts.

Research evidence provides statistics and probabilities, but these can be confusing and can be presented in many ways (Box 1.8). Relative risk describes the proportional increase in risk; it is a useful measure of the size of an effect. In contrast, absolute risk describes the actual chance of an event and is what matters to most patients.

i

1.8 Explaining the risks and benefits of therapy

Would you take a drug once a day for a year to prevent stroke if:

- it reduced your risk of having a stroke by 47%?
- it reduced your chance of suffering a stroke from 0.26% to 0.14%?
- there was one chance in 850 that it would prevent you having a stroke?
- 849 out of 850 patients derived no benefit from the treatment?
- there was a 99.7% chance that you would not have a stroke anyway?

All these statements are derived from the same data and describe an equivalent effect*

*MRC trial of treatment of mild hypertension (bendroflumethiazide vs placebo). BMJ 1985; 291:97–104.

Fig. 1.4 Visual portrayal of benefit and risks. The image refers to an operation that is expected to relieve symptoms in 90% of patients, but cause stroke in 2% and death in 1%.

Terms such as 'common', 'rare', 'probable' and 'unlikely' are elastic. Whenever possible, the clinician should quote numerical information using consistent denominators (e.g. '90 of every 100 patients who have this operation feel much better, 1 will die during the operation and 2 will suffer a stroke'). Positive framing ('There is a 99% chance of survival') and negative framing ('There is a 1% chance of death') may both be appropriate. A variety of visual aids can be used to present complex statistical information in a digestible way (Fig. 1.4).

Finally, it is essential to allow the patient to place his or her own weighting on the potential benefits and adverse effects of each course of action. Thus, some patients may choose to sacrifice a good chance of pain relief because they are not prepared to run even a small risk of paralysis, whilst others may opt to proceed with very high-risk spinal surgery because they find their current circumstances intolerable.

Clinical decision-making

Assimilating symptoms, signs and results of investigations into a diagnosis and then planning treatment are highly complex tasks that require not only factual knowledge but also a highly developed set of skills in decision-making. Diagnostic decision-making is guided by Ockham's razor, originally expressed by the 14th-century Englishman William of Ockham as 'plurality should not be posited without necessity.' In short, all things being equal, the simplest explanation is the best. In practice, clinicians formulate hypotheses about the underlying diagnosis (or shortlist of diagnoses, the 'differential' diagnosis) during the consultation with the patient and refine this hypothesis both by collecting selected additional information and by choosing to ignore other information which they regard as irrelevant, in order to reach the most parsimonious diagnosis.

Decision-making in health care often operates under conditions of uncertainty, where it is uncertain what is wrong with the patient or which treatment is most appropriate. This can lead to variations in how clinicians make decisions, and subsequently variations in the care that patients receive. Clinicians often employ a process of 'ad hoc' decision-making, where they use some form of global judgement about what might be the best course of action for an individual patient. These ad hoc decisions may be based on a number of factors, including what a clinician has been taught, his or her clinical experience of other patients with that particular disease, or what is common practice within a particular institution. However, such decisions may be governed by heuristics or bias, which may lead to errors. Heuristics are cognitive processes or 'rules of thumb' used unconsciously when making decisions (Box 1.9). Such processes may lead to mistakes, most commonly when there is a lack of evidence to inform practice. Whenever possible, clinical decision-making should be guided by evidence-based medicine.

Evidence-based medicine

Patient treatment should be based on the integration of best research evidence alongside clinical expertise and patient values. The discipline of evidence-based medicine (EBM) came into being in order to introduce a more

1.9 Heuristics in clinical decision-making

Availability

- The probability of an event is estimated based on how easily an individual can recall a similar event from his or her memory
- E.g. a doctor judges that a patient has a particular disease because the case reminds him or her of a similar case seen recently
- This can lead to errors, as individuals often recall recent or vivid events more easily, rather than considering the actual likelihood of an event in the wider population

Representativeness

- The probability of an event is estimated based on how similar (or representative) it is of a wider category of events
- E.g. a doctor judges that a patient has a particular disease because the patient's signs and symptoms are 'representative' of that disease
- This can lead to errors such as neglecting to take into account the prevalence of the disease in a specific patient population

Anchoring and adjustment

- The probability of an event is estimated by taking an initial reference point (anchor) and then adjusting this to reach a final judgement about likelihood
- E.g. a doctor judges that the likelihood of a patient having a particular disease is 60%. The doctor collects information (perhaps from diagnostic tests) and reassesses his or her estimation on the basis of these results to reach a final diagnosis
- This can lead to errors, as final estimations of likelihood are linked to the original anchor, so if this is incorrect, the final judgement is also likely to be inaccurate

systematic approach to the use of evidence in making clinical decisions. This was made possible by:

- the development of statistical methods to analyse data systematically
- recognition of the importance of analysing all data, both published and unpublished
- the development of databases of relevant information and systems by which to access such information.

The principles of EBM are based on the tenet that well-formulated questions about medical management can be answered by:

- conducting high-quality randomised controlled trials
- tracing all the available evidence
- critically appraising the evidence
- applying the evidence to the management of the individual patient.

EBM categorises different types of clinical evidence and ranks them according to their freedom from the various biases that beset medical research. It therefore places greater emphasis on evidence from a meta-analysis of randomised controlled trials than on a series of case reports or expert opinion (Box 1.10).

Guidelines and protocols

The terms 'clinical guidelines' and 'protocols' are often used together, yet they are inherently different.

1.10 Categories in evidence-based medicine (EBM)*

Levels of evidence (in descending order of strength)

Ia	Evidence obtained from meta-analysis of randomised clinical trials
Ib	Evidence obtained from at least one randomised controlled trial
IIa	Evidence obtained from at least one well-designed controlled study without randomisation
IIb	Evidence obtained from at least one other type of well-designed quasi-experimental study
III	Evidence obtained from well-designed non-experimental descriptive studies, such as comparative studies, correlation studies and case studies
IV	Evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities

Grades of recommendation

A	Directly based on level I studies
B	Directly based on level II studies <i>or</i> extrapolations from level I studies
C	Directly based on level III studies <i>or</i> extrapolations from level I or II studies
D	Directly based on level IV studies <i>or</i> extrapolations from level I, II or III studies

*From the Scottish Intercollegiate Guidelines Network (SIGN; see www.sign.ac.uk). This scheme is widely used, although other modified schemes exist.

Guidelines

Clinical guidelines aim to guide clinicians on how to manage specific clinical scenarios using the best available evidence. They have been in existence throughout the history of medicine, although many were based on tradition or authority. A large number of local, national and international bodies have produced guidelines, following a range of different methodologies (see www.library.nhs.uk/guidelinesfinder). Some are based on systematic reviews of the medical literature and others on consensus of expert opinion. When considering guidelines, it is important for clinicians to be aware of the strength of the evidence on which the recommendations are based (see Box 1.10).

Properly developed guidelines recognise that medicine is an art as well as a science and that the evidence on which the guidelines are based is, strictly speaking, only applicable to the study population in the trial(s). Clinicians must therefore use their judgement to ascertain whether the recommendations are applicable to the patient in front of them and follow the guidance accordingly.

Some guidelines are formulated not only from evidence-based best practice but also from cost effectiveness (see below). An example in the UK is guidance produced by the government-commissioned body, the National Institute for Health and Clinical Excellence (NICE; see www.nice.org.uk). These guidelines recognise that health services have limited resources, and that treatments should be funded which offer the greatest improvement in health for the largest number of people per unit of resource.

Protocols

Whilst guidelines recognise the individuality of the patient and help clinicians decide on which action is best, protocols are far more directive and are written to be followed exactly. Protocols usually apply in situations where the clinical decision has already been made and the treatment or intervention is then being instigated. Protocols aim to ensure that treatment will be identical irrespective of where and by whom it is given. For example, a guideline may help a multidisciplinary team decide which modality of treatment is best for someone with lung cancer; it will allow the team to evaluate the best evidence alongside the individual psychosocial needs of the patient. However, once a decision has been made in favour of a certain treatment, e.g. chemotherapy, the clinician will be expected to follow a strict protocol outlining dosages, routes of administration, monitoring and so on to ensure parity of treatment wherever the chemotherapy is given.

Cost-effectiveness

The best available health care can be expensive. No country can now afford to provide unlimited state-of-the-art medicine for all its citizens. Health-care systems must therefore take account of the cost-effectiveness of the treatments they provide. This can create difficult dilemmas for clinicians who may be asked to withhold expensive but effective therapies (e.g. implantable defibrillators) from individual patients on the basis that the money will do more good for more patients if it is spent elsewhere (e.g. offering angioplasty to all acute myocardial infarction patients). Assessing the cost-effectiveness of interventions and allocating resources accordingly follows ethical principles such as justice, which are covered in greater detail below. One way to assess the cost-effectiveness of an intervention is to calculate the number of quality-adjusted life years that an intervention will provide for a patient.

Quality-adjusted life years

Outcomes from health care can be measured in terms of changes in the quality and quantity of life. Life expectancy is easily defined but quality of life is difficult to measure. Nevertheless, it is possible to construct a continuum between perfect health (score 1), survival with no quality of life (score 0) and states that are perceived to be worse than death (minus score). Quality and quantity of life can then be combined in a measure known as the quality-adjusted life year (QALY). For example, an intervention that results in a patient living an additional 4 years with an average quality of life rated as 0.6 on the continuum would yield 2.4 QALYs (4×0.6). Thus a cost per QALY can be calculated and compared with other interventions. This sort of approach has many failings but, for the time being at least, offers the best means of comparing the cost-effectiveness of a wide range of treatments.

Practising medicine in low-resource settings

The problems associated with medical care in low-resource areas cluster in four domains:

- *Prevention versus cure.* Prevention is easier, cheaper and more effective than cure for many diseases. On

the other hand, curative medicine is immediate, highly visible and glamorous. This tension is most evident when a disease is common and the benefits of prevention have yet to be realised. The allocation of adequate resources for long-term prevention needs both political will and social acceptance.

- *Acute versus chronic care.* Acute medical care produces immediate and often gratifying results whilst treating chronic illness can be time-consuming and less rewarding. Facilities for chronic care are therefore accorded a low priority in many health-care systems. Unfortunately, this often results in patients who require long-term care being denied treatment altogether or being managed inappropriately (at high cost) in the acute sector.
- *The ideal versus the possible.* Most medical management guidelines are derived from studies that were conducted in well-resourced health-care systems. In trying to apply this knowledge to the developing world, there are tensions between best practice and what is possible. For example, anticoagulant therapy (p. 1014) may pose risks that were not evident in the studies that underpin guidelines if it is prescribed in areas where reliable laboratories are not available and medications that interact with warfarin are commonly purchased 'over the counter'.
- *Channels of health-care provision.* In developing countries health care may be delivered through government-run public clinics (usually free or subsidised services) or non-governmental organisations (sometimes subsidised but usually privately funded services). Many of the available services are too costly for the average patient, so for the benefit of the community as a whole there is a need for constructive cooperation between all of the health-care sectors.

The best possible practice is that which can be delivered within the available resources in a specific setting. Compassionate care given with empathy, understanding and good communication is always within the physician's reach, even when physical resources are inadequate.

MEDICAL ETHICS

Ethics is the 'science' of morality. Medical ethics is concerned both with the standards of conduct and competence expected of members of the medical profession, and with the study of ethical problems raised by the practice of medicine. Recent advances in biomedical science and their application to clinical care have thrown up many difficult ethical problems. These include human cloning, predictive genetic testing, eugenics, women's health, new reproductive technologies, antenatal screening, abortion, priority-setting, global medicine, underserved populations, brain death, organ transplantation, end-of-life issues, assisted suicide and advance directives. Detailed discussion of these is beyond the scope of this chapter but a framework for the application of ethics to medical practice will be described.

In general, ethical problems relate to the intentions or motives of those involved, their actions, the consequences of their actions, and the context in which their

actions take place. Ethical problems can be analysed in a variety of ways, and different analytical approaches may lead to different conclusions. To find the best solution, it may be necessary to apply several different analytical approaches and attempt to reconcile the conclusions. In modern medical practice there is not always time to do this systematically. However, the process of applying an ethical framework to a given situation is a key element in clinical decision-making and helps to ensure that a decision is both morally acceptable and legally defensible.

- *Virtue ethics* is concerned with the character of the persons involved and with their actions. Are my intentions (what my actions aim at) and my motives (what moves me to act) good or bad, wise or unwise, sensible or unrealistic, patient-centred or self-centred, and so on? Is the course of action I propose to take one which would be considered appropriate by a prudent doctor—or by a prudent patient? The focus here is on the characteristics of a virtuous person. Right action flows from the nature of that person.
- *Deontological ethics* is concerned with whether a proposed action or course of action, in itself and regardless of its consequences, is right or wrong. Is it ever right or always wrong to kill, to tell a lie, to break a promise? Deontological (from the Greek for 'duty') considerations include rights as well as duties, and omissions as well as acts. An action is right if it is in accordance with an established moral rule or principle.
- *Teleological ethics* (or consequentialism) is concerned with the consequences of a proposed action or course of action. Are they likely to be good or bad, in the short term and long term, for the patient, doctor, family and society? What will promote a net balance of good over harm for the individual as well as 'the greatest good for the greatest number'? Who decides (or can predict) what is the 'best' outcome?

An ethical problem can therefore be addressed by trying to decide what a virtuous person would do, whether an action or course of action is right or wrong in itself, or what its consequences might be. Yet the circumstances in which any decision is made will vary, and what may be right in one context may be wrong in another. *Situation ethics* recognises this, emphasising the need to consider carefully the context (or situation) in which a course of action is chosen.

Ethics are applied to the practice of medicine in three broad areas:

- *Clinical ethics* deal with the relationship between clinicians and individual patients, as described below.
- *Public health ethics* deal with the health issues of groups of people—the community. Examples include the banning of smoking in public places, where the autonomy of the individual may be coerced for the greater good of the community.
- *Research ethics* deal with issues related to clinical research. This is to ensure not only that research is conducted safely but also that the rights of the participants are paramount. No research can be undertaken unless it has undergone ethical scrutiny.

Key principles of clinical ethics

In clinical ethics, four key principles are frequently used to underpin the analysis of a problem, and are often abbreviated to 'autonomy, beneficence, non-maleficence and justice'.

Respect for persons and their autonomy

This respect is a significant aspect of the relationship between patient and doctor. The patient seeks out a doctor based on a desire to attain freedom from a disability or disease which limits his or her ability to exercise autonomy (the power or right of self-determination). Unless the patient is a child, is unconscious or is mentally incapacitated, it is the patient's choice to seek advice. The physician must therefore respect the patient's autonomy. This includes the patient's right to refuse therapy. The doctor must also actively seek to empower the patient with adequate information.

Respect for persons and their autonomy has important implications for truth-telling, informed consent and confidentiality.

Truth-telling

Telling the truth is essential to generating and maintaining trust between the doctor and the patient. This includes providing information about the nature of the illness, expected outcome and therapeutic alternatives, and answering questions honestly. The facts should not be given 'brutally' but with due sensitivity to appropriate timing and to the patient's capacity to cope with bad news. However, the clinical uncertainties described earlier in the chapter must also be acknowledged. There are two rare situations where the truth may, at least for a time, be withheld:

- If it will cause real harm to the patient (e.g. a depressed patient likely to commit suicide who has to be told that he or she has cancer). This is sometimes called 'therapeutic privilege', since it should be exercised only in the patient's vital interests and for very serious clinical reasons.
- If the patient makes it clear that he or she does not want to hear the bad news (but always bearing in mind that this may be a stage in the patient's adjustment to the condition).

In no case should false information be given, and the physician should always be prepared to justify any decision to withhold relevant information.

Informed consent

This term describes the participation of patients in decisions about their health care. In order to facilitate this, the clinician must provide the patient with an adequate explanation of the nature of the decision, and details of the relevant risks, benefits and uncertainties of each possible course of action. The amount of information to provide will vary, depending on the patient's condition and the complexity of the treatment, and on the physician's assessment of the patient's understanding of the situation. Not all options need be explained, but those that a 'prudent patient' would consider significant should be explored—for example, by open questioning (see Box 1.4, p. 4).

From both a legal and an ethical perspective the patient retains the right to decide what is in his or her best interests. All adults have decision-making capacity if they can understand the relevant information (which

may have to be explained in simple terms), consider the implications of the relevant options, and make a communicable decision. If a patient makes choices that seem irrational or are at variance with professional advice, it does not mean that they lack capacity.

When the patient does lack decision-making capacity, the clinician should always act in the best interests of the patient. In an emergency, consent may be presumed, but only for treatment immediately necessary to preserve the patient's life and health, and if there is no clear evidence that this would be against the previous settled wishes of the patient when competent (for example, blood transfusion in the case of an adult Jehovah's Witness). If the patient has a legally entitled surrogate decision-maker, the consent of the latter should be sought wherever possible. It is also good practice to involve close relatives in decision-making but the hierarchy of surrogate decision-makers will depend on local laws and culture.

Confidentiality

Confidentiality in relation to the appropriate management of patient-specific information is important in generating and maintaining trust in the doctor-patient relationship. Health-care teams must take precautions to prevent unauthorised access to patient records, and may disclose patient-identifying information only when the patient has given consent or when required by law. Where such information is shared with other health-care professionals in order to optimise individual patient care, this should be done on a strictly 'need-to-know' basis.

Beneficence

This is the principle of doing good, or acting in another person's best interests. In clinical ethics, the term refers to the good of the individual patient. It means considering the patient's view of his or her own best interests as well as his or her medical best interests. Situations may arise where there is a conflict between what is good for the individual and what is best for society, but the traditional medical approach is that stated in the Declaration of Geneva (World Medical Association): 'The health of my patient will be my first consideration.'

Non-maleficence

This is the principle of doing no harm: in medicine, the traditional 'primum non nocere'. In balancing beneficence and non-maleficence (benefit versus risk), the clinician must share the relevant information with the patient, who can then be helped to make an informed decision.

Justice

In the context of clinical ethics, justice relates primarily to the distribution of medical care and the allocation of resources. In order to distribute health resources justly, the concept of utility—'greatest good for the greatest number'—must be considered. In the case of individual patients, however, justice is also equated with being 'fair' and 'even-handed'. The concept of fair delivery of health care can be viewed from three perspectives:

- Respect for the *needs* of the individual. Health care is delivered first to those who need it most. This perspective is particularly relevant when need must be assessed by some kind of triage.

- Respect for the *rights* of a person. Everyone who needs health care is entitled to a fair share of the resources available. This perspective is particularly relevant when local or global economic, social, educational or other inequalities prevent or reduce equitable access to health care.
- Respect for *merit*. Health care is delivered on the basis of value judgements, according to financial, political, social or other factors relating to the value of the individual to society. For example, the President of the USA is cared for by an in-house personal physician and the White House Medical Unit. The relevance of this perspective to health care is widely disputed, not least because such value judgements are difficult to make in practice and to defend ethically.

Types of ethical problem

When faced with an ethical problem, it is often helpful to characterise it in terms of certain patterns which can be recognised (Fig. 1.5).

A gap or block

The ideal goal is clearly seen but there are major obstacles to achieving it. The obstacles may be economic or social, or in the belief system of the patient. The obvious answer—to bridge the gap or remove the block—may not be possible within the available time frame and resources. A young boy from a poor family in a developing country,

Fig. 1.5 A classification of ethical problems.

who has Wilson's disease and needs a liver transplant, is an example of an economic block. Some problems of this kind cannot be resolved satisfactorily in the clinical context until or unless they are resolved in the economic or political context.

Priority-setting

The right course of action is clear but prioritisation is necessary and the principles to guide that process have to be defined. A decision to allot the last bed in intensive care to either an 80-year-old patient with pneumonia or a 20-year-old with advanced lymphoma is an example. While it is not possible to cover all eventualities, guidelines agreed in advance with relevant stakeholders are often helpful.

A moral dilemma

Acting in accordance with one ethical principle may conflict with another ethical principle. This can create a moral dilemma—a choice between two alternatives, neither of which is ethically satisfactory. For example, a physician may decide that a particular mode of therapy is best (principle of beneficence) while the patient makes a different choice (principle of respect for autonomy). In theory, the dilemma can be resolved only if one of the ethical principles is given priority; ethical analysis (see below) can help to achieve resolution. True moral dilemmas are less common in practice than in theory; apparent dilemmas can often be resolved by good doctor–patient communication.

Resolving conflict

A conflict of opinion may arise between members of the team responsible for care of the patient. Differing views should normally be resolved through discussion, but if this does not work, decision-making authority allocated in advance may have to be invoked. The challenge then is to ensure consistent and accurate implementation of the decision.

Ethical analysis

Ethical analysis (or moral reasoning) is the process of thinking through ethical problems and reaching a conclusion. It helps the decision-maker to grow personally and professionally, allows communication of the process by which a decision is made, and permits the process to be constructively criticised. It can be used systematically: for example, in retrospective review of difficult cases. When, in everyday practice, time for reflection is limited, knowledge of methods of moral reasoning provides a useful background and aid for decision-making, and is often employed in ways analogous to those of 'the novice–expert shift' (see Box 1.13, p. 14). Some approaches that can be applied are as follows:

- *A principles approach.* This involves analysing an ethical problem in terms of the principles of respect for autonomy, beneficence, non-maleficence and justice. If all of these principles support a particular course of action, then that course of action is probably correct and there may in fact no longer be an ethical problem. If, however, different principles suggest different courses of action, this approach has no intrinsic mechanism for deciding which principle has priority. On the other hand, analysing the problem in terms of these principles can help
- to clarify the nature of the ethical problem and the issues which need to be addressed if the problem is to be resolved.
- *A casuistry (cases) approach.* This uses precedent as a guide to what to do. A case is recalled or imagined which is similar to that under discussion but where the right choice of action/behaviour was obvious. Then the features which make the present case different, if any, are analysed and considered to see if and why they lead to a different conclusion. A variation on this approach, related to virtue ethics, is to imagine what a physician who was particularly skilled or experienced in this type of situation would do, or how a previous patient might have viewed the problem.
- *A perspectives (or narrative) approach.* A perspectives approach involves considering the views of all the stakeholders: the patient, the family or carers, the health-care team, the health service and society. The greater the degree of concordance of these views on a particular outcome, the more likely it is that the decision leading to that outcome is right. A narrative approach is similar to this but involves listening attentively to the different 'stories' told by the stakeholders about the problem and how they perceive it in their own experience. Where these stories differ can provide clues to a more nuanced understanding of the problem and how, if possible, it might be resolved.
- *A counter-argument approach.* A particular course of action is chosen and the best ethical arguments against it are then marshalled and evaluated. This may or may not cause the decision to be reconsidered.
- *Application of rules.* In certain common and clearly defined situations, externally imposed rules (including the law) may require, or guide towards, a specific course of action. This does not obviate the need for ethical analysis. Moreover, any such rules must be reviewed regularly.

While all of these approaches may be useful, it is important to remember that none of them removes the need on the one hand for the exercise of judgement, and on the other for good communication and consensus decision-making. No less important is the requirement for all of this to be based on sound and shared information about the clinical and human facts of the case. In this respect a useful, integrated way of addressing ethical problems is provided by what has been called:

- *An onion-peel approach.* This uses a layered framework to analyse the problem systematically (Box 1.11).

Discussion with colleagues and others is crucial in reaching ethical decisions. Many hospitals have a clinical ethics committee to review difficult decisions. Up-to-date, accurate, valid and reliable data should inform the decision-making progress. Local legal issues must be considered. Once a conclusion has been reached, a strategy to complete the action must be implemented. Post-hoc evaluation of decisions is important, and again is best carried out collectively by an ethics committee or some other means of retrospective review.

A clinical ethics scenario

A 70-year-old man who has chronic obstructive pulmonary disease, hypertension and diabetes mellitus is admitted to hospital with pneumonia. His memory

1.11 Ethical analysis: an 'onion-peel' approach

Patient preferences: data gathered from patient and relatives/carers

- What is the quality of life expected after therapy—from the patient's perspective?
- If the patient is competent, has he or she been offered options and made choices?
- If the patient is not competent, who will make the decisions?

Medical goals: data gathered from literature, guidelines, expert opinion

- What are the prospects of a successful outcome?
- What are the best therapeutic options available based on evidence?
- Has the therapy been optimised and matched to this individual patient?

Regional issues: data gathered from local sources

- What decisions are most consistent with local laws and with social and cultural values?

Basic ethical principles, type of ethical problem, ethical analysis (see text)

- Consider the basic principles of medical ethics
- Consider the type of ethical problem
- Choose the ethical analytical approach(es) to use and apply it/them to the problem

has been deteriorating for 3 years with a rapid decline in cognition over the last 3 months and he now needs help to carry out his activities of daily living. A neurologist has evaluated him and has excluded reversible causes of dementia. The patient deteriorates and needs mechanical ventilation. His wife states that he told her (when he was well) that he did not want to be put on 'life support machines' and is therefore opposed to mechanical ventilation. Two of his children fail to confirm this and request active treatment. What care should be given?

On the one hand, considered mainly in teleological terms:

The patient is incapable of making an autonomous decision. The closest surrogate indicates that he would have preferred to forego life-sustaining therapy at this stage. (Respect for autonomy might support this.) The consequences of ventilation would probably be to prolong the process of dying (which non-maleficence could argue against) rather than increase his chances of recovery to a good quality of life. Beneficence requires that he receive general care and symptom relief immediately. An appropriate action therefore is not to ventilate the patient but to continue basic medical (fluids, oxygen and antibiotics) and nursing care in a general ward setting in order to optimise patient comfort.

On the other hand, considered in deontological as well as teleological terms:

The present illness is due to a potentially reversible infection. The patient's real preference is uncertain and his family, who have difficulty in looking after him, have expressed differing views. In terms of the duty of a doctor to make the patient's health the first consideration, and of the patient's right to appropriate health care regardless of his age or mental condition, it would

therefore be appropriate to institute all possible care, including ventilation on an intensive care unit.

In practice:

The physician responsible for the patient's care should consider the different courses of action suggested, but not determined, by these ethical analyses, explain the reasons for and against each course of action to the patient's family and, if one of them is the patient's legal surrogate, help that person come to a decision. Where there is no legal surrogate, the physician will have to reach a judgement about what is in the patient's best interests, recognising that, while judgement is always fallible, whatever decision is made must be defensible if challenged on legal or ethical grounds. Decisions that are reached on the basis of ethical and moral reasoning will be relatively easy to defend.

In this case, further discussion of the relevant issues with the relatives and other members of the health-care team led to concordance. The patient was treated by artificial ventilation in the intensive care unit for 3 days. He made a good recovery and appeared grateful for the care he had received.

Some basic concepts related to end-of-life care are discussed in Chapter 12.

PERSONAL AND PROFESSIONAL DEVELOPMENT

Good doctors never stop learning, and continue to develop their knowledge, skills and attributes throughout their working lives, to the benefit of their patients and themselves. This has become an essential component of clinical governance, which is a mechanism for ensuring high standards of clinical care (Box 1.12). Personal and professional development (PPD) requires a reflective and self-directed approach to the study and practice of medicine (Fig. 1.6), and will maximise both lifelong effectiveness and personal satisfaction. Linked to this is the concept of the novice–expert shift (Box 1.13).

PPD begins in the first days at medical school and continues through postgraduate training and subsequent professional practice. Maintaining competence and expertise requires continuous professional development (CPD). In the UK this is formally regulated by professional bodies such as the Royal Colleges, and is linked to processes of appraisal (Box 1.14) and re-accreditation for established practitioners.

To support this process, outcomes and competences for PPD are being defined at all levels of medical training, including undergraduate and postgraduate study. These sit alongside and complement curricula that focus on discipline-based knowledge and skills. As adult learners, doctors are expected to reflect on their own practice and identify their own particular learning or

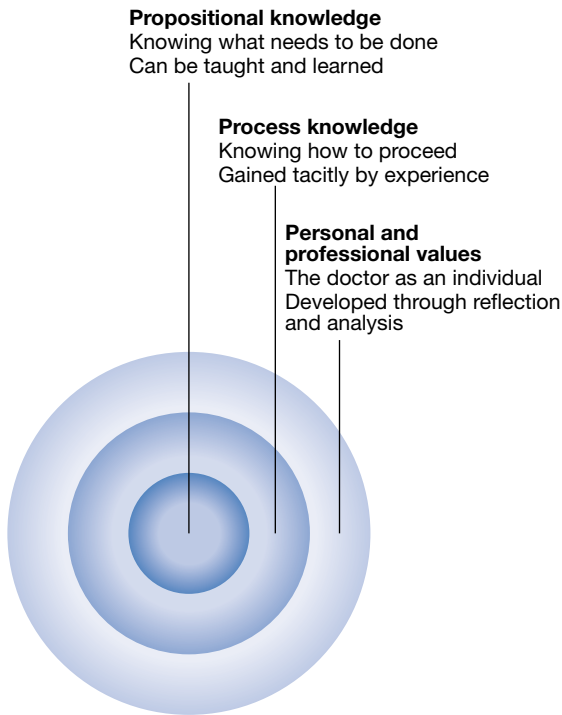

Fig. 1.6 The personal and professional development of a doctor.

1.13 The novice–expert shift

- **Novices** use pre-determined methods which they learn
- **Advanced beginners** recognise that these methods are not effective in all circumstances and can adapt them according to context
- **Competent professionals** are able to make conscious, independent choices and can manage and regulate their own practice
- **Proficient professionals** make use of intuition based on experience, and integrate multiple aspects of practice into a holistic model
- **Experts** function largely through ‘unconscious competence’ and are inseparable from the tasks they undertake

1.14 Some techniques used in the appraisal process

- Formal, structured assessment (e.g. postgraduate examinations)
- 360° assessment (surveying colleagues from medicine and other disciplines who work alongside the practitioner)
- Educational supervision and mentoring (a specific colleague has nominated responsibility to guide, and also assess, the practitioner)
- Logbooks (records of work undertaken and outcomes)
- Portfolio-based assessment (the practitioner accumulates a record of educational and clinical experiences together with evidence of reflective practice)

developmental needs. This recognises that doctors will have different learning needs throughout their career which will be affected by their current clinical practice, their future career plans and any areas of educational need that have become apparent through the appraisal process.

Whilst the individual learning needs of doctors are important, each doctor has a duty to ensure that his or her clinical knowledge and skills are up-to-date and comparable with his or her peers. Clinical audit is one method of assessing practice in this context.

Clinical audit

Clinical audit is the process by which the clinical practice of a doctor or medical team and the outcomes of that practice are evaluated against an agreed standard. Where practice fails to meet the standard, changes to practice are implemented; after a period, practice can be re-evaluated to identify any improvement. The continuing evaluation, implementation of change and re-evaluation process is known as the audit loop or cycle (Fig. 1.7). The standard against which practice is measured is usually an externally agreed one, rather than a local one. It is important to know that clinical care is comparable to that delivered elsewhere. For this reason, national standards are the norm in most countries, often set alongside national guidelines which signpost the practice necessary to achieve them. Clinical audit may be conducted by the doctor or team themselves, or by an external body. Outcome measures may include success rates or complication rates of clinical procedures such as surgical operations; process variables such as waiting times for clinical care; or the perspective of patients and relatives. In the UK, all practising clinicians are now expected to participate in audit, and it is an integral part of appraisal procedures and proposals for revalidation and relicensing of doctors.

Fig. 1.7 The clinical audit loop.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

Complementary and alternative medicine (CAM) refers to a group of medical and health-care systems, practices and products that are not considered to be part of conventional medicine. It covers an enormous and ever-changing range of activities, from well-established physical therapies such as osteopathy to spiritual measures such as prayer specifically for health. Proponents suggest that CAM focuses on the whole person: his or her lifestyle, environment, diet, and mental, emotional and spiritual health, as well as physical complaints.

‘Complementary medicine’ is the term used to describe the use of these treatments in conjunction with conventional medicine (e.g. acupuncture to reduce pain

after surgery). 'Alternative medicine' describes their use in place of conventional medicine (e.g. reflexology instead of anti-inflammatory drugs for arthritis). Clearly, most forms of treatment can be used in either way, so the term CAM is often used generically. 'Integrative medicine' describes the use of conventional therapy in combination with one or more complementary therapies for which there is evidence of efficacy and safety.

A variety of different taxonomies are used for CAM therapies. The National Center for Complementary and Alternative Medicine in the USA uses the following classification:

- *Alternative medical systems.* These have their own constructs of theory and practice, often based on ancient historical beliefs. Examples are homeopathy, naturopathy, traditional Chinese medicine and Ayurveda.
- *Mind-body interactions.* These rely on the mind's capacity to influence physical function. Examples are meditation, prayer, mental healing, music therapy and dance.
- *Biologically based therapies.* These involve the use or regulation of an extraneous agent or preparation. Examples include herbal medicine, dietary supplementation and nutritional medicine.
- *Manipulative and body-based methods.* These are based on manipulation or movement of parts of the body. They include osteopathy, chiropractic, reflexology and massage (which is often combined with aromatherapy).
- *Energy therapies.* These involve use of energy fields. Examples include gi gong, reiki and therapeutic touch.

Some forms of CAM are embedded in the cultural norms of particular social and ethnic groups, e.g. traditional Chinese medicine. In Western society, the use of CAM is extensive and growing. For example, in 2002 in the USA, at any one time 36% of the population were using some form of CAM. If prayer for health reasons was included, this figure rose to 62%. The most common medical conditions involved were back, neck, head or joint pain, upper respiratory tract infections, anxiety or depression, gastrointestinal symptoms and sleep disturbance.

The popularity of CAM may reflect a lack of confidence in conventional medicine, particularly a belief that it will not help the condition or may cause harm. CAM is particularly popular with cancer patients who have disease which is unresponsive to conventional medicines. In addition, it may reflect the increasing ease of access to information and therapies via the Internet, although such information is not formally regulated. CAM is often perceived to be completely safe; patients may therefore be willing to experiment with it as a 'no-lose' measure. Moreover, many forms of CAM are, regardless of any therapeutic benefit, inherently pleasurable.

Safety

Not all CAM therapies are entirely safe; some are toxic in their own right (e.g. dietary supplements containing ephedrine alkaloids, now banned in the USA) and others are harmful if used in combination with conventional treatment (e.g. garlic supplements that interfere

with the action of anti-HIV chemotherapy). Others have been reported to be associated with rare but serious side-effects, which can be life-threatening (e.g. bowel perforation from coffee enemas, hyponatraemia from noni juice).

There is also a potential for harm when alternative medicine is used to treat serious or life-threatening medical conditions if the resultant delay in seeking conventional treatment compromises clinical outcome, in a way that patients would not have chosen had they been fully informed at the outset.

On balance, however, the relative safety of most CAM therapies is a positive feature; homeopathy is an obvious example.

Evidence

In an era where EBM is the norm, practitioners and advocates of CAM are increasingly challenged to justify these treatments through independent, well-conducted, randomised controlled clinical trials. In some cases this may be difficult (e.g. the placebo arm of a double-blind trial of acupuncture). In addition, it can be argued that different types and standards of evidence, focusing on patient satisfaction and subjective benefit rather than measurable clinical outcomes, are more appropriate for CAM. The literature in this area is growing rapidly but, at present, only a minority of CAM therapies are supported by evidence that would be acceptable for conventional medicine. These are primarily the 'big five' CAM therapies: homeopathy, osteopathy, chiropractic, acupuncture and herbal medicine. Moreover, where evidence does exist, it is often limited to a small subset of the clinical conditions for which the treatment is used.

Regulation

Many CAM therapies have professional regulatory frameworks in place, and others are following suit. Nevertheless, for many CAM therapies, there is still no established structure of training, certification and accreditation, and practice is effectively open to all. Set against the demanding training and life-long continuous professional development that pertain to conventional medicine, this constitutes an important barrier to integrative medicine.

Integrated health care

There is a considerable popular and political impetus behind moves to integrate CAM with conventional medicine and health care at the level of resource allocation, service design, clinical practice, education and research. Almost 50% of general practices in the UK now offer some form of access to CAM and this is an increasing trend in hospitals. Historically, patients using both types of therapy have often experienced conflicting advice and value judgements, poor or absent communication between practitioners, and even hostility or ridicule. They often revert to secrecy, an inherently undesirable and potentially dangerous outcome. Integrated health care aims to understand and remove the barriers that create such dilemmas for patients. It aims to let them exercise their choice of treatment in an open environment characterised by good communication, respect, and due consideration of autonomy, efficacy and risk.

WHAT MAKES A GOOD PRESCRIBER?

The purpose of drug therapy is to cure or ameliorate disease or to alleviate symptoms. However, all drugs have adverse effects and before a drug is prescribed clinicians need to weigh the potential benefit of therapy against the potential for doing harm. A good prescriber:

- prescribes only when necessary, having carefully assessed the balance of benefit and harm
- chooses medicines that are appropriate for the disease and the patient
- chooses a dosage regimen that is appropriate to the disease and the patient
- continues therapy for an appropriate time and alters doses when necessary.

BASIC PRINCIPLES OF PHARMACOLOGY RELEVANT TO PRESCRIBING

The essence of good prescribing is to pick the most appropriate drug for the disease in question, taking pathophysiology into account. For example, rheumatoid arthritis and osteoarthritis both cause joint pain. Although some aspects of management are similar (such as the use of analgesics), other aspects differ (such as the use of immunosuppressives in rheumatoid arthritis) because the pathophysiology is different. Similar comments apply to the treatment of haemorrhagic as compared with embolic stroke.

Mechanisms of action of drugs

Drugs act on a wide variety of targets, as discussed below.

Drugs that act on receptors

Many drugs act by binding to receptors, which are proteins that affect cellular function by modulating intracellular signalling pathways (p. 46). Although most receptors are located on the cell surface, some—such as steroid hormone receptors—are located intracellularly. There are four subtypes of drugs that interact with receptors:

- *Agonists* cause activation of receptors and their downstream intracellular signalling pathways.
- *Pure antagonists* prevent agonists from binding and inhibit receptors and their downstream intracellular signalling pathways.
- *Partial agonists* activate receptors to an extent, but not to the same degree as a full agonist; depending on the milieu, they can act as agonists or antagonists.
- *Inverse agonists* bind to receptors and block the effects of endogenous ligands, but also stimulate the receptor, causing effects opposite to those of agonists.

Drugs that act on transport processes

Many drugs act on ion channels, which are responsible for transporting cations (such as sodium, potassium and calcium) and other substances (such as organic acids in the kidneys and neurotransmitters in the nervous sys-

tem) across cell membranes. Drugs that act on transport proteins can exert their effects in several ways:

- by blocking transport of an endogenous substance
- by increasing release of an endogenous ligand
- by inhibiting reuptake of an endogenous ligand.

Drugs that act on enzymes

Several drugs act on enzymes and work by modulating synthesis of a second messenger or a substance involved in the pathophysiology of disease.

Drug action by other miscellaneous effects

- *Chelating agents* bind metal ions and are used to treat, for example, iron and copper overload syndromes.
- *Osmotic agents* are used as diuretics and in the treatment of cerebral oedema.
- *General anaesthetics* do not have a specific molecular target but act on the lipid matrix of biological membranes, changing its biophysical properties.
- *Enzymes* are used as replacement therapy in patients with deficiency or to activate specific pathways.

Stereoisomerism and drug action

If a carbon atom has four different substituents it is called asymmetric; the conformation of the four other atoms or molecules around it can vary. Sometimes other atoms (such as phosphorus) are asymmetric in an analogous way. This leads to forms with different optical activities, rotating polarised light to the left or right. By convention, a substance that rotates polarised light to the right is called dextrorotatory (d), while a substance that rotates polarised light to the left is called laevorotatory (l). If the actual spatial arrangement of the molecules is known, the right- and left-handedness of the configuration about an asymmetric atom is designated by 'R' and 'S' (Latin, *rectus* and *sinister*), or 'D' and 'L'. Stereoisomers are of two types, enantiomers and diastereomers (or 'epimers').

- In *enantiomers*, asymmetry occurs at all the centres of potential asymmetry (chiral centres). Enantiomers can be considered as 'mirror images' of one another (Fig. 2.1) and tend to have similar physicochemical properties.
- In *diastereomers*, asymmetry occurs at only one chiral centre, even though the molecule may have more than one; in such cases the isomers are not mirror images of each other. Diastereomers do not usually share similar physicochemical properties.

About 40% per cent of the drugs used in routine clinical practice are chiral, and about 90% of these are marketed in the racemic form (as an equal mixture of the two stereoisomers). Examples of drugs that are marketed as single stereoisomers include naproxen, levodopa (L-dopa), levothyroxine (L-thyroxine) and dextrose (D-glucose). Often there are important pharmacological differences between stereoisomers, as the following examples show:

- S-warfarin is about five times more potent than R-warfarin; the two isomers are differently metabolised and are subject to different drug interactions.
- L-sotalol is a beta-adrenoceptor antagonist while D-sotalol is a class III anti-arrhythmic drug.
- R-thalidomide is a hypnotic, while S-thalidomide is immunomodulatory and teratogenic.

Although it is theoretically desirable to take advantage of these differences by using individual isomers,

Fig. 2.1 An example of stereoisomerism. The central carbon atom in amino acids is asymmetrical, i.e. it is attached to four different moieties; two configurations are possible, mirror images of each other and not superimposable. These are L-alanine and D-alanine. Levodopa (L-dihydroxyphenylalanine) has a similar structure to L-alanine, but the CH_3 group is replaced by $\text{C}_6\text{H}_3(\text{OH})_2\text{CH}_2$.

it is generally too difficult to prepare them in practice, and in any case administration of a single isomer often results in back-conversion to the racemic form *in vivo*. In a few cases drug companies have extended the patent lives of some of their drugs by marketing them as isomers; examples include esomeprazole and escitalopram. These drugs generally have few or no advantages over the corresponding racemic mixtures.

Pharmacokinetics

Following administration, disposition of drugs in the body is determined by drug absorption, distribution, metabolism and excretion. Taken together, these processes define the pharmacokinetics of a drug. A few simple pharmacokinetic principles are worth knowing in relation to practical prescribing.

Drug absorption and systemic availability

After oral administration drugs are mainly absorbed in the small bowel. The *speed* of absorption is affected by the rate of gastric emptying and the formulation. The absolute *amount* of absorption is generally unaffected by these factors. Some drugs are inactivated in the gut and need to be given parenterally, whereas others are removed by metabolism during absorption, or by enzymes in the gut and liver. This is called first-pass metabolism. The systemic availability of a drug (bioavailability) depends on the extent to which it is absorbed and metabolised. Drug interactions that involve inhibition of gut or liver metabolism reduce bioavailability. Impaired liver function reduces first-pass metabolism and increases bioavailability.

Drug distribution

Drugs are distributed by binding to plasma and tissue proteins. In the plasma, acidic drugs, such as warfarin and phenytoin, are bound to albumin, whereas basic drugs, such as propranolol, are bound to alpha₁ acid glycoproteins (such as C-reactive protein). Changes in the concentrations of these proteins can alter the disposition of drugs markedly. Furthermore, the affinity of albumin for drugs changes in chronic renal failure, probably because of dialysable endogenous inhibitors of binding.

Drug metabolism

Most drug metabolism occurs in the liver. The main routes are through:

- oxidation by the family of enzymes known as cytochrome P450 (CYP)
- conjugation to glucuronides, sulphates and other derivatives (acetyl, methyl) by various enzymes
- direct enzymatic breakdown.

The CYP family plays a key role in drug metabolism, and the various subtypes are designated by a combination of letters and numbers (e.g. CYP3A4, CYP2D6). Each metabolises a range of drugs, and they can also be inhibited by drugs. Many clinically important drug interactions occur through inhibition of CYP activity.

Drug excretion

The main route of drug excretion is by the kidney, where drugs are filtered at the glomerulus and reabsorbed or secreted by the renal tubules. Drug excretion is reduced in renal insufficiency, and this can result in toxicity unless the dosage is adjusted. For some drugs, excretion also occurs through the gut as the result of secretion by enterocytes, with subsequent reabsorption. The secretory process is active, mediated by P glycoprotein, and is potentially susceptible to inhibition by other drugs. After overdose, reabsorption after enteric secretion can be prevented by repeated administration of activated charcoal, increasing the rate of clearance. This can be used to treat overdose with some drugs such as carbamazepine, theophylline and cardiac glycosides.

THE BALANCE OF BENEFIT AND HARM IN DRUG THERAPY

The balance of benefit and harm in drug therapy depends on various factors (Box 2.1). Generally, it will be favourable if the disease is life-threatening, the drug highly effective and the only one available, and the risk of serious adverse effects negligible. For example, acetylcysteine is highly effective in preventing liver damage after paracetamol overdose (p. 211), its adverse effects are

2.1 Factors that determine the balance of benefit and harm in drug therapy

Factor	Balance of benefit and harm	
	Favourable	Unfavourable
Seriousness of the disease	Life-threatening	Trivial
Efficacy of the drug	High	Low
Seriousness of adverse effects	Trivial	Serious
Frequency of adverse effects	Rare	Frequent
Efficacy of alternative drugs	Poor	Good
Safety of alternative drugs	Poor	Good

2.2 Some drugs with a low therapeutic index

- Aminoglycoside antibiotics
- Anticoagulants
- Anticonvulsants
- Antihypertensive drugs
- Cardiac glycosides
- Cytotoxic and immunosuppressant drugs
- Drugs that act on the central nervous system
- Oral contraceptives

uncommon and usually mild, and no other agent is as effective. The balance of benefit and harm is unfavourable when the disease is trivial, the drug poorly effective with more effective and safer competitors, and the risk of serious adverse effects high. For example, aminophenazone, used in some countries to treat headache, can cause severe bone marrow depression, and there are much safer and equally effective alternatives. Most cases lie somewhere between these two extremes.

When assessing the balance of benefit and harm, remember that some drugs can cause adverse effects when given in dosages that are within or only a little above the usual therapeutic range; these drugs are said to have a low therapeutic index (Box 2.2). Assessment of the balance of benefit and harm is best made by using evidence-based medicine.

EVIDENCE-BASED MEDICINE IN DRUG THERAPY

For many years doctors have based decisions about the use of drugs or other therapeutic measures on the available evidence, but until recently this was done in a haphazard fashion. For example, treatment strategies would often be formulated using selected pieces of evidence that experts in the field judged to be the most valuable or relevant. Inevitably, bias occurred. The discipline of evidence-based medicine (EBM) introduced a more systematic approach. The tenets of EBM are shown in Box 2.3.

The most important but most difficult task is to apply EBM to management of the individual patient. This is because evidence from large-scale clinical trials is often derived from populations that may not have included

2.3 Principles of evidence-based medicine

- Carrying out high-quality, randomised, controlled clinical trials
- Tracing all the available evidence (published and unpublished)
- Analysing the evidence systematically
- Determining how valid and useful the evidence is
- Developing computerised databases of relevant information
- Applying that evidence to the management of the individual patient

patients like those the prescriber wants to treat. For example, trials that are undertaken by pharmaceutical companies to gain marketing authorisation often have strict inclusion and exclusion criteria and may not be representative of 'real-life' patients. Methods for dealing with this are available, but are not as well developed or easily applied as the methods for obtaining the evidence. In addition, there are many therapeutic problems for which evidence from high-quality randomised trials is not available, and in such cases the prescriber has to use clinical judgement and whatever evidence is available. The evidence-based medicine movement has tended to devalue forms of evidence that are not based on randomised trials, but this view needs to be corrected; observational studies and sometimes even anecdotal reports can contribute usefully in different circumstances and should be used when necessary.

Beneficial effects and the number needed to treat for benefit (NNT_b)

Benefit in drug therapy is often expressed as the so-called number needed to treat (NNT or NNT_b), which is the number of patients who need to be treated in order to produce benefit. A simple example illustrates how this is calculated. Of 239 patients with the acute pain of third molar extraction, 122 were given placebo, of whom 9 (7.4%) had at least 50% pain relief by 6 hours, compared with 65 (55.6%) of the 117 patients who were given ibuprofen; the difference was therefore $55.6 - 7.4 = 48.2\%$, or an effect size of 0.482. This is known as the absolute risk reduction, and the NNT_b is the inverse of this: $1/0.482 = 2.1$. In other words 1 out of every 2 people who take a single dose of ibuprofen will have better than 50% pain relief in the 6 hours after the dose. The 95% confidence interval of this estimate (the calculation of which is more complicated) was 1.7–2.6; in other words, the mean estimate of the NNT_b was 2.1 and there was a 95% chance that the true value lay between 1.7 and 2.6.

When a drug is given repeatedly, rather than as a single dose, the duration of therapy also has to be considered. For example, in a systematic analysis of the use of warfarin to prevent strokes in patients with atrial fibrillation there were 53 strokes in 1450 patients who took warfarin (3.66%) and 133 in 1450 patients who took placebo (9.17%). The effect size was thus $9.17 - 3.66 = 5.51\%$ (0.0551) and the NNT_b was 18 ($1/0.0551$). The confidence interval was 14–27. So, on the basis of these results, if 18 patients were treated with warfarin for 1 year, one stroke would be prevented. It is not valid to extrapolate effects to durations of treatment that were not studied in the original trial; in other words, we cannot conclude that if 18 patients were treated for 2 years, two strokes would be prevented; a longer trial would be needed to investigate this.

For a further perspective on NNT_B , consider oral contraception. On average a woman who has unprotected sex for 1 year has a 40% chance of becoming pregnant, while a woman who takes some form of oral contraception has a 3% chance; this 37% difference translates into an NNT_B of 2.7 ($1/0.37$). Now because oral contraception is so effective it might be expected that the NNT_B would be very close to 1 but that is not so, since the NNT_B takes into account the rate that occurs without treatment. In other words, if 100 women are treated for a year with an oral contraceptive only 37 (100/2.7) pregnancies that would otherwise have occurred will be prevented, because the other 63 women would not have become pregnant anyway. However with the passage of time, the NNT_B for oral contraceptives falls and approaches 1.0, as unprotected sexually active women will mostly become pregnant eventually.

Adverse effects and the number needed to treat for harm (NNT_H)

The other side of the coin, the number needed to treat for harm to occur (NNT_H), can be similarly calculated from data on adverse effects of drugs. For example, in a meta-analysis of 13 trials of the effect of thiazide diuretics in essential hypertension, 205 out of 3275 patients taking a thiazide had erectile impotence (6.26%), compared with 67 out of 5295 patients taking placebo (1.27%); the difference is 5% and so the NNT_H for this effect is 20 (Box 2.4).

The balance of benefit and harm assessed from the NNT_B and NNT_H

Although one might expect to be able to express the balance of benefit to harm as the simple ratio of the NNT_B to

the NNT_H , the comparison is not straightforward, since the quality of the benefit and the severity and seriousness of the harm need to be weighed against each other.

Consider tamoxifen, which prolongs survival in breast cancer (by an anti-oestrogenic effect on the tumour) and reduces the risk of myocardial infarction, but causes endometrial cancer and venous thromboembolism (by oestrogenic effects on lipids, the endometrium and clotting factors):

- NNT_B to prevent one death = 17
- NNT_B to prevent one myocardial infarction = 29
- NNT_H for one case of endometrial cancer = 143
- NNT_H for one venous thromboembolism = 130.

These figures suggest that treating 1000 women with breast cancer for 2–5 years with tamoxifen will prevent about 60 deaths and 34 myocardial infarctions, at the cost of 7 cases of endometrial cancer and 7 cases of venous thromboembolism, clearly a favourable benefit to harm balance. However, calculations of this sort yield probabilities that relate to the patients that have been studied in clinical trials. They do not necessarily apply to the whole population and do not predict what the outcome will be in the individual patient.

There are other ways of expressing results of this kind. For example, it is possible to calculate the risk ratio (RR) or odds ratio (OR), each with its confidence interval (see Box 2.4). The larger the effect, the higher the odds ratio is relative to the risk ratio; at incidences of up to about 15% the risk ratio and odds ratio are very similar, but at higher incidences the odds ratio starts to overestimate the risk ratio considerably. Note that two treatments can have exactly the same risk ratio but different values of NNT_H . For example, a treatment that increases the risk

i

2.4 Calculation of NNT_H , risk ratio and odds ratio

(A) A THEORETICAL CASE				(B) A REAL CASE*			
Group	Number with the adverse event	Number without the adverse event	Total	Group	Number with the adverse event	Number without the adverse event	Total
Active treatment	a	b	a+b	Drug	205	3070	3275
Placebo	c	d	c+d	Placebo	67	5228	5295
Total	a+c	b+d	a+b+c+d	Total	272	8298	8570
1. Calculation of number needed to treat for harm (NNT_H) Rate of event in treated group = $a/(a+b)$ Rate of event in placebo group = $c/(c+d)$ Difference (absolute harm increase) = $a/(a+b) - c/(c+d) = A$ $NNT_H = 1/A$				1. Calculation of number needed to treat for harm (NNT_H) Rate of event in treated group = $205/3275$ Rate of event in placebo group = $67/5295$ Difference (absolute harm increase) = $205/3275 - 67/5295 = 0.0499$ $NNT_H = \frac{1}{0.0499} = 20$			
2. Calculation of risk ratio (RR) Rate of event in treated group = $a/(a+b)$ Rate of event in placebo group = $c/(c+d)$ Relative risk = $[a/(a+b)]/[c/(c+d)]$				2. Calculation of risk ratio (RR) Rate of event in treated group = $205/3275$ Rate of event in placebo group = $67/5295$ Relative risk = $[205/3275]/[67/5295] = 5.0$ (i.e. a five-fold risk)			
3. Calculation of odds ratio (OR) Odds of event in treated group = a/b Odds of event in placebo group = c/d Odds ratio = $(a/b)/(c/d)$				3. Calculation of odds ratio (OR) Odds of event in treated group = $205/3070$ Odds of event in placebo group = $67/5228$ Odds ratio = $[205/3070]/[67/5228] = 5.2$ (i.e. relative odds of about 5 to 1 on)			

*Erectile impotence with thiazide diuretics in hypertension over a mean of 4 years, a meta-analysis of 13 RCTs (Hypertension 1999; 34:710).

of an adverse event from 1% to 2% would have a risk ratio of 2 but an NNT_H of 100 (1/0.01), while a treatment that increased the risk of an adverse event from 25% to 50% would also have a risk ratio of 2 but an NNT_H of 4 (1/0.25), a much more important effect. When it was reported that third-generation progestogens approximately doubled the risk of deep venous thrombosis compared with older progestogens, the announcement caused some women to panic; they did not appreciate that the baseline risk was very low and the NNT_H therefore very high.

Obtaining the best evidence

Randomised trials are highly desirable as sources of evidence that treatments are effective. However, randomised trials are not perfect. They may be underpowered and give results that are contradictory or implausible. Conversely, non-randomised evidence is sometimes sufficient to make a clear case for the effectiveness of an intervention. Some ways of obtaining evidence are listed in Box 2.5. Depending on the quality of the design and conduct, the evidence that any of these forms of study provides can be

2.5 Some methods of obtaining evidence in drug therapy

- Systematic review (meta-analysis)
- Systematic review (other types of analysis)
- Prospective, randomised, double-blind, placebo-controlled trial
- Prospective, randomised, double-blind, comparative trial (drug vs. drug)
- Cohort study
- Case-control study
- Point prevalence study
- Subgroup analysis of a large trial (generates hypotheses for further trials)
- N-of-one trial
- Other trials (e.g. non-randomised, non-controlled, historical controls, retrospective analysis)
- Case series and case reports
- Non-systematic review

of value in clinical decision-making. Accordingly, there is no absolute index of the usefulness of evidence, because in different circumstances one form of evidence may be better than another.

Any form of evidence of causation can be assessed, using guidelines to help decide whether an association is causative or an intervention effective (Box 2.6). The guidelines, adapted from ones originally devised by Sir Austin Bradford Hill, can be organised into three categories:

1. direct evidence from studies (randomised or non-randomised) that a probabilistic association between intervention and outcome is causal and not spurious
2. mechanistic evidence for the alleged causal process that connects the intervention and the outcome
3. parallel evidence that supports the causal hypothesis suggested in a study, by noting that related studies have consistent results.

DRUG DISCOVERY AND DEVELOPMENT

Most drug discovery nowadays is carried out by pharmaceutical companies. However, they rely heavily on research in academic institutions, and governments in developed countries spend about twice as much on drug research as pharmaceutical companies. Current estimates of the costs to a company of developing a new drug range from \$250 million to \$1000 million.

Drug discovery

There are several ways in which drugs are discovered:

- *from herbal remedies*: for example, morphine from the opium poppy (*Papaver somniferum*) and digoxin from foxgloves (*Digitalis lanata*)
- *from studies of endogenous agents in animals*: for example, the anticoagulant hirudin from the medicinal leech (*Hirudo medicinalis*)
- *serendipity*: for example, penicillins from Alexander Fleming's chance observation of the effect of *Penicillium* mould on bacterial growth

2.6 Guidelines for assessing the strength of evidence for a cause and effect relationship of interventions*

Type of evidence	Guideline	Comment
Direct	Size of effect not attributable to plausible confounding Appropriate temporal and/or spatial proximity	The larger the effect and the fewer the identifiable confounding factors, the stronger the evidence in favour of an association The cause/intervention should precede the effect and the effect should occur after a plausible interval; the effect should occur at the same site as the intervention
	Dose-responsiveness and reversibility	The presence of dose-responsiveness and reversibility provides strong evidence in favour of an association; its absence is unhelpful
Mechanistic	Evidence for a mechanism of action Coherence	The absence of biological, chemical or mechanical plausibility provides evidence against an association Absence of consistency with the current scientific paradigm provides strong evidence against an association
Parallel	Replicability	Replicability in different settings and at different times provides strong evidence in favour of an association
	Similarity	If similar effects are produced by analogous interventions, this provides strong evidence in favour of an association

*Adapted from Howick J, et al. J R Soc Med 2009; 102:186–194.

- *metabolites of existing drugs*: for example, mesalazine (the active metabolite of sulfasalazine)
- *applied pharmacology and empirical chemistry*: for example, the development of β -adrenoceptor antagonists (β -blockers) based on the structure of isoprenaline
- *rational drug design based on knowledge of pathophysiology*: for example, the development of tumour necrosis factor alpha (TNF- α) blocking agents for the treatment of rheumatoid arthritis, based on the finding of increased TNF- α concentrations in the joints of affected patients
- *rational design based on the human genome*: for example, the development of cathepsin K inhibitors as bone resorption inhibitors, based on the observation that mutations of cathepsin K result in increased bone mass with reduced bone resorption.

The current issue of the *British National Formulary* (BNF) contains about 1200 compounds. About 75% of these have human targets; the rest are either antimicrobial drugs or have no specific pharmacological targets (e.g. vitamins, plasma substitutes). About 150 pharmacological targets are known. A comparison of this figure with the number of genes in the human genome (about 25000) shows how much therapeutic potential there is still to be realised. Of these targets, about 25% are G protein-coupled receptors, 25% enzymes, 20% other types of receptor (ionotropic, kinase-linked and nuclear receptors), 10% ion channels and transporters, and 10% a variety of proteins (including TNF- α , VEGF, HER-2, interferons, cell surface antigens such as CD20, CD25 and CD52, and various tumour-associated antigens).

Targets can be discovered by understanding the pathophysiology of the disease, by analysing the mechanisms of action of existing drugs, or by analysing the human genome. Examples of targets that have been discovered in these respective ways are angiotensin-converting enzyme in the management of hypertension, cyclo-oxygenase in the development of non-steroidal anti-inflammatory drugs (NSAID), and *Abl* kinase in the development of anticancer drugs.

Drug development

When a new drug has been discovered it goes through a defined development process, after which it is licensed for use and marketed.

Preclinical pharmacology and toxicology

Preclinical studies include extensive pharmacological testing in vitro and in animals, including short- and long-term toxicity testing.

Clinical testing (volunteer studies)

Next the pharmacokinetics of the drug are studied after single and multiple doses. If it has measurable effects in healthy people, its pharmacology is studied and clinical, biochemical and haematological adverse effects are assessed. In some cases (for example, drugs for AIDS or cancer), healthy volunteer studies are not possible and the drug is tried immediately in patients.

Phase 0 studies

Phase 0 studies are first-in-human studies that involve the administration of tiny doses (microdoses) of the drug in a few subjects, in order to collect preliminary pharma-

cokinetic and pharmacodynamic information. They do not cover safety or efficacy.

Phase I studies

Phase I studies in patients or healthy volunteers concentrate on the clinical pharmacology of the drug, short-term safety, efficacy, pharmacological effects and pharmacokinetics. These early studies also provide information about the likely dose range to be used in phase II studies.

Phase II studies

In phase II studies further evidence of safety and efficacy is obtained in larger numbers of patients, often with a surrogate clinical endpoint, with further attention to dose-ranging and adverse effects.

Phase III studies

Phase III studies are full-scale clinical trials, in which the effects of the drug are studied in relation to an important clinical endpoint. These may be placebo-controlled studies or comparisons with other active compounds. In comparative studies the intention is usually to demonstrate superiority or, at the very least, non-inferiority. So-called 'real-life' trials involve a comparison of the new agent with standard therapy; such trials often include a pharmacoeconomic assessment of the added value that a new treatment brings in relation to its cost.

Phase IV studies

Phase IV studies are carried out after a drug has been marketed. They are designed to obtain information on the effects of the drug in populations who have not been studied before marketing and to detect adverse drug reactions or interactions. The latter are sometimes called phase V studies.

Marketing and post-marketing surveillance

If the regulatory authorities are convinced about quality, safety and efficacy, the drug will be formulated as a medicinal product, and will receive marketing authorisation and a product licence. Marketing authorisations are issued by different regulatory authorities in different countries (e.g. the Medicines and Healthcare products Regulatory Agency in the UK and the Food and Drug Administration in the USA) or by a supranational organisation, such as the European Medicines Evaluation Agency (EMA).

Surveillance of the effects of a new drug continues after marketing, both formally and informally. There is a post-marketing event monitoring (PEM) scheme in the UK, for research into adverse drug reactions after marketing, and doctors are also encouraged to report suspected adverse effects informally to regulatory agencies (for example, the yellow card scheme in the UK and Medwatch in the USA). If new serious adverse effects are noted, the drug may be withdrawn or its licensed indications may be changed. Examples in the UK include:

- *aspirin*, which is now restricted to those over 16 years of age, because of the risk of Reye's syndrome
- *clozapine*, for which a blood monitoring scheme is mandatory to detect neutropenia, should it occur
- *rofecoxib*, which was voluntarily withdrawn from the market by the manufacturers in 2004 because of an increased risk of cardiovascular disease.

PRACTICAL PRESCRIBING

When to prescribe a drug

Drug therapy is not always necessary. For example, a mild tremor in Parkinson's disease may not be unduly troublesome and drug treatment to alleviate it may cause harm, outweighing the benefit. Do not be tempted to prescribe a drug simply to end a consultation. If a patient expects drug therapy, discuss the pros and cons. Try to estimate the balance of benefit and harm and prescribe only if it seems favourable.

How to choose a drug to prescribe

After deciding to prescribe a drug, first choose the therapeutic class. The choice may be restricted or wide, as a few examples illustrate (Box 2.7).

Having chosen the class of drug, choose a therapeutic subgroup (Box 2.8). For example, the choice of an anticoagulant depends partly on whether short-term or long-term treatment is indicated. Drug interactions can also affect treatment choice, as in the case of antibiotics (Box 2.9).

2.7 Examples of choosing a therapeutic class of drug

Indication	Therapeutic class
Infection	Antibiotic
Depression	Antidepressant
Acute attack of asthma	Bronchodilators
Diabetes mellitus	Insulin Oral or parenteral (non-insulin) hypoglycaemic drugs
Congestive cardiac failure	Diuretics ACE inhibitors Vasodilators
Hypertension	Diuretics ACE inhibitors β -adrenoceptor antagonists Calcium channel blockers

2.8 Examples of choosing a group of drugs from within a class

Therapeutic class	Therapeutic group
Anticoagulants	Coumarin anticoagulants Heparins Anticoagulant factor inhibitors (e.g. direct thrombin inhibitors)
Diuretics	Thiazides Loop diuretics Potassium-sparing diuretics
Antibiotics	Penicillins Cephalosporins Tetracyclines Aminoglycosides Macrolides Quinolones

2.9 Examples of drug interactions with antibiotics

Antibiotic	Interacting drug	Mechanism	Effect
Gentamicin	Furosemide	Additive	Ototoxicity
Metronidazole	Alcohol	Inhibition of aldehyde dehydrogenase	'Disulfiram reaction'
Metronidazole	Warfarin	Inhibition of metabolism	Potential of anticoagulation
Rifampicin	Oestrogens (oral contraceptives)	Induction of metabolism	Reduced contraceptive effect
Rifampicin	Warfarin	Induction of metabolism	Reduced effect of warfarin
Tetracycline	Antacids	Chelation	Reduced effect of tetracycline
Tetracycline	Warfarin	Altered clotting factor activity	Potential of anticoagulation

Finally, choose a specific drug from within the class. In doing so, take account of the characteristics of the drugs that are available. For example, in a patient with cardiac failure, when the gut is congested with fluid, bumetanide may be preferable to furosemide because it is better absorbed from the gut. Similarly, the choice of β -blocker will depend upon whether selectivity is required for a receptor subtype, on whether vasodilatory actions are desirable and on other properties (Box 2.10). In other cases the choice may be unimportant; for example, all thiazide diuretics have equal efficacy and similar adverse effects, and there is little to choose between them.

How to make a rational choice

Many factors dictate the choice of a particular drug:

- *Absorption.* It is generally advisable to choose drugs that are well absorbed from the gut.
- *Distribution.* The distribution of a drug to a particular tissue sometimes dictates choice; for example, tetracyclines and rifampicin are

2.10 Examples of choosing a particular drug from within a group

Drug	Distinguishing features
Atenolol	Moderately β_1 -selective; water-soluble (poor brain penetration); poor vasodilator
Bisoprolol	Highly β_1 -selective; good vasodilator
Carvedilol	Non-selective and also an α -blocker; excellent vasodilator
Metoprolol	Moderately β_1 -selective; short-acting; good vasodilator
Propranolol	Non-selective; lipid-soluble; poor vasodilator
Sotalol	Non-selective; poor vasodilator; double action (β -blockade + class III anti-arrhythmic action)

concentrated in the bile, and lincomycin and clindamycin in bones.

- **Metabolism.** In severe liver disease try to avoid drugs that are extensively metabolised (for example, opiate analgesics). Genetic factors can influence the extent of metabolism of a drug, and many examples of genetically determined variations in response have been described. These factors do not make a large impact on drug prescribing but there are some important exceptions (Box 2.11).
- **Excretion.** In renal insufficiency try to avoid drugs that are excreted by the kidney; for example, avoid the aminoglycoside antibiotics if alternatives are suitable.

2.11 Some examples of genetic factors that cause variability in drug response

Genetic factor	Example of drug affected	Clinical outcome
Pharmacokinetic		
Acetylation	Isoniazid	Better response and increased risk of some adverse effects (e.g. peripheral neuropathy) in slow acetylators
Oxidation (CYP2D6)	Nortriptyline	Increased risk of toxicity in poor metabolisers
Oxidation (CYP2C18)	Proguanil (active metabolite cycloguanil)	Reduced efficacy in poor metabolisers
Oxidation (CYP2C9)	Warfarin	Polymorphisms partly determine dosages
Sulphoxidation	Penicillamine	Increased risk of toxicity in poor metabolisers
Pseudocholinesterase	Suxamethonium (succinylcholine)	Prolonged duration of effect in pseudocholinesterase deficiency
Pharmacodynamic		
Glucose-6-phosphate dehydrogenase (G6PD)	Many antimalarial drugs	Risk of haemolysis in G6PD deficiency
Porphyria	Enzyme-inducing drugs	Increased risk of an acute attack
SLC01B1 polymorphism	Statins	Increased risk of rhabdomyolysis
HLA-B*5701 polymorphism	Abacavir	Increased risk of skin hypersensitivity reactions
HLA-B*5801 polymorphism	Allopurinol	Increased risk of skin rashes in Han Chinese
HLA-B*1502 polymorphism	Carbamazepine	Increased risk of skin hypersensitivity reactions in Han Chinese

- **Efficacy.** It is best to choose drugs with the greatest efficacy, although this is not always necessary if the less efficacious drug works adequately and is easier or safer to use. For example, insulin is more efficacious at lowering the blood sugar than the oral hypoglycaemic drugs but type 2 diabetes can usually be adequately controlled without the need for insulin.
- **Features of the disease.** Choose an antibiotic to match the known or suspected sensitivity of the infective organism: for example, amoxicillin + erythromycin for a patient with a community-acquired bronchopneumonia (p. 680), since the likeliest organisms will be *Streptococcus pneumoniae* or *Legionella pneumophila*.
- **Severity of disease.** Choose a drug appropriate to the severity of the disease. For example, mild pain will generally respond well to paracetamol, whereas more severe pain may require more potent analgesics, such as opiates.
- **Coexisting diseases.** In hypertension coexisting left ventricular failure would prompt the use of a diuretic combined with an ACE inhibitor, whereas coexisting angina pectoris would prompt the use of a β -blocker.
- **Avoiding adverse effects.** Make sure that the treatment chosen does not worsen an associated condition. For example, β -blockers should be avoided as treatment for hypertension in patients with asthma.
- **Avoiding adverse drug interactions.** Try to avoid giving combinations of drugs that might interact, either directly or indirectly. For example, avoid NSAIDs in patients taking warfarin, since they increase the risk of bleeding, both by inhibiting platelet aggregation and by causing gastric ulceration; their effects on warfarin protein binding are probably not important.
- **Patient adherence to therapy.** Try to choose drugs with a simple dosing schedule. For example, when using an ACE inhibitor it is better to choose an agent that can be given once daily (e.g. enalapril) as opposed to one that needs to be given several times a day (e.g. captopril).
- **Cost.** Choose the cheaper drug if two drugs are of equal efficacy and safety. However, the true costs of drug therapy cannot always be calculated simply on the basis of the relative costs of the medication. For example, a more expensive drug that is better tolerated might be better value than a cheaper drug because of the difference in adherence to therapy.

Choosing the route of administration

There are several reasons for choosing a particular route of administration, as some examples illustrate (Box 2.12).

Choosing a formulation

Drugs come in various different formulations. The formulation can essentially be considered as a sort of packaging that influences the mode of administration and the frequency with which the drug needs to be taken. Oral formulations include tablets, capsules, granules, elixirs and suspensions. Drugs for injection come as lyophilised

2.12 Reasons for choosing a particular route of administration	
Reason	Example
Only one route possible	Dopamine (intravenous) Glibenclamide (oral)
Patient adherence	Phenothiazines and thioxanthenes (intramuscular depot injections in schizophrenia)
Poor absorption	Furosemide (intravenous, in severe heart failure)
Vomiting	Phenothiazines (rectal or buccal) Sumatriptan (nasal spray)
Avoiding first-pass metabolism	Glyceryl trinitrate (sublingual)
Rapid action	Glyceryl trinitrate (sublingual) Insulin (intravenous, in diabetic ketoacidosis)
Direct access to the site of action	Bronchodilators (inhalation, in asthma) Corticosteroids (rectal, in ulcerative colitis) Local application to skin, eyes, etc.
Ease of access	Benzodiazepines (rectal diazepam if intravenous access is difficult in status epilepticus) Subcutaneous fluids (hypodermoclysis)
Controlled release	Insulin (subcutaneous)

powders for reconstitution before injection or as solutions ready for injection; solutions come in single-dose ampoules, single-dose or multiple-dose vials, and half-litre or litre bottles for infusion. Some examples show how the choice of formulation can be important.

Lithium salts and theophylline come in several different ordinary and modified-release formulations, each with different absorption characteristics. A formulation that produces adequate serum lithium or theophylline concentrations in one patient may not be suitable for another, and it is sometimes worth changing the formulation if serum concentrations are suboptimal. These are examples of drugs that should be prescribed by specific brand name rather than the International Non-proprietary Name (INN), which is otherwise recommended.

Iron salts are available as tablets for twice- or thrice-daily administration or as modified-release formulations for once-daily administration. Adverse effects are fewer with the modified-release formulations, but the iron is more erratically absorbed. It is usual to start with an ordinary formulation of iron and change to a modified-release formulation if adverse effects occur.

Choosing a dosage regimen

The dose of the drug and the frequency and timing of its administration constitute the dosage regimen. Each prescription should be treated as an experiment to try to find the regimen that produces the best therapeutic effect with minimal adverse effects, according to some simple principles:

- Generally, start with a dose at the lower end of the recommended range. There are some exceptions to this rule; glucocorticoids and carbimazole are initially given at high doses and then the dose is reduced to a

maintenance level. Drugs such as digoxin, warfarin and amiodarone are also given using a 'loading dose' followed by a maintenance dose.

- Increase the dose slowly, monitoring the therapeutic effect at regular intervals and looking for adverse effects.
- If adverse effects occur, reduce the dose or try another drug; in some cases lower doses may be possible by combining drugs (for example, the immunosuppressant azathioprine reduces glucocorticoid requirements in patients with inflammatory disease).
- Think of drug interactions and avoid potentially dangerous combinations.
- Remember that pharmacokinetic and pharmacodynamic variability can alter dosage requirements, as discussed below.
- Take particular care with drugs that have a low therapeutic index (see Box 2.2, p. 20).

Pharmacokinetic variability

Because absorption, distribution and elimination of drugs vary from patient to patient, flexibility in dosages is necessary. The examples in Box 2.13 show how to respond to differences or changes in pharmacokinetics.

Pharmacodynamic variability

Pharmacological responses are usually governed by the dose-response curve, an example of which is shown in Figure 2.2: the effects of the loop diuretics bumetanide and furosemide on urinary sodium excretion. The two diuretics have different *potencies* (reflected by the fact that the curve for bumetanide lies to the left of the curve for furosemide), which can be dealt with by using different doses; however, they both have the same *efficacy* (reflected by the maximum height that the dose-response curve reaches), so that comparable doses produce the same diuretic effect.

2.13 Therapeutic approaches to pharmacokinetic problems	
Pharmacokinetic problem	Therapeutic approach
Poor absorption	Increase the dose Choose another route of administration Use another drug
Altered tissue distribution	One-off doses may have to be altered Usually does not affect chronic therapy, unless distribution to the target tissue is altered; may have to choose a different drug
Altered protein binding	Usually does not affect long-term therapy (but does alter steady-state total plasma drug concentration of low-clearance drugs*)
Reduced renal elimination	Reduce dosage (use creatinine clearance or eGFR as a guide)
Reduced hepatic elimination	Low-clearance drugs*: reduce oral and intravenous doses High-clearance drugs*: reduce oral (but not intravenous) doses
*See Box 2.16	

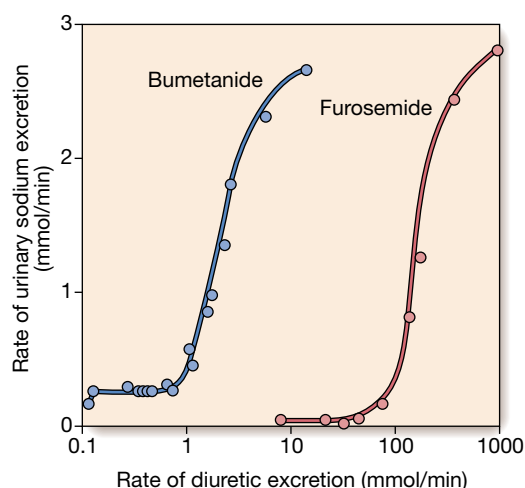

Fig. 2.2 Dose-response curves for bumetanide and furosemide. The two drugs have different potencies (the doses required to produce the same effect differ) but the same efficacy (the maximal effect is the same).

Variability in dose-responsiveness dictates flexibility in prescribing. If a therapeutic effect does not occur with the first dosage chosen, an effect may be achieved by making small increases within the therapeutic dosage range. Of course, increasing the dosage will also increase the risk of adverse effects. Certain diseases can alter a dose-response curve (for example, there is resistance to digoxin in hyperthyroidism) and the pharmacodynamics of one drug can be affected by another drug.

Choosing the frequency of drug administration

Patient adherence to therapy is probably inversely related to the number of doses that are required per day. In general, therefore, try to choose drugs that can be given no more than twice daily. A modified-release formulation can be useful in this respect. In some special cases the frequency of drug administration is an important consideration in therapy (Box 2.14).

Choosing the time of drug administration

For many drugs the time of administration is unimportant. However, there are occasionally pharmacokinetic or therapeutic reasons for giving drugs at particular times (see Box 2.14). Meal times do not usually affect drug administration, since although food may reduce the speed of absorption of a drug, it generally does not reduce the extent of absorption; notable exceptions are bisphosphonates and tetracyclines, since their absorption is greatly reduced by divalent and trivalent cations, and they should not be taken with food or antacids. Food sometimes helps to reduce adverse gastrointestinal effects; for instance, the effects of aspirin on the stomach are partly reduced by taking it with food.

Prescribing in special circumstances

Prescribing in renal insufficiency

If a drug or its active metabolites are eliminated by the kidneys, the maintenance dose must be altered in

2.14 Some special examples of frequency and timing of drug administration

Drug	Recommended frequency or timing	Reasons
Furosemide	Once in the morning	Kidney refractory to a second dose within 6 hrs; night-time diuresis undesirable
Glucocorticoids	Once in the morning	Minimises inhibitory effects on adrenal function
Salmeterol	Once at night	Prevents early morning symptoms
Antidepressants	Once at night	Allows adverse effects to occur during sleep
Digoxin	Once at night	So that when blood samples for plasma concentration measurement are taken it is at least 6 hrs (preferably 11 hrs) after the last dose
Glyceryl trinitrate (sublingual)	When required	Relief of acute symptoms
Glyceryl trinitrate patches or long-acting nitrates	Staggered doses (see <i>British National Formulary</i>)	To avoid tolerance
Tetracyclines	2 hours before or after food or antacids	Divalent and trivalent cations chelate tetracyclines, preventing absorption
Opiates	In anticipation of pain	Better relief in chronic pain
Levodopa	Several times a day	Dictated by the duration of action (often wears off quickly during long-term therapy)
Statins	Once at night	Inhibition of HMG CoA reductase is greater at night

renal insufficiency, although it is not usually necessary to alter a one-off dose. Creatinine clearance can be used as a guide to reducing maintenance dosages. Nowadays this is usually estimated (eGFR) by measurement of serum creatinine, taking age, sex and ethnic group into account. Many laboratories now report eGFR along with the serum creatinine concentration. In some cases dosages should be reduced because the pharmacological effects interact with renal impairment (for example, ACE inhibitors worsen potassium retention). Some drugs should be avoided entirely in renal insufficiency, for either pharmacokinetic or pharmacodynamic reasons (Box 2.15).

Diuretics are relatively ineffective in severe renal insufficiency because they cannot gain access to their site of action, the luminal epithelium. Potassium-sparing diuretics should not be used because of the increased risk of hyperkalaemia.

2.15 Some drugs whose dosages are affected by renal insufficiency	
Mild renal insufficiency (GFR 20–50 mL/min or serum creatinine 150–300 µmol/L)	
<ul style="list-style-type: none"> • ACE inhibitors (monitor carefully; increase dosages if renal function does not worsen with low doses) • Aminoglycosides • Chlorpropamide 	<ul style="list-style-type: none"> • Digoxin • Fibrates • Lithium • Zidovudine
Moderate renal insufficiency (GFR 10–20 mL/min or serum creatinine 300–700 µmol/L)	
<ul style="list-style-type: none"> • Some β-blockers (e.g. atenolol, sotalol) 	<ul style="list-style-type: none"> • Opioid analgesics
Severe renal insufficiency (GFR < 10 mL/min or serum creatinine > 700 µmol/L; many of these patients receive renal replacement therapy, which can affect drug pharmacokinetics)	
<ul style="list-style-type: none"> • Azathioprine • Cephalosporins • Cimetidine • Isoniazid • Penicillins 	<ul style="list-style-type: none"> • Sulphonylurea hypoglycaemic drugs (gliclazide, glipizide, gliquidone)
Drugs to avoid in renal insufficiency	
Any degree of renal insufficiency	
<ul style="list-style-type: none"> • Mesalazine • Metformin • NSAIDs 	<ul style="list-style-type: none"> • Tetracyclines (except doxycycline and minocycline)
Moderate or severe renal insufficiency	
<ul style="list-style-type: none"> • Lithium 	<ul style="list-style-type: none"> • Methotrexate
Severe renal insufficiency	
<ul style="list-style-type: none"> • Sulphonylurea hypoglycaemic drugs (chlorpropamide, glibenclamide) 	<ul style="list-style-type: none"> • Chloramphenicol • Chloroquine • Fibrates
(GFR = glomerular filtration rate)	

Prescribing in hepatic failure

The liver has a large capacity for drug metabolism and hepatic insufficiency has to be considerable before drug dosages need to be modified. In patients with chronic liver disease who have jaundice, ascites, hypoalbuminaemia, malnutrition or encephalopathy, clinically important impairment of drug metabolism is likely. Hepatic drug clearance may also be reduced in acute hepatitis, in hepatic congestion due to cardiac failure, and if there is intrahepatic arteriovenous shunting (for example, in hepatic cirrhosis).

There is no easy way of calculating dosage changes in patients with impaired hepatic function, since there are no good tests of hepatic drug-metabolising capacity or of biliary excretion. Doses of drugs that are metabolised by the liver should therefore be altered according to the therapeutic response, with careful monitoring for adverse effects.

If a drug has a high rate of hepatic clearance (Box 2.16) it will be mostly cleared during its first passage through the liver (so-called 'first-pass' metabolism). In such cases, hepatic impairment increases the amount of drug that escapes metabolism in the liver after oral administration, reducing oral dosage requirements

2.16 Some drugs of low and high hepatic clearance rates	
Low	
<ul style="list-style-type: none"> • Aspirin • Codeine • Diazepam • Isoniazid • Nortriptyline • Paracetamol 	<ul style="list-style-type: none"> • Phenobarbital • Phenytoin • Procainamide • Quinidine • Theophylline • Warfarin
High	
<ul style="list-style-type: none"> • Clomethiazole • Glyceryl trinitrate • Labetalol • Lidocaine 	<ul style="list-style-type: none"> • Morphine • Pethidine • Propranolol • Simvastatin

2.17 Some drugs whose actions are increased in liver disease	
Drug	Adverse effect
Oral anticoagulants	Increased anticoagulation (reduced clotting factor synthesis)
Metformin	Lactic acidosis
Chloramphenicol	Bone-marrow suppression
NSAIDs	Gastrointestinal bleeding
Sulphonylureas	Hypoglycaemia

but not altering intravenous dosage requirements. For example, clomethiazole is extensively metabolised by the liver, and metabolism is reduced by chronic liver disease. It is therefore important to ensure that overdose does not occur when using oral clomethiazole in a patient with liver disease. The pharmacological effects of several drugs are altered in liver disease, with increased risks of adverse effects (Box 2.17).

Prescribing for older people

The handling of, and response to, drugs change as people age, and responses to drugs are much more variable in older people. Great care must be exercised when prescribing in old age and the broad principles are outlined in Box 2.18. The dosage regimens of many drugs need to be adjusted and toxicity is more likely for several reasons (Box 2.19).

Inappropriate polypharmacy is common in old people and the scope for drug interactions is large (p. 173); in patients over 60 years of age the error rate in taking drugs is about 60% and the rate of errors increases markedly if more than three drugs are prescribed. However,

2.18 How to prescribe in old age

- Use as few drugs as possible
- Start with low doses, and increase carefully only if required
- Choose oral drugs with easily swallowed formulations
- Keep therapy as simple as possible
- Take great care in frail old people

2.19 Mechanisms of drug toxicity in old age

- **Reduced renal function:** impaired urinary excretion.
- **Smaller liver:** reduced hepatic metabolism.
- **Impaired homeostatic mechanisms:** exaggerated response.
- **Swallowing difficulty:** medication sticks in oesophagus.
- **Polypharmacy and cognitive impairment:** wrong medication taken or medication missed.
- **Increased proportion of body fat:** accumulation of lipid-soluble drugs.

polypharmacy may be appropriate and justified in some elderly people.

Many old people find it difficult to swallow tablets. Some tablets and capsules can adhere to the oesophageal mucosa and drugs should be taken with at least 60 mL of water to avoid this. Elixirs may be preferable but not all drugs are available in this form. Drug distribution may be altered in old people and dosages should be adjusted for body weight, particularly for drugs with a low therapeutic index. Some of these principles are illustrated in Figure 2.3, which shows the difference in nifedipine pharmacokinetics and pharmacodynamic responses between young and old men. After an intravenous dose of nifedipine (2.5 mg) the old men had higher plasma nifedipine concentrations and a fall in blood pressure; the difference in blood pressure response was partly due to the difference in plasma concentration, but was mostly due to a difference in baroreceptor reflexes, as shown by the difference in heart rate responses.

Examples of drugs for which special care is required in older people are shown in Box 2.20.

2.20 Drugs whose actions are frequently altered in old age

Drug	Mechanism	Consequence
Digoxin	Increased sensitivity of Na/K pump Renal impairment Hypokalaemia due to diuretics	Increased risk of toxicity
Antihypertensive drugs	Reduced baroreceptor function	Increased risk of postural hypotension
Antidepressants Hypnotics Sedatives Tranquillisers	Increased brain sensitivity; reduced metabolism	Increased risk of toxicity
Warfarin	Increased sensitivity to inhibition of clotting factor synthesis	Increased risk of bleeding
Clomethiazole Lidocaine Nifedipine Phenobarbital Propranolol Theophylline	Metabolism reduced	Increased risk of toxicity

Fig. 2.3 Differences between young men and old men given an intravenous dose of nifedipine. **A** Old men have higher plasma concentrations than young men. **B** and **C** Old men have a greater fall in blood pressure and a smaller rise in heart rate than young men.

Prescribing in pregnancy

Drug therapy in relation to pregnancy may be required either for a pre-existing problem (e.g. epilepsy, asthma, hyperthyroidism, hypertension) or for a problem that arises or threatens to arise as a result of pregnancy (e.g. morning sickness, anaemia, prevention of neural tube defects, hypertension).

About 35% of women take drug therapy at least once during pregnancy and 6% take drug therapy during the first trimester (excluding iron, folic acid and vitamins). The most commonly used drugs are simple analgesics, antibacterial drugs and antacids. The principles of prescribing in pregnancy are summarised in Box 2.21. Problems can arise under several headings:

2.21 Prescribing in pregnancy

- Avoid drugs unless the benefit to the mother greatly outweighs the risk to the fetus
- Only use drugs when there is previous experience
- Use the lowest dose for the shortest time possible
- Choose the least harmful drug if a range of alternatives is available

- altered pharmacokinetics in pregnancy
- teratogenesis and management of the pregnant woman who has taken a possible teratogen
- adverse effects of drugs on the fetus during the later stages of pregnancy
- therapeutic intervention on behalf of the fetus
- termination of pregnancy and the management of preterm labour and of labour (beyond the scope of this text)
- breastfeeding.

Altered pharmacokinetics

Vomiting can affect drug absorption. Plasma albumin concentration falls during pregnancy and the albumin-bound fraction of drugs may be altered; for example, the unbound fraction of phenytoin increases during pregnancy and total plasma phenytoin concentrations fall because of increased clearance, but the concentration of *unbound* phenytoin does not fall to the same extent. This means that care must be taken in adjusting dosages and in interpreting plasma concentrations. The glomerular filtration rate increases by about 70% during pregnancy and drugs that are mainly eliminated by renal excretion are cleared more quickly.

Teratogenesis

Teratogenesis is the induction of a developmental abnormality in a fetus by a drug taken during the early stages of pregnancy; the period from 2 to 8 weeks of gestation is the most critical. Information about teratogenic risks in humans is scarce but well-known examples include thalidomide, retinoids (e.g. isotretinoin) and cytotoxic drugs. The *BNF* contains a list of drugs that should be avoided or used with care. If a woman takes a potentially teratogenic drug, identify the exact time of exposure and the likely time of conception; investigations may be necessary to determine whether fetal abnormalities are present and specialist advice should be sought about the question of termination. Some conditions such as epilepsy are difficult to manage during pregnancy because of the risk of teratogenesis.

Later stages of pregnancy

Some drugs adversely affect the fetus at any time during pregnancy. Tetracyclines adversely affect growing teeth and bones; sulphonamides displace fetal bilirubin from plasma proteins and the unbound bilirubin enters the brain, potentially causing kernicterus; sulphonylureas can cause fetal and neonatal hypoglycaemia. Anticoagulation in pregnancy is highly problematic because of the teratogenic effects of warfarin in the first trimester. Heparin is usually used as an alternative, but it has potential adverse effects on the fetus and mother around term, and potential adverse effects such as osteoporosis in the mother.

Therapeutic intervention on behalf of the fetus

Examples include the administration of anti-D immunoglobulin to a mother to prevent rhesus disease of the newborn and the use of anti-arrhythmic drugs in the treatment of fetal arrhythmias.

Breastfeeding

Drugs that are excreted in breast milk can cause adverse effects in the baby if they are present in large enough amounts or if they cause hypersusceptibility reactions in small amounts (e.g. penicillin hypersensitivity; haemolysis in G6PD deficiency). The *BNF* contains a list of drugs that should be avoided or used with care.

When to stop drug treatment

The duration of drug treatment is straightforward for conditions that require one-off therapy (e.g. post-operative analgesia) and those that require life-long treatment (e.g. thyroxine for hypothyroidism). However, the optimal duration of drug treatment has not been established for many diseases, partly because the clinical trials that form the basis of marketing authorisation for many drugs often have short durations. For example, it is still not clear for how long treatment with warfarin should be continued in the treatment of deep venous thrombosis and pulmonary embolism (p. 1015). When a drug treatment is started, it is wise to plan the likely duration of therapy. It is also important to review long-term treatment at regular intervals to assess whether continued treatment is required. A hospital admission is often an opportunity for revising drug therapy, and it is not uncommon for drugs to be withdrawn temporarily, or even permanently, following an acute severe illness.

Prescribing in constrained circumstances

Prescribing in a developing country may have economic constraints, limiting the list of drugs available. The World Health Organization (WHO) has published a so-called Model Formulary, including a list of essential medicines and helpful advice about how to use them.

However, economic constraints can also affect developed countries, since health budgets are limited. Also, new drugs are more expensive than long-established treatments, since pharmaceutical companies need to recoup the costs of development to make a profit and to support further research and development. In some countries expenditure is controlled by limiting prescribing to drugs that are considered to be cost-effective. In the UK the National Institute for Health and Clinical Excellence (NICE) and the Scottish Medicines Consortium (SMC) issue advice about the cost-effectiveness of medicines after they have been approved for therapy by the regulatory authorities. This is based on the incremental cost-effectiveness ratio (ICER), which is the cost of the drug per quality-adjusted life year (QALY) gained. If the ICER for the use of an intervention in a particular condition is greater than £20 000, the intervention is generally considered not to be cost-effective and its use is not recommended, although the restrictions may be relaxed for end-of-life treatments. The calculations involved are based on complicated economic models. Individual National Health Service trust hospitals often restrict the use of drugs to those contained in a local formulary, the contents of which are based on similar considerations.

Even for interventions that are considered to be cost-effective, prescribing may be limited to certain individuals. For a junior doctor (e.g. a doctor in the Foundation Years in the UK) the ability to prescribe will be constrained by limited knowledge and experience. A suggested formulary of drugs with which medical students should familiarise themselves as a first step in learning the art of prescribing is listed on the Davidson website (www.studentconsult.com). Similar considerations apply to some other prescribers; for example, a UK nurse prescriber in a coronary care unit, although theoretically empowered to prescribe any drug in the *British National Formulary*, will prescribe only drugs that are relevant to the work of the unit. Some drugs are limited to specialist use, such as those that are used to treat cancer.

ADVERSE DRUG REACTIONS

Adverse drug reactions are classified mechanistically and clinically. This can be done using two complementary classification systems: EIDOS and DoTS (Fig. 2.4). Understanding adverse reactions in this way contributes to areas such as drug development and regulation, pharmacovigilance, monitoring therapy, and the prevention, diagnosis and treatment of adverse drug reactions.

Mechanistic classification of adverse drug reactions—EIDOS

The EIDOS mechanistic classification of adverse drug effects considers five elements:

- the Extrinsic species that initiates the effect
- the Intrinsic species that it affects
- the Distribution of these species in the body
- the (physiological or pathological) Outcome
- the Sequela, which is the adverse effect.

Extrinsic species

This can be the parent compound, an excipient, a contaminant or adulterant, a degradation product, or a derivative of any of these (e.g. a metabolite).

Intrinsic species

This is usually the endogenous molecule with which the extrinsic species interacts. This can be a nucleic acid,

an enzyme, a receptor, an ion channel or transporter, or some other protein.

Distribution

A drug will not produce an adverse effect if it is not distributed to the same site as the target protein that mediates the adverse effect. Thus, the pharmacokinetics of the extrinsic species can affect the occurrence of adverse effects.

Outcome

Interactions between extrinsic and intrinsic species in the production of an adverse effect can result in physiological or pathological changes. Physiological changes can involve either increased actions (e.g. clotting due to tranexamic acid) or decreased actions (e.g. bradycardia due to β -blockers). Pathological changes can involve cellular adaptations (atrophy, hypertrophy, hyperplasia, metaplasia and neoplasia), altered cell function (e.g. mast cell degranulation in IgE-mediated anaphylactic reactions) or cell damage (e.g. cell lysis, necrosis or apoptosis).

Sequela

The sequela of the changes induced by a drug describes the clinically recognisable adverse drug reaction, of which there may be more than one. Sequelae can be classified using the DoTS system.

Clinical classification of adverse drug reactions—DoTS

The DoTS clinical classification of adverse drug reactions takes into account three aspects of the interaction between the patient and the drug that produces an adverse effect (see Fig. 2.4):

- the relation of the adverse effect to the **Dose** of the drug
- the **Time** course of the effect
- the **Susceptibility** of the patient.

Dose-responsiveness of adverse drug reactions

There are three types of adverse drug effect:

- A *toxic effect* is one that occurs as an exaggeration of the desired therapeutic effect and occurs at doses at or near the top of the dose-response curve. For example, syncope due to a β -blocker is a toxic effect; it occurs by the same mechanism as the therapeutic effect (lowering of the blood pressure).
- *Collateral effects* occur at doses in the middle of the usual dose-response curve but in a tissue other than

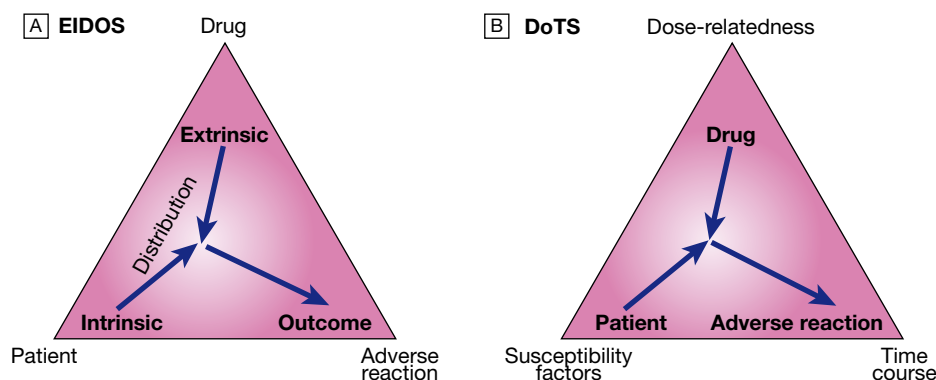

Fig. 2.4 Two complementary forms of classification of adverse drug reactions. **A** The EIDOS mechanistic classification describes how the combination of drug and patient causes the adverse reaction. **B** The DoTS clinical classification defines the important aspects of the drug (dose-relatedness), the patient (susceptibility factors) and the reaction (its time course).

that in which the therapeutic action is sought. They can occur:

- through the same pharmacological effect as that whereby the therapeutic action is produced (for example, colour vision disturbance from sildenafil)
- through a distinct pharmacological effect (for example, a dry mouth due to an anticholinergic effect of a tricyclic antidepressant).
- *Hypersusceptibility effects* occur at subtherapeutic doses in susceptible patients. Penicillin allergy is a hypersusceptibility effect.

Toxic effects can be avoided by using dosages at the lower end of the recommended range and increasing cautiously, monitoring carefully for therapeutic and adverse effects. Collateral adverse effects may not be avoidable; if they occur despite careful dosage adjustment, it may be necessary to use a different drug. Hypersusceptibility effects can be avoided by identify-

ing the susceptibility factors that contribute to them; for example, a history of penicillin allergy is a contraindication to the use of any penicillin.

Time courses of adverse effects

The different patterns of time course of adverse reactions are listed in Box 2.22, with illustrative examples.

Susceptibility to adverse drug reactions

The sources of the various factors that can increase the susceptibility of an individual to an adverse effect of a drug are listed in Box 2.23.

DRUG INTERACTIONS

A drug interaction occurs when the effects of one drug (the object drug) are altered (increased or decreased) by the effects of another drug (the precipitant drug).

2.22 Time-related classification of adverse drug reactions

Type of reaction	Examples	Implications
Time-independent		
Due to a change in dose or concentration (<i>pharmaceutical effects</i>)	Toxicity due to increased systemic availability	Beware of changing formulations of some drugs (e.g. modified-release formulations of lithium)
Due to a change in dose or concentration (<i>pharmacokinetic effects</i>)	Digitalis toxicity due to renal insufficiency	Forewarn the patient; monitor carefully throughout treatment; alter dosage when pharmacokinetics change (e.g. renal insufficiency); avoid interacting drugs
Occurring without a change in dose (<i>pharmacodynamic effects</i>)	Digitalis toxicity due to hypokalaemia	Forewarn the patient; monitor carefully throughout treatment; avoid precipitating (pharmacodynamic) factors; avoid interacting drugs
Time-dependent		
Rapid (due to rapid administration)	Red man syndrome (vancomycin) Hypertension (digitalis) Hypotension (adipiodone)	Administer slowly
First dose (of a course)	Hypotension (α_1 -adrenoceptor antagonists and ACE inhibitors) Type I hypersensitivity reactions	Take special precautions for the first dose Careful history taking; if a reaction occurs, avoid re-exposure; counsel the patient
Early tolerant (abates with repeated exposure)	Adverse reactions that involve tolerance (e.g. nitrate-induced headache)	Monitor during the early stages; give appropriate reassurance; expect adverse effects if strategies to avoid tolerance are adopted
Early permanent (occurs early and does not abate)	Some adverse effects of corticosteroids	Monitor during the early stages; withdraw or use preventive measures
Intermediate (risk increases at first, then diminishes)	Venous thromboembolism (antipsychotic drugs) Hypersensitivity reactions types II, III and IV	Monitoring not needed after the high-risk period unless susceptibility changes; withdraw drug if a reaction develops
Late (risk increases with time)	Osteoporosis (glucocorticoids) Tardive dyskinesia (dopamine receptor antagonists) Retinopathy (chloroquine) Tissue phospholipid deposition (amiodarone)	Assess baseline function; forewarn the patient; monitor periodically during prolonged treatment
Late (effects occur after withdrawal)	Withdrawal syndromes: opiates, benzodiazepines, hypertension (clonidine and methyldopa), myocardial infarction (β -blockers)	Withdraw slowly; forewarn the patient; replace with a longer-acting drug if withdrawal is not possible
Delayed	Carcinogenesis (cyclosporin, diethylstilbestrol) Teratogenesis (thalidomide)	Avoid or screen; counsel or forewarn the patient

2.23 Sources of altered susceptibility to adverse drug reactions

Source of susceptibility	Examples	Implications
Genetic (see also Box 2.11, p. 25)	Porphyria Suxamethonium (succinylcholine) sensitivity Malignant hyperthermia CYP isozyme polymorphisms HLA polymorphisms	Screen for abnormalities; avoid specific drugs
Age	Neonates (chloramphenicol) Elderly people (hypnotics)	Adjust doses according to age
Sex	Alcohol intoxication Mefloquine, neuropsychiatric effects ACE inhibitors, cough Lupus-like syndrome (e.g. hydralazine)	Use different doses in men and women
Physiology altered	Phenytoin in pregnancy	Alter dose or avoid
Exogenous factors	Drug interactions Interactions with food (e.g. grapefruit juice with drugs cleared by CYP3A4)	Alter dose or avoid co-administration
Disease	Renal insufficiency (e.g. lithium) Hepatic cirrhosis (e.g. morphine)	Screen for abnormalities; avoid specific drugs; use reduced doses

2.24 Classification of drug interactions by mechanism

Mechanism	Example		
	Object drug	Precipitant drug	Result
Pharmaceutical	Sodium bicarbonate	Calcium gluconate	Precipitation of insoluble calcium carbonate
Pharmacokinetic			
Reduced absorption	Tetracyclines	Calcium, aluminium, magnesium salts	Reduced tetracycline absorption
Reduced protein binding	Phenytoin	Aspirin	Reduced phenytoin plasma concentration with same therapeutic effect
Reduced metabolism (CYP3A4)	Terfenadine	Grapefruit juice	Cardiac arrhythmias (prolonged QT interval, p. 529)
Reduced metabolism (CYP2C19)	Phenytoin	Ticlopidine	Phenytoin toxicity
Reduced metabolism (CYP2D6)	Clozapine	Paroxetine	Clozapine toxicity
Reduced metabolism (other enzymes)	Azathioprine (xanthine oxidase) Catecholamines (monoamine oxidase)	Allopurinol Monoamine oxidase inhibitors	Azathioprine toxicity Hypertensive crisis due to monoamine toxicity
Increased metabolism (induction)	Ciclosporin	St John's wort	Loss of immunosuppression
Reduced renal elimination	Lithium	Diuretics	Lithium toxicity
Pharmacodynamic			
Direct antagonism	Opiates	Naloxone	Reversal of opiate effects
Direct potentiation	Alcohol	Antidepressants	Increased sedation
Indirect potentiation	Anti-arrhythmic drugs	Diuretics	Cardiac arrhythmias (hypokalaemia)

Although a drug interaction usually results in an adverse effect, in some cases it can prove beneficial. An example is pharmacodynamic synergy between diuretics and ACE inhibitors in the treatment of hypertension. The classification of drug interactions by mechanism is shown in Box 2.24.

Pharmaceutical interactions

Pharmaceutical interactions are physicochemical interactions, either of a drug with an intravenous infusion solution or of two drugs in the same solution, resulting in the loss of activity of the drugs involved. Pharmaceutical

interactions are too numerous to remember in detail, but they can be simply avoided:

- by giving intravenous drugs via bolus injection or an infusion burette or syringe pump
- by using only dextrose or saline for drug infusion
- by not mixing drugs in the same infusion solution, unless the mixture is known to be safe (e.g. potassium chloride with insulin).

Pharmacokinetic interactions

Pharmacokinetic interactions occur when the absorption, distribution or elimination (metabolism or excretion) of one drug is altered by another drug.

Absorption interactions

Absorption interactions are seldom important. Exceptions include impaired absorption of tetracyclines, bisphosphonates and fluoroquinolones by chelation with divalent and trivalent cations. Parenteral metoclopramide increases the rate of gastric emptying and this hastens the absorption of analgesics in the treatment of an acute attack of migraine, a beneficial interaction.

Distribution interactions: protein-binding displacement

Protein-binding displacement causes an increase in the circulating concentration of unbound drug. However, this is only important if the object drug is highly protein-bound (greater than 90%) and is not widely distributed to body tissues. In practice, important interactions of this type occur with warfarin and phenytoin. When these drugs are displaced, their clearance rate increases in proportion to the degree of displacement, and so at steady state the total concentration of drug in the plasma falls to a new equilibrium value and the unbound *concentration* is the same as it was before the precipitant drug was introduced, in spite of an increase in the unbound *fraction*. This means that the interaction may not have significant clinical consequences, provided the patient can 'weather' the increase in unbound concentration of the object drug until a new steady state is reached.

Metabolism interactions

Drug interactions involving metabolism are important. They occur when the metabolism of one drug is either inhibited or increased by another drug. There are two phases of hepatic drug metabolism. Phase I metabolic reactions (for example, dealkylation, deamination, hydroxylation, sulfoxidation) are carried out by isoenzymes of the mixed-function oxidase (cytochrome p450 or CYP) system and are subject to interactions. Phase II reactions are conjugations (for example, acetylation, methylation, glucuronidation, sulphatation); they are not affected by interactions. Some drugs are metabolised by specific enzymes and may be the subject of interactions.

- *Induction of drug metabolism.* Induction of the metabolism of a drug reduces the amount of drug in the body and therefore reduces its effects. An important example is unwanted pregnancy when an enzyme-inducing drug such as carbamazepine, phenytoin or rifampicin is taken along with an oral contraceptive.
- *Inhibition of drug metabolism.* Drug metabolism can be reduced by inhibition of either CYP isoenzymes

or other metabolic pathways. Examples of the former include inhibition of warfarin metabolism by chloramphenicol, cimetidine, erythromycin, ketoconazole, metronidazole and quinolones, inhibition of phenytoin metabolism by isoniazid, and inhibition of theophylline metabolism by quinolone and macrolide antibiotics (for example, erythromycin). Examples of the latter include inhibition by allopurinol of xanthine oxidase, inhibiting the metabolism of azathioprine and 6-mercaptopurine, and inhibition of the metabolism of dietary amines by monoamine oxidase inhibitors.

Excretion interactions

Competition for renal tubular secretion reduces drug excretion. For example, probenecid inhibits the tubular secretion of penicillin, increasing the blood concentration of penicillin and prolonging its therapeutic effects: a beneficial interaction. Amiodarone, quinidine and verapamil inhibit the tubular secretion of digoxin by inhibiting the transport protein P glycoprotein, increasing plasma digoxin concentrations and potentially causing toxicity.

Pharmacodynamic interactions

In pharmacodynamic interactions the effect of a drug is altered at its site of action. Such interactions are either direct or indirect.

Direct pharmacodynamic interactions

Direct pharmacodynamic interactions occur when two drugs either act at the same site (antagonism or synergism) or act at two different sites with a similar end result. For example, naloxone reverses the effects of opiates and vitamin K reverses the effects of warfarin. The anticoagulant effects of warfarin are increased in direct synergistic interactions with anabolic steroids and tetracyclines. Any drug that has a depressant action on central nervous function can potentiate the effect of another such drug, whether or not the two drugs have effects on the same receptors; for example, alcohol potentiates the action of any other centrally acting drug.

Indirect pharmacodynamic interactions

Indirect pharmacodynamic interactions occur when one drug affects the pharmacological, therapeutic or toxic effect of another drug, but the two effects are independent. For example, the effects of anticoagulants can be increased by three indirect effects:

- reduced platelet aggregation (due for example to salicylates, dipyridamole, clopidogrel and NSAID)
- gastrointestinal ulceration (due, for example, to NSAID)
- increased fibrinolysis (due, for example, to metformin).

Diuretic-induced alterations in fluid and electrolyte balance (especially potassium) increase the effects of cardiac glycosides and class I anti-arrhythmic drugs (for example, lidocaine, quinidine, flecainide and phenytoin).

Avoiding adverse drug interactions

The simple way of avoiding adverse drug interactions is to avoid combinations that are known to be dangerous. If that is not possible, the dosage of the object drug should be reduced in advance of starting the precipitant

drug and the precipitant drug should be introduced slowly. When a theoretical interaction is anticipated on the basis of the known properties of two drugs, even if it has not been previously described, careful monitoring may help recognise adverse effects early.

WRITING A DRUG PRESCRIPTION

A prescription should be a precise, accurate, clear, readable set of instructions, sufficient for a nurse to administer a drug accurately in hospital, or for a pharmacist to provide a patient with both the correct drug and the instructions on how to take it. The information that should be written on a prescription is given in Box 2.25.

Writing drug doses

- Quantities of 1 gram or more should be written in grams. For example, write 2 g.
- Quantities less than 1 gram but more than 1 milligram should be written in milligrams. For example, write 100 mg, not 0.1 g.
- Quantities less than 1 milligram should be written in micrograms or nanograms as appropriate. Do not abbreviate micrograms or nanograms. For example, write 100 micrograms, not 0.1 mg, 100 µg, 100 mcg or 100 ug.
- If a decimal point cannot be avoided for values less than 1, write a zero before it. For example, write 0.5 mL, not .5 mL.
- For liquid medicines given orally the dose should be stated as the number of milligrams in either 5 mL or 10 mL of solution.

Prescribing controlled drugs

Because of the problems of drug addiction and misuse of drugs, in the UK drugs likely to be abused are the subject of the *Misuse of Drugs Act* (1971), the *Misuse of Drugs (Notification of and Supply to Addicts) Regulations* (1973) and the *Misuse of Drugs Regulations* (1985). The requirements for prescription of controlled drugs in the UK are listed in Box 2.26. Doctors in other countries should make themselves familiar with local regulations.

Abbreviations

Some abbreviations that are used in prescribing are listed in Box 2.27. Other abbreviations should be avoided and instructions should be written in plain English whenever possible.

2.25 Information to be given on a UK prescription outside hospital

- The date
- The patient's name, initials and address
- The age of a child under 12
- The name of the drug, preferably in capitals (use generic names when possible)
- The formulation to be prescribed
- The strength of the formulation
- The dose
- The frequency of administration
- The route of administration
- The doctor's name, address and signature

2.26 How to write a prescription for a controlled drug

- Complete the prescription in handwriting in ink
- Sign and date it
- Include your address
- Include the name and address of the patient
- State the form and strength (if appropriate) of the drug
- State the total quantity of the drug or the number of dose units to be dispensed in both words and figures
- State the exact size of each dose in both words and figures

2.27 Acceptable abbreviations in prescriptions

Abbreviation	Latin meaning	English meaning
b.d. or b.i.d.	Bis in die	Twice a day
gutt.	Guttae	Drops
i.m.	–	Intramuscular(ly)
i.v.	–	Intravenous(ly)
o.d.	Omni die	(Once) every day
o.m.	Omni mane ¹	(Once) every morning
o.n.	Omni nocte ¹	(Once) every night
p.o.	Per os	By mouth
PR	Per rectum	By the anal route
p.r.n.	Pro re nata	Whenever required
PV	Per vaginam	By the vaginal route
q.d.s.	Quater die sumendum ²	Four times a day
s.c.	–	Subcutaneous(ly)
stat.	Statim	Immediately
t.d.s.	Ter die sumendum ²	Three times a day

¹Sometimes written simply as 'mane' or 'nocte'.

²The abbreviation t.i.d. or q.i.d. (ter or quater in die) is sometimes used instead; do not use q.d. to mean once a day.

DRUG NOMENCLATURE

Drugs have different kinds of name:

- The chemical name, whose form generally follows the rules issued by the International Union of Pure and Applied Chemistry (IUPAC).
- The approved (official or generic) name. This is usually the International Non-proprietary Name (INN), either recommended (rINN) or proposed (pINN) by the WHO, but it may be some locally approved name (for example, the British Approved Name (BAN) or United States Adopted Name, (USAN)).
- The proprietary name (brand name or trade name), given to it by the manufacturer.
For example:
- chemical name: (R)-1-(3,4-dihydroxyphenyl)-2-methylaminoethanol
- INN: epinephrine; BAN: adrenaline
- proprietary names: Epipen® for intramuscular injection and Eppy® or Simplene® eyedrops.

Since the chemical name is generally unsuitable for routine prescribing, either the approved name or proprietary name is used. Which should one choose? For some drugs the question is trivial, since only one proprietary formulation exists; for example, trastuzumab is currently available in the UK only as Herceptin®.

However, several proprietary formulations of the same chemical entity usually become available when the patent expires on a drug with a previously unique proprietary name. For instance, amoxicillin was first marketed as Amoxil®. When the patent expired the number of proprietary brands multiplied. This can cause prescribing and dispensing problems. For example, in the UK, whether the prescriber writes 'trastuzumab BP' or 'Herceptin' the patient will receive Herceptin®. However, if the prescriber writes 'amoxicillin BP' the pharmacist may dispense any proprietary formulation, provided that it conforms to the description laid out in the *British Pharmacopoeia* (BP), and will generally dispense the cheapest available.

By writing the proprietary name the prescriber can ensure that a particular formulation of a drug is prescribed. However, in some UK hospitals the pharmacy may stock only one formulation, and even if the hospital doctor writes 'Amoxil' on a prescription chart, the pharmacist may dispense some other approved formulation for which the hospital will have negotiated an economic deal with the supplier.

There are advantages and disadvantages to the prescribing of drugs by their generic (non-proprietary) as opposed to their proprietary names. The advantages include:

- *Awareness of the prescription.* The name of the compound often indicates to what class it belongs, usually by virtue of its suffix; e.g. -vastatin (HMGCoA reductase inhibitors), -olol (β -blockers, although beware stanozolol), -floxacin (quinolone antibiotics).
- *Drug stocks.* If, say, 'Amoram' rather than 'amoxicillin' is prescribed and a pharmacy stocks only Amoxil, the pharmacist cannot legally dispense

the prescription without first consulting the doctor; clearly, this can cause inconvenience to all concerned and can result in delayed treatment.

- *Expense.* It is generally cheaper to prescribe by the approved name, since the pharmacist will dispense the cheapest variant held in stock.

The disadvantages of prescribing by non-proprietary name include:

- *Remembering names.* Proprietary names are chosen by pharmaceutical companies because they are catchy, usually easier to remember than the corresponding generic name, and shorter and easier to spell (compare, for example, 'Serc' with 'betahistine'). Furthermore, a single proprietary name will do when the formulation contains two or more drugs (compare, for example, 'Fefol' with 'ferrous sulphate plus folic acid'). In a few cases, to counteract this problem, BANs have been coined for common combinations of drugs; for example, the combination of dihydrocodeine with paracetamol (acetaminophen) is known as co-dydramol.
- *Quality of product.* For a few drugs a change in tablet excipients has large effects on the absorption of the drug from the formulation. Important examples include lithium salts, nifedipine and theophylline, which should always be prescribed by brand name.
- *Continuity of treatment.* Patients not infrequently become confused if the drug they are being given changes its form with every prescription. Continuity can be achieved by prescribing the same proprietary formulation every time.

2.28 Usual therapeutic and toxic plasma concentrations of commonly measured drugs

Drug	Optimal sampling time	Concentration below which a therapeutic effect is unlikely		Concentration above which a toxic effect is more likely	
		Mass units	Molar units	Mass units	Molar units
Carbamazepine	Just before next dose	4 mg/L	17 μ mol/L	10 mg/L	42 μ mol/L
Cardiac glycosides					
Digitoxin	Just before next dose	15 μ g/L	20 nmol/L	30 μ g/L	39 nmol/L
Digoxin	11 hrs after last dose	0.8 μ g/L	1.0 nmol/L	2 μ g/L	2.6 nmol/L
Ciclosporin*	Just before next dose	125 μ g/L	104 nmol/L	200 μ g/L	166 nmol/L
Lithium	12 hrs after last dose	–	0.4 mmol/L	–	1.0 mmol/L
Phenytoin	Just before next dose	10 mg/L	40 μ mol/L	20 mg/L	80 μ mol/L
Theophylline	Just before next dose	10 mg/L	55 μ mol/L	20 mg/L	110 μ mol/L

*Measured in whole blood by specific radioimmunoassay or high-performance liquid chromatography (hplc).

Notes

1. Care should be taken in comparing results between different laboratories (particularly with ciclosporin).
2. The concentration below which a therapeutic effect is unlikely and the concentration above which a toxic effect is more likely together constitute a target range within which satisfactory therapy is likely to be achieved; however, dosages should be adjusted according to the clinical response, not the concentration, which should only be used as a guide.
3. Note the units used when interpreting results. Laboratories may report in SI mass units (e.g. mg/L) or SI molar units (e.g. μ mol/L), or both. The volume term should ideally be the litre, but for mass units some laboratories use millilitres instead: μ g/L = ng/mL; mg/L = μ g/mL.
4. Remember that pharmacokinetics differ from individual to individual. For within-patient comparisons always use the same time after the last dose. For lithium the sample must be taken at 12 hours after the previous dose.
5. Remember that pharmacodynamics differ from individual to individual and that different individuals respond differently to the same concentration of drug. Other factors that can alter the individual response should be considered.
6. For paracetamol, see Figure 9.2 (p. 211).
7. For aminoglycosides, consult your laboratory.

In hospital it is usually better to prescribe by approved name, since the pharmacy will dispense whatever formulation is held in stock. The proprietary name can be used when a combination product is prescribed for which no single approved name exists (for example, 'Fefol'). In general practice it is also usually best to prescribe by approved name. Doctors who make the effort to prescribe by approved name when possible will generally find it just as easy as prescribing by proprietary name.

Countries in the European Community are required to use INNs, except for adrenaline and noradrenaline (BANs that are permitted instead of the rINNs epinephrine and norepinephrine, primarily for reasons of safety).

MONITORING DRUG THERAPY

There is no space here for a detailed discussion of how to monitor drug therapy, which should be done using (in order of preference) clinical, pharmacodynamic or pharmacokinetic methods. For some drugs whose effects can be monitored by measuring plasma concentrations, target concentrations are given in Box 2.28.

Almost all diseases have a genetic component, and many disorders that cause long-term morbidity and mortality in children and young adults are genetically determined. The past decade has witnessed an exponential increase in identification of the genes that are mutated in genetic diseases and in our understanding of the abnormalities in cell function responsible for the clinical presentation. There is also an increasing appreciation that a combination of common genetic variants can contribute to the aetiology of common diseases like inflammatory bowel disease, rheumatoid arthritis and osteoporosis. In this chapter, we review key principles of cell biology, cellular signalling and molecular genetics, with a specific emphasis on the diagnosis and assessment of patients with genetic diseases.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Cell and molecular biology

All human cells are derived from the zygote (the fertilised ovum), a single totipotent stem cell capable of producing all cell types. During development, organs and tissues are formed by the integration of four closely regulated cellular processes: cell division, migration, differentiation and programmed cell death. These processes continue in adult life by small populations of stem cells capable of self-renewal. These cells can also differentiate to maintain and repair the tissues in which they are found. Cell biology is the study of these processes and of intracellular compartments, called organelles, which maintain cellular homeostasis. Dysfunction of any of these processes may lead to disease.

DNA, chromosomes and chromatin

The nucleus is a membrane-bound compartment found in all cells, with the exception of erythrocytes and platelets. In humans, the nucleus contains 46 chromosomes, each of which comprises a single linear molecule of deoxyribonucleic acid (DNA), which is intimately complexed with proteins in the form of chromatin. The basic unit of chromatin is the nucleosome, which is a structure of approximately 147 base pairs (bp) of DNA bound round a complex of four different histone proteins.

The vast majority of chromosomal DNA is double-stranded, with exception of the ends of chromosomes where 'knotted' domains of single-stranded DNA, called telomeres, are found. Telomeres prevent degradation and accidental fusion of chromosomal DNA.

The human genome comprises approximately 3.1 billion bp of DNA. Each nucleus contains two copies of the genome and thus humans are diploid organisms. The diploid status is present as 22 identical chromosomal pairs—the autosomes—named 1–22 in descending size order (see Fig. 3.9, p. 54), and two sex chromosomes (XX in females and XY in males). Each DNA strand consists of a linear sequence of four bases—guanine (G), cytosine (C), adenine (A) and thymine (T)—covalently linked by phosphate bonds. The sequence of one strand of double-stranded DNA determines the sequence of the opposite strand because the helix is held together by hydrogen bonds between adenine and thymine or guanine and cytosine.

Fig. 3.1 RNA synthesis and its translation into protein. Gene transcription involves binding of RNA polymerase II to the promoter of genes being transcribed with other proteins (transcription factors) that regulate the transcription rate. The primary RNA transcript is a copy of the whole gene and includes both introns and exons, but the introns are removed within the nucleus by splicing and the exons are joined to form the messenger RNA (mRNA). Prior to export from the nucleus, a methylated guanosine nucleotide is added to the 5' end of the RNA ('cap') and a string of adenine nucleotides are added to the 3' ('poly A tail'). This protects the RNA from degradation and facilitates transport into the cytoplasm. In the cytoplasm the mRNA binds to ribosomes and forms a template for protein production.

Genes and transcription

Genes are functional units of the chromosome that result in a flow of information from the DNA template via the production of messenger ribonucleic acid (mRNA) to the production of proteins. The human genome contains an estimated 21 500 different genes. Genes may be silent or active; genes that are active undergo transcription which requires binding of an enzyme called RNA polymerase II to a segment of DNA at the start of the gene termed the promoter. Once bound, RNA polymerase II proceeds along one strand of DNA, producing an RNA molecule which is complementary to the DNA template. A DNA sequence close to the end of the gene, called the polyadenylation signal, acts as a signal for termination of the RNA transcript (Fig. 3.1). The activity of RNA polymerase II is regulated by transcription factors. These proteins bind to specific DNA sequences at the promoter or to enhancer elements that may be many thousands of base pairs away from the

promoter. The enhancer region forms a loop, enabling the transcription factors to interact directly with other proteins bound to the promoter.

There are over 1200 different transcription factors in humans and mutations in many of these can cause genetic diseases (Fig. 3.2). Alterations of the DNA sequence within promoters and enhancers also cause disease. For example, the blood disorder alpha-thalassaemia can result from loss of an enhancer located more than 100 000 bp from the alpha-globin gene promoter, leading to greatly reduced transcription. Similarly, variation in the promoter of the gene encoding intestinal lactase determines whether or not this is 'shut off' in adulthood, producing lactose intolerance (p. 886).

The availability of the gene promoter to bind RNA polymerase II is regulated by the configuration of chromatin. Chromosomal regions that are transcriptionally active are maintained in a state in which the chromatin is in an open configuration. Conversely, the chromatin is

Fig. 3.2 Examples of genetic diseases caused by mutations in genes encoding either transcription factors or receptors.

very densely packed into heterochromatin in regions of the genome which are not being transcribed. The DNA and histone proteins associated with heterochromatin are chemically distinct from those of open chromatin. A proportion of the cytosine molecules are enzymatically modified by addition of a methyl group (methylation). This silences transcription, since methyl cytosines are usually not available for transcription factor binding or RNA transcription. The histone proteins associated with chromatin can also be methylated, phosphorylated or acetylated at specific amino acid residues in a pattern that reflects the functional state of the chromatin; this is called the histone code. Such modifications are termed epigenetic, as they do not alter the primary sequence of the DNA code but do have biological significance in chromosomal function. Abnormal epigenetic changes are increasingly recognised as important events in the progression of cancer, allowing re-expression of genes which are normally silenced during development to support cancer cell dedifferentiation (see Fig. 3.7 and Box 3.3, pp. 49 and 51).

RNA splicing, editing and degradation

Transcription produces an RNA molecule that is a copy of the whole gene, termed the primary or nascent transcript. RNA differs from DNA in three main ways:

- RNA is single-stranded.
- The sugar residue within the nucleotide is ribose, rather than deoxyribose.
- Uracil (U) is used in place of thymine (T).

The nascent RNA molecule then undergoes a process called splicing, to generate an mRNA molecule which provides the template for protein production. Splicing involves the removal of regions of the RNA molecule which are not required to make protein (introns) from those which are retained in the mRNA to make protein (exons). Splicing is a highly regulated process which is carried out by a multimeric protein complex called the spliceosome. Following splicing, the mRNA molecule is exported from the nucleus and used as a template for protein synthesis. It should be noted that many genes produce more than one form of mRNA (and thus protein) by a process termed alternative splicing. This allows production of different proteins from the same gene, which can have entirely distinct functions. For example, the calcitonin gene expressed in thyroid C cells produces mRNA molecules with one complement of exons encoding the osteoclast inhibitor calcitonin (p. 736), but the same gene is differently spliced in neurons to produce an alternative mRNA encoding the neurotransmitter calcitonin-gene-related peptide.

Most mRNA molecules contain a segment called the open reading frame (ORF), which contains the code that directs synthesis of a protein product. This code comprises a contiguous series of three sequential bases (codon), which specifies that a particular amino acid should be incorporated into the protein. There are 64 different codons; 61 of these specify incorporation of one of the 20 amino acids, whereas the remaining three codons—UAA, UAG and UGA (stop codons)—cause termination of the growing polypeptide chain. ORFs in humans most commonly start with the amino acid methionine. All mRNA molecules have domains before and

after the ORF called the 5' untranslated region (5'UTR) and 3' untranslated region (3'UTR), respectively. The start of the 5'UTR contains a cap structure that protects mRNA from enzymatic degradation, and other elements within the 5'UTR are required for efficient translation. The 3'UTR also contains elements that regulate efficiency of translation and mRNA stability, including a stretch of adenine bases known as a polyA tail.

There are approximately 4500 genes in humans in which the transcribed RNA molecules do not code for proteins. There are various categories of non-coding RNA (ncRNA), including transfer RNA (tRNA), ribosomal RNA (rRNA), ribozymes and microRNA (miRNA). There is increasing evidence to suggest that miRNAs play a role in normal development, cancer and common degenerative disorders by regulating the stability of other RNA molecules.

Translation and protein production

Following splicing and export from the nucleus, mRNAs associate with ribosomes, which are the sites of protein production (see Fig. 3.1). Each ribosome consists of two subunits (40S and 60S), which comprise non-coding rRNA molecules complexed with proteins. During translation, tRNA binds to the ribosome. The tRNAs deliver amino acids to the ribosome so that the newly synthesised protein can be assembled in a step-wise fashion. Individual tRNA molecules bind a specific amino acid and 'read' the mRNA ORF via an 'anticodon' of three nucleotides that is complementary to the codon in mRNA. Some ribosomes are bound to the membrane of the endoplasmic reticulum (ER), a complex tubular structure that surrounds the nucleus. Proteins synthesised on these ribosomes are translocated into the lumen of the ER, where they undergo folding and processing. From here the protein may be transferred to the Golgi apparatus, where it undergoes post-translational modifications, such as glycosylation (covalent attachment of sugar moieties), to form the mature protein that can be exported into the cytoplasm or packaged into vesicles for secretion. The clinical importance of post-translational modification of proteins is shown by the severe developmental, neurological, haemostatic and soft tissue abnormalities that are associated with the dozen or so congenital disorders of glycosylation, rare deficiencies of the enzymes that catalyse the addition of chains of sugar moieties to proteins (e.g. phosphomannose isomerase deficiency). Post-translational modifications can also be disrupted by the synthesis of proteins with abnormal amino acid sequences. For example, the most common mutation in cystic fibrosis ($\Delta F508$) results in an abnormal protein that cannot be exported from the ER and Golgi.

Mitochondria and energy production

The mitochondrion has both an inner and outer membrane, and is the main site of energy production within the cell. Mitochondria arose via the symbiotic association with an intracellular bacterium at some point during evolution. Energy, in the form of adenosine triphosphate (ATP) production, is mostly derived from the metabolism of glucose and fat (Fig. 3.3). Glucose cannot enter mitochondria directly but is first metabolised to pyruvate via glycolysis. Pyruvate is then imported into the mito-

Fig. 3.3 Mitochondria. **A** Mitochondrial structure. There is a smooth outer membrane surrounding a convoluted inner membrane which has inward projections called cristae. The membranes create two compartments: the inter-membrane compartment, which plays a crucial role in the electron transport chain, and the inner compartment (or matrix), which contains mitochondrial DNA and the enzymes responsible for the citric acid (Krebs) cycle and the fatty acid β-oxidation cycle. **B** Mitochondrial DNA. The mitochondrion contains several copies of a circular double-stranded DNA molecule which has a non-coding region (NCR), and a coding region which encodes the genes responsible for energy production, mitochondrial tRNA molecules and mitochondrial rRNA molecules. **C** Mitochondrial energy production. Fatty acids enter the mitochondrion conjugated to carnitine by carnitine-palmitoyl transferase type 1 (CPT I) and, once inside the matrix, are unconjugated by CPT II to release free fatty acids (FFA). These are broken down by the β-oxidation cycle to produce acetyl-CoA. Pyruvate can enter the mitochondrion directly and is metabolised by pyruvate dehydrogenase (PDH) to produce acetyl-CoA. The acetyl-CoA enters the Krebs cycle, leading to the production of NADH and FADH₂, which are used by proteins in the electron transport chain to generate a hydrogen ion gradient across the inter-membrane compartment. Reduction of NADH and FADH₂ by proteins I and II respectively releases electrons (e), and the energy released is used to pump protons into the inter-membrane compartment. As these electrons are exchanged between proteins in the chain, more protons are pumped across the membrane, until the electrons reach complex IV (cytochrome oxidase) which uses the energy to reduce oxygen to water. The hydrogen ion gradient is used to produce ATP by the enzyme ATP synthase which consists of a proton channel and catalytic sites for the synthesis of ATP from ADP. When the channel opens, hydrogen ions enter the matrix down the concentration gradient and energy is released which is used to make ATP.

chondrion and metabolised to acetyl-CoA. Fatty acids are transported into the mitochondria following conjugation with carnitine and are sequentially catabolised by a process called β-oxidation to produce acetyl-CoA. The acetyl-CoA from both pyruvate and fatty acid oxidation is used in the citric acid (Krebs) cycle—a series of enzymatic reactions that produces CO₂, NADH and FADH₂. Both NADH and FADH₂ then donate electrons to the respiratory chain, which transfers the electrons in a complex series of reactions which results in the pro-

duction of a proton gradient across the inner mitochondrial membrane. The proton gradient is then used by the inner mitochondrial membrane protein, ATP synthase, to produce ATP. ATP is then transported to other parts of the cell, where it can be dephosphorylated to produce the energy required for most reactions within the cell.

Each mitochondrion contains 2–10 copies of a 16 kilobase (kB) double-stranded circular DNA molecule (mtDNA). mtDNA contains 13 protein-coding genes, all involved in the respiratory chain, and the ncRNA

genes required for protein synthesis within the mitochondria (see Fig. 3.3). The mutational rate of mtDNA is relatively high due to the lack of protection by chromatin. Several mtDNA diseases characterised by defects in ATP production have been described. mtDNA diseases are inherited exclusively down the maternal line (see Fig. 3.6, p. 48), since all mtDNA is derived from the mother, as sperm contribute no mitochondria to the zygote. Mitochondria are most numerous in cells with high metabolic demands, such as muscle, retina and the basal ganglia, and these tissues tend to be the ones most severely affected in mitochondrial diseases (Box 3.1). There are many other mitochondrial diseases that are caused by mutations in nuclear genes, which encode proteins that are then imported into the mitochondrion and are critical for energy production.

Protein degradation

The cell has developed three organelles, the lysosome, the peroxisome and the 26S proteasome, for the degradation of proteins and other molecules that are damaged, are potentially toxic or have simply served their purpose. The proteasome is the main site of protein degradation within the cell. The first step in proteasomal degradation is ubiquitination—the covalent attachment of a protein called ubiquitin as a side chain to the target protein. Ubiquitination is carried out by a large group of enzymes called E3 ligases, whose function is to recognise specific proteins that should be targeted for degradation by the proteasome. The E3 ligases ubiquitinate their target protein, which is then transported to a large multiprotein complex called the 26S proteasome, where it is degraded. There is mounting evidence that defects in the proteasome are responsible for many diseases; a severe genetic disease termed Angelman's syndrome is due to a mutation in a specific E3 ligase.

Proteins with complex post-translational modifications are degraded in membrane-bound structures called lysosomes, which have an acidic pH and contain proteolytic enzymes that degrade proteins. There are many inherited defects in lysosomal enzymes which result in failure to degrade intracellular toxic substances.

For instance, in Gaucher's disease, mutations of the gene encoding lysosomal (acid) beta-glucosidase lead to undigested lipid accumulating in macrophages, producing hepatosplenomegaly and, if severe, deposition in the brain leading to mental retardation.

Peroxisomes are small single membrane-bound cytoplasmic organelles containing many different oxidative enzymes such as catalase. Peroxisomes are involved in the degradation of hydrogen peroxide, bile acids and amino acids. However, the beta-oxidation of very long-chain fatty acids appears to be their most important function since mutations in the peroxisomal beta-oxidation enzymes (or the proteins that import these enzymes into the peroxisome) result in the same severe congenital disorder as mutations that cause complete failure of peroxisomal biogenesis. This group of disorders is called Zellweger's syndrome (cerebrohepato-renal syndrome) and is characterised by severe developmental delay, seizures, hepatomegaly and renal cysts; the biochemical diagnosis is made on the basis of elevated plasma levels of very long-chain fatty acids.

The cell membrane and cytoskeleton

The cell membrane is a phospholipid bilayer, with hydrophilic surfaces and a hydrophobic core (Fig. 3.4). The cell membrane is, however, much more than a simple wall. Cholesterol-rich 'rafts' float within the membrane, with proteins anchored to them via the post-translational addition of complex lipid moieties. The membrane also hosts a series of transmembrane proteins that function as receptors, pores, ion channels, pumps and associated energy suppliers. These proteins allow the cell to monitor the extracellular milieu, import crucial molecules for function, and exclude or exchange unwanted substances. Many proteins within the cell membrane are highly dynamic and associate and disassociate to subserve their functions.

The cell membrane is permeable to hydrophobic substances such as anaesthetic gases. Water is able to pass through the membrane via a pore formed by aquaporin

3.1 The structure of the respiratory chain complexes and the diseases associated with their dysfunction

Complex	Enzyme	nDNA subunits ¹	mtDNA subunits ²	Diseases
I	NADH dehydrogenase	38	7	MELAS, bilateral striatal necrosis, LHON, myopathy and exercise intolerance, Parkinsonism, Leigh's disease, exercise myoglobinuria, leukodystrophy/myoclonic epilepsy
II	Succinate dehydrogenase	4	0	Phaeochromocytoma
III	Cytochrome bc ₁ complex	10	1	Parkinsonism/MELAS, cardiomyopathy, myopathy, exercise myoglobinuria
IV	Cytochrome c oxidase	10	3	Sideroblastic anaemia, myoclonic ataxia, deafness, myopathy, MELAS, mitochondrial encephalomyopathy, motor neuron disease-like, exercise myoglobinuria
V	ATP synthase	14	2	Leigh's disease, NARP, bilateral striatal necrosis

¹nDNA subunits (nDNA = nuclear DNA)
²mtDNA subunits = number of different protein subunits in each complex that are encoded in the nDNA and mtDNA respectively.
 (LHON = Leber hereditary optic neuropathy; MERRF = myoclonic epilepsy and ragged-red fibres; MELAS = myopathy, encephalopathy, lactic acidosis and stroke-like episodes; mtDNA = mitochondrial DNA; NARP = neuropathy, ataxia and retinitis pigmentosa).

Fig. 3.4 An archetypal human cell. The basic cell components required for function within a tissue: (1) cell-to-cell communication taking place via gap junctions and the various types of receptor that receive signals from the extracellular environment and transduce these into intracellular messengers; (2) the nucleus containing the chromosomal DNA; (3) intracellular organelles including the mechanisms for proteins and lipid catabolism; (4) the cellular mechanisms for import and export of molecules across the cell membrane. (ABC = ATP-binding cassette transporters; ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; CFTR = cystic fibrosis transmembrane regulator; CREB = cAMP response element-binding protein; GDP/GTP = guanine diphosphate/triphosphate; LDL = low-density lipoproteins)

proteins; mutations of an aquaporin gene cause congenital nephrogenic diabetes insipidus (p. 792). Other molecules, including ions, glucose and other fuels, amino acids and peptides, must be actively transported using either channels or pumps. Channels are responsible for the transport of ions and other small molecules across the cell membrane. They open and close in a highly regulated manner. The cystic fibrosis transmembrane conductance regulator (CFTR) is an example of an ion channel which is responsible for transport of chloride ions across epithelial cell membranes. Mutation of the CFTR chloride channel, highly expressed in the lung and gut, leads to defective chloride transport, producing cystic fibrosis. Pumps are highly specific for their substrate and often use energy (ATP) to drive transport against a concentration gradient.

Endocytosis is a cellular process that allows internalisation of larger complexes and molecules via an invaginated fold of plasma membrane. Such engulfing is typically mediated by specific binding of the particle to surface receptors. This can involve phagocytosis of large particles and whole cells. An example of endocy-

tosis of smaller structures is the uptake of low-density lipoprotein (LDL) cholesterol, which binds to cell membranes via a specialised region of the membrane called a clathrin pit LDL receptor. In familial hypercholesterolaemia (p. 451), mutation of the receptor leads to failure to bind LDL cholesterol. Intriguingly, in some families, mutations in a specific tyrosine in the intracellular tail of the receptor, which normally attaches the protein to clathrin, prevents receptors concentrating in clathrin-coated pits and hence impairs uptake of LDL, even though the receptors are present elsewhere in the cell membrane.

The shape and structure of the cell are maintained by the cytoskeleton, which consists of a series of proteins which form microfilaments (actin), microtubules (tubulins) and intermediate filaments (keratins, desmin, vimentin, laminins) that facilitate cellular movement and provide pathways for intracellular transport. Dysfunction of the cytoskeleton may result in a variety of human disorders. For instance, some keratin genes encode intermediate filaments in epithelia. In epidermolysis bullosa simplex (p. 1249), mutations in keratin

genes (*KRT5*, *KRT14*) lead to cell fragility, producing the characteristic blistering on mild trauma.

Cellular signalling

Cells communicate with one another directly through gap junctions, and indirectly by release of hormones, cytokines and growth factors which bind to receptors on the target cell. Gap junctions are pores formed by the interaction of 'hemichannels' in the membrane of adjacent cells. This interaction results in a direct communication between the cytoplasm of adjacent cells. Many diseases are due to mutations in gap junction proteins, including the most common form of autosomal recessive hearing loss (*GJB2*) and the X-linked form of Charcot-Marie-Tooth disease (*GJB1*).

As organisms have become larger and more complex, mechanisms have evolved which enable communication between cells that operates over greater distances. Cell signalling is a very important mechanism in medicine. In a typical signalling pathway, a ligand will bind to a receptor that will then directly or indirectly activate gene expression to produce a cellular response (see Fig. 3.4).

There are several different signalling pathways; for example, in nuclear steroid hormone signalling, the ligands (steroid hormones or thyroid hormone) bind to their cognate receptor in the cytoplasm and the receptor/ligand complex then enters the nucleus, where it acts as a transcription factor to regulate the expression of target genes (Box 3.2). However, the most diverse and abundant types of receptor are located at the cell surface, and these usually activate gene expression and cellular responses indirectly. When a cell surface receptor is activated by its ligand, a series of events ensue, usually involving the phosphorylation and activation of a cascade of enzymes called kinases. This, in turn, typically culminates in phosphorylation and activation of transcription factors which bind DNA and modulate gene expression. Some membrane receptors, like the insulin receptor, contain a kinase domain which is activated by ligand binding. Others, like the tumour necrosis factor (TNF) receptor, do not have intrinsic kinase activity but recruit other effector proteins. Transmembrane receptors can be grouped into:

- ion channel-linked receptors (e.g. glutamate and the nicotinic acetylcholine receptor)
- G protein-coupled receptors (e.g. rhodopsin, olfactory receptors, parathyroid hormone receptor)
- receptors with intrinsic enzyme activity (e.g. insulin receptor, growth factor receptors)
- receptors which do not have intrinsic enzymatic activity, but which recruit other proteins with kinase activity to their intracellular domain when activated by ligand (TNF receptor, interleukin (IL)-1 receptor) (see Box 3.2).

Many receptors need to form dimers for full activity, and in some cases, active receptors form trimers. Mutations which interfere with receptor dimerisation can result in disease. For example, mutations of the insulin receptor which inhibit dimerisation have been described that lead to childhood insulin resistance and growth failure. Conversely, mutations in the fibroblast growth factor receptor 2 gene (*FGFR2*) have been described which cause constitutive dimerisation in the absence of ligand, producing bone overgrowth and an autosomal dominant form of craniosynostosis called Crouzon's syndrome.

Cell division, differentiation and migration

In normal tissues, molecules such as hormones, growth factors and cytokines provide the signal to activate the cell cycle, a controlled programme of biochemical events that culminates in cell division. During the first phase, G1, synthesis of the cellular components necessary to complete cell division occurs. In S phase, the cell produces an identical copy of each chromosome—which carries the cell's genetic information—via a process called DNA replication. The cell then enters G2, when any errors in the replicated DNA are repaired before proceeding to mitosis, in which identical copies of all chromosomes are segregated to the daughter cells. The progression from one phase to the next is tightly controlled by cell cycle checkpoints. For example, the checkpoint between G2 and mitosis ensures that all damaged DNA is repaired prior to segregation of the chromosomes. Failure of these control processes is a crucial factor in the pathogenesis of cancer, as discussed in Chapter 11 (p. 258).

3.2 Examples of molecules involved in specific signalling cascades

Ligand	Receptor (type)	Signal transduction	Effector/target genes	Medical significance
TNF-α	TNFR1 (TNFR)	TRADD, FADD IKK, NF κ B	Caspase 8 \rightarrow apoptosis Inflammatory cytokines	TNF- α is an important cytokine that results in apoptosis, but binding of the same receptor also activates inflammation by the NF κ B pathway
Insulin	Insulin receptor (RTK)	IRS1, PI3K, PIP3, AKT/ PKB, PDK1, mTORC2, GSK3	Glycogen synthase	Insulin has many roles; activation of this cascade stimulates conversion of blood glucose to muscle glycogen
Thyroid hormones	THRA or THRB (NHR)	Ligand/receptor complex	<i>GH</i> , <i>SERCA2A</i> , <i>PEPCK</i> etc.	Thyroid hormone signalling has many roles in embryogenesis and adult life. The different receptors seem to have subtly different roles
Gonadotrophin-releasing hormone (GnRH)	GnRHR (GPCR)	Gq/G(11), PLC β tal, PLA(2), PLD, PKC, MAPK	Gonadotrophin subunits, GnRHR	This cascade produces a pulsatile cascade that is important in control of fertility

(GPCR = G protein-coupled receptor; NHR = nuclear hormone receptor; RTK = receptor tyrosine kinase receptor; TNFR = tumour necrosis superfamily of receptors)

During development or tissue repair, cells must progressively replace their stem cell identity with the morphological and biochemical configuration of an individual tissue. This process is called differentiation and requires the programmed gain and loss of specific functions in individual cells. This is achieved by activation or repression of genes which are functional elements coded within the chromosomal DNA. It is the ability to switch genes on and off that allows cells containing the same genetic material to become very different in shape and function. The programme of differentiation is often deranged or partially reversed in cancer cells.

Another process that is of particular importance during development and tissue repair is cell migration. This requires the activation of a set of genes which give the cell polarity and enable the leading edge of the cell to interact with the extracellular environment to control the speed and direction of travel. Again, this process can be reactivated in cancer cells and is thought to facilitate tumour metastasis.

Cell death, apoptosis and senescence

With the exception of stem cells, human cells have only a limited capacity for cell division. The Hayflick limit is the number of divisions a cell population can go through in culture before division stops (senescence). The molecular nature of this 'biological clock' is of great interest in the study of the normal ageing process, and the study of rare human diseases associated with premature ageing has been very helpful in identifying the importance of DNA repair mechanisms in senescence (pp. 46 and 166).

A very different mechanism of cell death is seen in apoptosis, or programmed cell death. Apoptosis is an active process that occurs in normal tissues and plays an important role in development, tissue remodelling and the immune response. The signal that triggers apoptosis is specific to each tissue or cell type. This signal activates enzymes, called caspases, which actively destroy cellular components, including chromosomal DNA. This degradation results in cell death, but the cellular corpse contains characteristic vesicles called apoptotic bodies. The corpse is then recognised and removed by phagocytic cells of the immune system, such as macrophages, in a manner that does not provoke an inflammatory response.

A third mechanism of cell death is necrosis. This is a pathological process in which the cellular environment loses one or more of the components necessary for cell viability. Hypoxia is probably the most common cause of necrosis.

GENETIC DISEASE AND INHERITANCE

Meiosis

Meiosis is a special form of cell division that only occurs in the postpubertal testis and the fetal and adult ovary (Fig. 3.5). Meiosis differs from mitosis in two main ways. Firstly, there is extensive swapping of genetic material between homologous chromosomes, a process known as recombination, before the first of the two meiotic cell

Fig. 3.5 Meiosis and gametogenesis. The main chromosomal stages of meiosis in both males and female. A single homologous pair of chromosomes is represented in different colours. The final step is the production of haploid germ cells. Each round of meiosis in the male results in four sperm cells; in the female, however, only one egg cell is produced, as the other divisions are sequestered on the periphery of the mature egg as peripheral polar bodies.

divisions. As a result of recombination, each chromosome that a parent passes to his or her offspring is a mix of the chromosomes which the parent inherited from his or her own mother and father. Secondly, the cells that are produced as the result of meiosis (sperm and egg cells) are haploid, in that they each have only 23 chromosomes: one of each homologous pair of autosomes and

a sex chromosome. The requirement for this reductive process is obvious; when a sperm cell fertilises the egg, the resulting zygote will have a diploid chromosome complement of 46 chromosomes. The sperm thus determines the sex of the offspring, since 50% of sperm will carry an X chromosome and 50% a Y chromosome, with each egg cell carrying an X chromosome.

The individual steps in meiotic cell division are similar in males and females. However, the timing of the cell divisions is very different (see Fig. 3.5). In females, meiosis begins in fetal life but does not complete until after ovulation. A single meiotic cell division can thus take more than 40 years to complete. In males, meiotic division does not begin until puberty and continues throughout life. In the testes, both meiotic divisions are completed in a matter of days.

Patterns of disease inheritance

Five modes of genetic disease inheritance are discussed below and illustrated in Figures 3.6 and 3.7.

Autosomal dominant inheritance

Autosomal dominant disorders are caused by inheritance of a genetic abnormality in only one of

the two copies (alleles) of a single gene. The risk of an affected individual transmitting an autosomal disease to his or her offspring is 50% for each pregnancy, since half the affected individual gametes (sperm or egg cells) will contain the affected chromosome and half will contain the normal chromosome. However, even within a family, individuals with the same mutation rarely have identical patterns of disease due to variable penetrance and/or expressivity. Penetrance is defined as the proportion of individuals bearing a mutated allele who develop the disease phenotype. The mutation is said to be fully penetrant if all individuals who inherit a mutation develop the disease. Expression of a disease describes the degree to which the severity of various aspects of the disease phenotype may vary. Neurofibromatosis type 1 (*NF1*, neurofibromin, 17q11.2) is an example of a disease that is fully (100%) penetrant but which shows extremely variable expressivity. The factors that alter penetrance and expressivity are not clearly understood. It is very likely that other genes act as modifiers of the mutated gene's function, along with environmental factors. A good example of an environmental influence which can profoundly influence expression of autosomal dominant disease is seen in the triggering of malignant hyperpyrexia by anaesthetic agents in the presence of *RYR1*

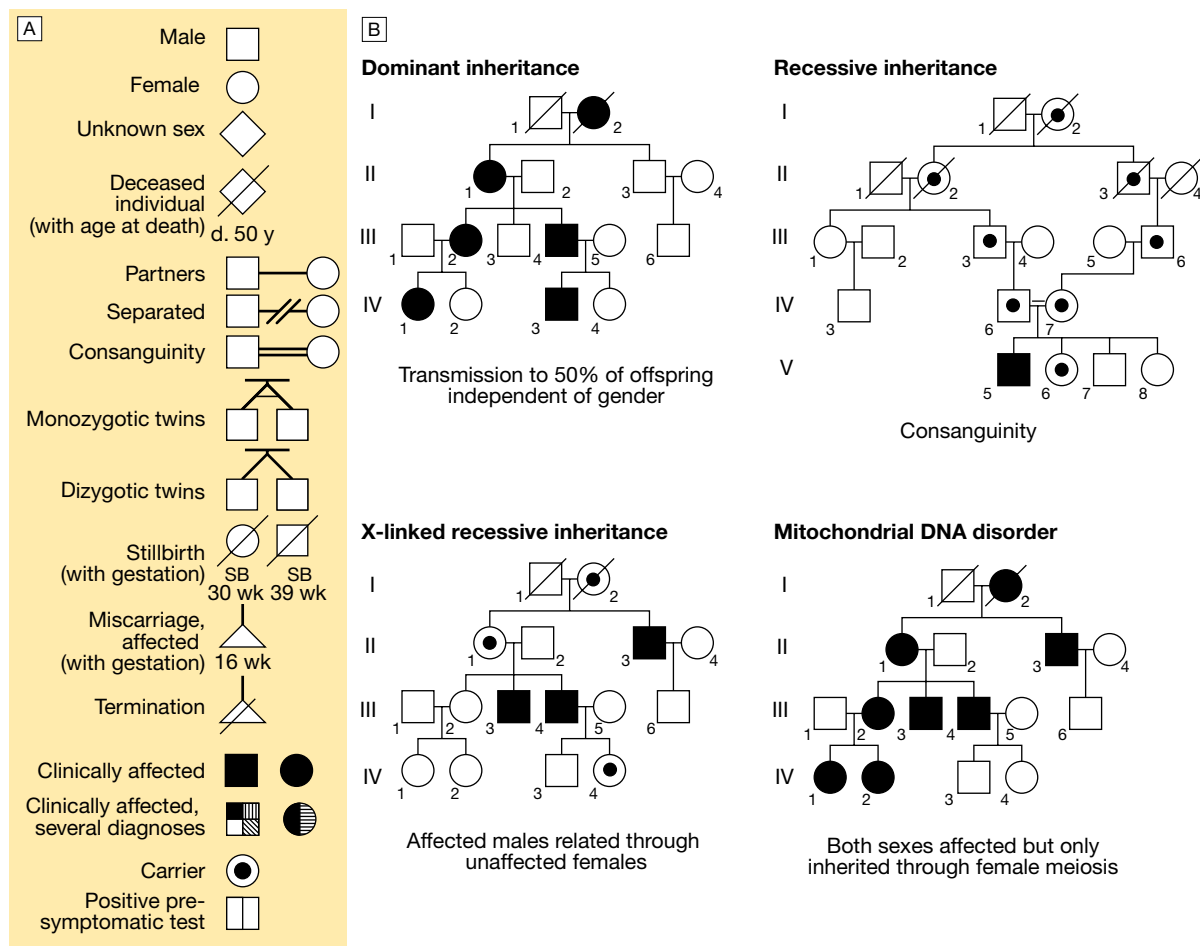

Fig. 3.6 Drawing a pedigree and patterns of inheritance. **A** The main symbols used to represent pedigrees in diagrammatic form. **B** The main modes of disease inheritance, as discussed in the text.

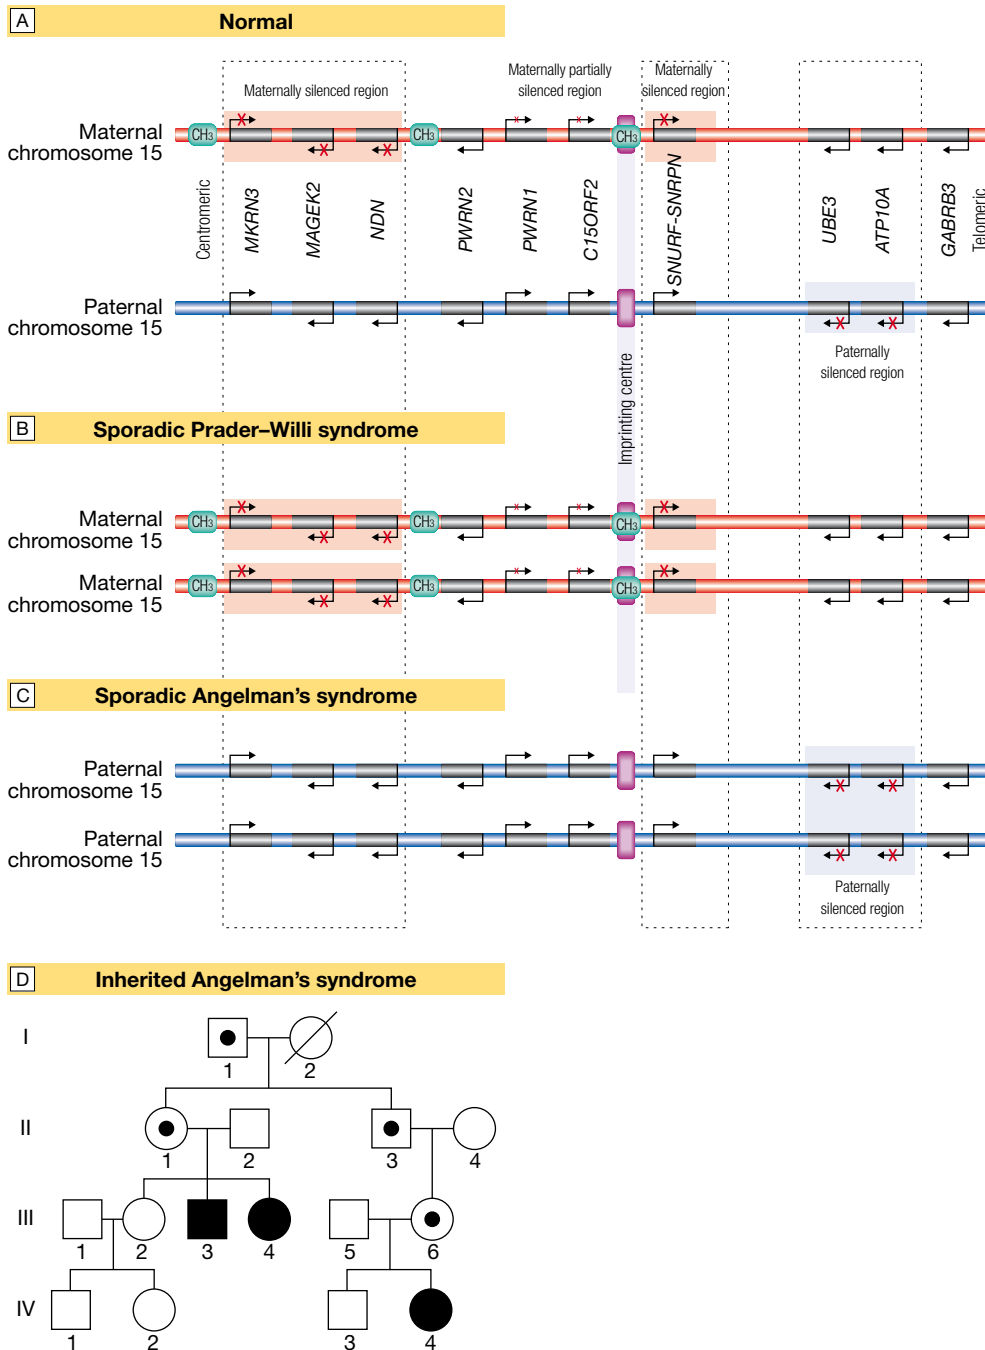

Fig. 3.7 Genomic imprinting and associated diseases. Several regions of the genome exhibit the phenomenon of imprinting whereby expression of one or a group of genes is influenced by whether the chromosome is derived from the mother or the father; one such region lies on chromosome 15.

A Normal imprinting. Under normal circumstances expression of several genes is suppressed (silenced) on the maternal chromosome (red), whereas these are expressed normally by the paternal chromosome (blue). However, two genes in the paternal chromosome (*UBE3* and *ATP10A*) are silenced.

B In sporadic Prader-Willi syndrome (PWS) there is a non-disjunction defect on chromosome 15, and both copies of the chromosomal region are derived from the mother (maternal uniparental disomy). In this case Prader-Willi syndrome occurs because there is loss of function of several paternally expressed genes, including *MKRN3*, *MAGEK2*, *NDN*, *PWRN2*, *C15ORF2* and *SNURF-SNRPN*.

C In sporadic Angelman's syndrome, both chromosomal regions are derived from the father (paternal uniparental disomy) due to non-disjunction during paternal meiosis. As a result, both copies of the *UBE3* gene are silenced and this causes Angelman's syndrome. Note that the syndrome can also be caused by deletion of this region on the maternal chromosome or a loss of function mutation on the maternal copy of *UBE3*, causing an inherited form of Angelman's as illustrated in panel D.

D Pedigree of a family with inherited Angelman's syndrome due to a loss of function mutation in *UBE3*. Inheriting this mutation from a father causes no disease (because the gene is normally silenced in the paternal chromosome) (see individuals I-1, II-1, II-3, III-6), but the same mutation inherited from the mother causes the syndrome (individuals III-3, III-4, IV-4), as this is the only copy expressed and the *UBE3* gene is mutated.

mutations. Other examples of autosomal dominant disorders (with the affected gene, the name of the protein encoded by the gene and the locus) include adult polycystic kidney disease type 1 (*PKD1*, polycystin I, 16p13.1) and hereditary motor and sensory neuropathy type 1 (*PMP22*, peripheral myelin protein 22, 17p11.2). Autosomal dominant disorders can occur as a result of either loss or gain of function of the affected gene.

Autosomal recessive inheritance

In autosomal recessive disorders, both alleles of a gene must be mutated before the disease is manifest in an individual, and an affected individual must inherit one mutant allele from each parent. The distinguishing feature of recessive diseases is that carrying one mutant allele does not produce a phenotype. Autosomal recessive disorders are rare in most populations. For example, the most common serious autosomal recessive disorder in the UK is cystic fibrosis, which has a birth incidence of 1:2500. The frequency of autosomal recessive disorders increases with the degree of inbreeding of a population because the risk of inheriting the same mutant allele from both parents (homozygosity) is increased. Genetic risk calculation for a fully penetrant autosomal recessive disorder is straightforward. Each subsequent pregnancy of a couple who have had a previous child affected by an autosomal recessive disorder will have a 25% (1:4) risk of being affected; a healthy individual who has a sibling with an autosomal recessive disorder will have 2/3 chance of being a carrier. The risk of an affected individual having children with the same condition is usually low but is dependent on the carrier rate of mutant allele of the gene in the population.

X-linked inheritance

Genetic diseases caused by mutations on the X chromosome have specific characteristics. X-linked diseases are mostly recessive and restricted to males who carry the mutant allele. This is because males have only one X chromosome, whereas females have two. Thus females who carry a single mutant allele are generally unaffected. Occasionally, female carriers may exhibit signs of an X-linked disease due to a phenomenon called skewed X-inactivation. All females will inactivate one of their two X chromosomes in each cell at a point during development. This process is random in each cell but if, by chance, there is a disproportionate inactivation of normal X chromosomes carrying the normal allele, then an affected female carrier will be more likely. X-linked recessive disorders have a recognisable pattern of inheritance, with transmission of the disease from carrier females to affected males and absence of father-to-son transmission. The risk of a female carrier having an affected child is 25% (1:4; half her male offspring). If the carrier status of a woman is unclear, then the risk may be altered by conditional information, as discussed in the autosomal dominant disease section above. Bayes' theorem is commonly used to calculate such modified risks and this is discussed in more detail later in this chapter (p. 64).

Mitochondrial inheritance

The inheritance of mtDNA disorders is characterised by transmission from females, but males and females are generally equally affected. Unlike all the other inheritance patterns mentioned above, mitochondrial inheri-

tance has nothing to do with meiosis but reflects the fact that mitochondrial DNA is transmitted by oocytes. Mitochondrial disorders tend to be very variable in penetrance and expressivity within families, and this is mostly accounted for by the fact that only a proportion of mtDNA molecules within mitochondria contain the causal mutation (the degree of mtDNA heteroplasmy).

Epigenetic inheritance (including imprinting)

Several loci have been identified where gene repression is inherited in a parent of origin-specific manner; these are called imprinted loci. Within these loci the paternal alleles of a gene may be active while the maternal one may be silenced, or vice versa (see Fig. 3.7). Mutations within imprinted loci lead to a very unusual pattern of inheritance where the phenotype is only manifest if inherited from the parent who contributes the transcriptionally active allele (see Fig. 3.7). Examples of these disorders are listed in Box 3.3.

Classes of genetic variant

There are many different classes of variation in the human genome (Fig. 3.8). Rare genetic variations which result in a disease are generally referred to as mutations, whereas common variations and those which do not cause disease are referred to as polymorphisms. These different types of variation are further categorised by the size of the DNA segment involved and/or by the mechanism giving rise to the variation.

Nucleotide substitutions

The substitution of one nucleotide for another is the most common type of variation in the human genome. Depending on their frequency and functional consequences, these changes are known as a point mutation or a single nucleotide polymorphism (SNP). They occur by misincorporation of a nucleotide during DNA synthesis or by the action of a chemical mutagen. When these substitutions occur within ORFs of a protein-coding gene, they are further classified into:

- *synonymous* (resulting in a change in the codon but no change in the amino acid and thus no phenotype)
- *missense* (altering a codon, resulting in an amino acid change in the protein)
- *nonsense* (introducing a premature stop codon, resulting in truncation of the protein).

Single-base changes can also affect splicing of a gene if they occur at the junction of an intron or an exon, and those which adversely affect splicing are called splice site mutations.

Insertions and deletions

One or more nucleotides may be inserted or lost in a DNA sequence, resulting in an insertion/deletion (indel) polymorphism or mutation (see Fig. 3.8). If an indel change affects one or two nucleotides within the ORF of a protein-coding gene, this can have serious consequences because the triple nucleotide sequence of the codons is disrupted, resulting in a frameshift mutation. The effect upon the gene is typically severe because the amino acid sequence is totally disrupted.

3.3 Epigenetic disease

Disease	Locus and genes	Notes
Imprinting disorders		
Beckwith–Wiedemann syndrome	11p15 <i>p57^{KIP2}</i> <i>HASH2</i> , <i>INS2</i> , <i>IGF2</i> , <i>H19</i>	General 'over-growth', advanced bone age and increased childhood tumours. Some cases due to mutations in <i>p57^{KIP2}</i>
Prader–Willi syndrome	15q11–q13 <i>SNRPN</i> , <i>Necdin</i> and others	Obesity, hypogonadism and learning disability. Lack of paternal contribution (due to deletion of paternal 15q11–q13, or inheritance of both chromosome 15q11–q13 regions from the mother)
Angelman's syndrome (AS)	15q11–q13 <i>UBE3A</i>	Severe mental retardation, ataxia, epilepsy and inappropriate laughing bouts. Due to loss-of-function mutations in the maternal <i>UBE3A</i> gene. The neurological phenotype results because most tissues express both maternal and paternal alleles of <i>UBE3A</i> , whereas the brain expresses predominantly the maternal allele
X-inactivation disorders		
Duchenne muscular dystrophy (DMD) in females	<i>Xp22</i> , <i>DMD</i>	If, by chance, a sufficient number of the X chromosomes containing the normal <i>dystrophin</i> gene are inactivated in muscle, heterozygous females may rarely develop full-blown DMD. Conversely, if a higher proportion of the disease gene-carrying chromosome is inactivated, a carrier female may test negative on biochemical screening for elevated creatine kinase levels
Epigenetic silencing (oncogenesis)		
Colon cancer	3p21 <i>MLH1</i>	Hypermethylation of the promoter results in silencing of <i>MLH1</i> , which encodes a DNA repair gene

Simple tandem repeat mutation

Variations in the length of simple tandem repeats of DNA are thought to arise as the result of slippage of DNA during meiosis and are termed microsatellite (small) or minisatellite (larger) repeats. These repeats are unstable and can expand or contract in different generations. This instability is related to the size of the original repeat, in that longer repeats tend to be more unstable. Many microsatellites and minisatellites occur in introns or in chromosomal regions between genes and have no obvious adverse effects. However, some genetic diseases, including Huntington disease and myotonic dystrophy, are caused by microsatellite repeats which result in duplication of amino acids within the affected gene product or affect gene expression (Box 3.4).

Copy number variations

Variation in the number of copies of an individual segment of the genome from the usual diploid (two copies) content can be categorised by the size of the segment involved. Rarely, individuals may gain or lose a whole chromosome. Such numerical chromosome anomalies most commonly occur by a process known as meiotic non-dysjunction (Box 3.5). This is the most common cause of Down's syndrome, known as trisomy (three copies) of chromosome 21.

Large insertions or deletions of chromosomal DNA also occur and are usually associated with learning disability and/or malformations. Such structural chromosomal anomalies arise as the result of two different processes:

- non-homologous end-joining
- non-allelic homologous recombination.

Random double-stranded breaks in DNA are a necessary process in meiotic recombination and also occur during mitosis at a predictable rate. The rate of these breaks is dramatically increased by exposure to ionising radiation.

When such breaks occur, they are usually repaired accurately by DNA repair mechanisms within the cell. However, a proportion of breaks will undergo non-homologous end-joining, which results in the joining of two segments of DNA that are not normally contiguous. If the joined fragments are from different chromosomes, this results in a translocation. If they are from the same chromosome, this will result in either an inversion or a deletion (Fig. 3.9). Large insertions and deletions may be cytogenetically visible as chromosomal deletions or duplications. If the anomalies are too small to be detected by microscopy, they are termed microdeletions and microduplications. Many microdeletion syndromes have been described and most stem from non-allelic homologous recombination between locus-specific repeat of highly similar DNA sequences, which results in identical chromosome anomalies – and clinical syndromes – occurring in unrelated individuals (see Fig. 3.9 and Box 3.5).

Polymorphic copy number variants (CNVs)

It has recently been appreciated that, in addition to the disease-causing structural chromosomal anomalies mentioned above, there are also a considerable number of CNVs that exist as common genetic polymorphisms in humans. These involve duplication of large segments of the genome, often containing multiple genes and regulatory elements. These duplications usually result from non-allelic homologous recombination via misalignment of tandem repeated DNA elements in the chromosome during recombination (see Fig. 3.9). The consequences of CNV for genetic disease have not been fully explored, although recent studies have shown a strong association between an increased copy number of the gene *FCGR3B* and the risk of systemic lupus erythematosus.

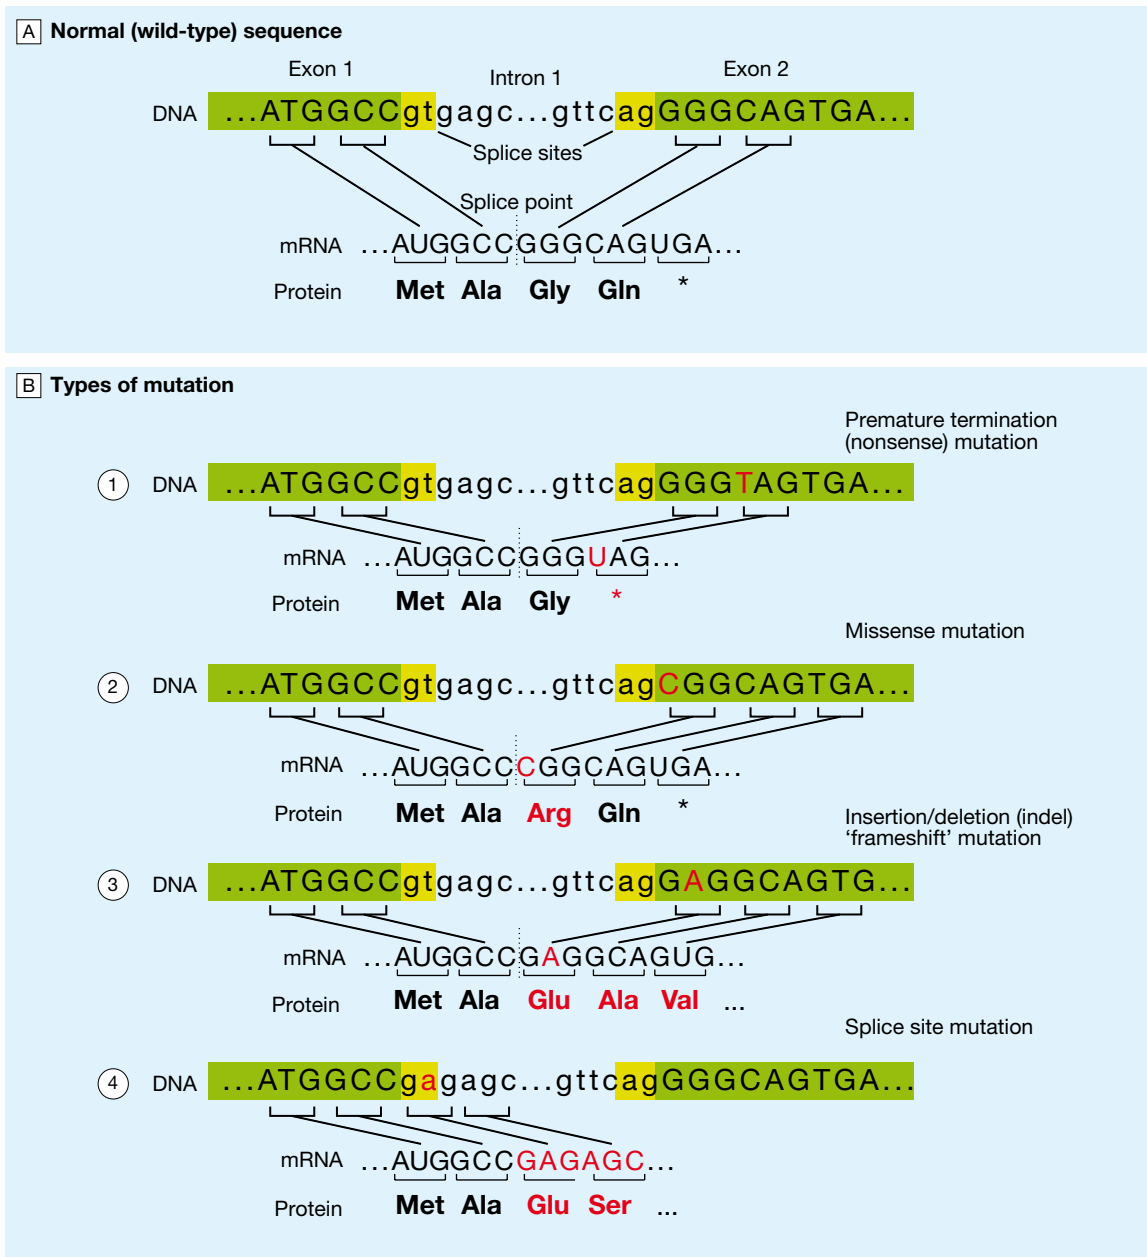

Fig. 3.8 Categories of mutation and summary of mutation types. **A** Normal genomic DNA spanning two exons and an intervening intron. Note that the 'coding strand' DNA sequence is shown; RNA is actually read from the complementary strand and, following splicing, the intron is removed, giving rise to the mRNA and protein sequence as shown (see also Fig. 3.1, p. 40). **B** Various examples of mutation are illustrated.

1. A nonsense mutation results in change from the normal sequence (CAG), encoding glutamine to a stop codon (TAG) which causes premature termination of the polypeptide chain; this would be expected to result in loss of protein function.
2. A missense mutation in exon 2 results in a change from the normal sequence encoding glycine (GGG) to (CGG) which encodes arginine. The change from a neutral amino acid to a charged residue would be expected to alter protein function.
3. An insertion of a single 'A' nucleotide in exon 2 causes a 'frameshift' mutation, resulting in disruption of the normal triple nucleotide sequence. The amino acids downstream of the insertion are completely different from those of the normal protein. This usually results in a loss of function mutation.
4. A splice site mutation which changes the second nucleotide of intron 1 from a 't' to an 'a' residue disrupts the normal 'gt' splice site donor motif, causing the RNA to 'read' through the intron and producing an abnormal protein. Splice site mutations often result in the production of mRNA molecules with a premature termination codon downstream of the mutation.

Consequences of genetic variation

Genetic variants can generally be classed into three groups:

- those with no detectable (neutral variants)
- those which cause loss of function
- those which cause a gain of function of the gene product.

The consequence of an individual mutation depends on many factors, including the mutation type, the nature of the gene product and the position of the variant in the protein. Mutations can have profound effects or subtle effects on gene and cell function (Box 3.6). Variations which have profound effects are responsible for 'classical' genetic diseases, whereas those with subtle effects

3.4 Diseases associated with triplet and other repeat sequences

	Repeat	No. of repeats		Gene	Gene location	Inheritance
		Normal	Mutant			
Coding repeat expansion						
Huntington disease	[CAG]	6–34	> 35	<i>Huntingtin</i>	4p16	AD
Spinocerebellar ataxia (type 1)	[CAG]	6–39	> 40	<i>Ataxin</i>	6p22–23	AD
Spinocerebellar ataxia (types 2, 3, 6, 7)	[CAG]	Various	Various	Various	Various	AD
Dentatorubral-pallidoluysian atrophy	[CAG]	7–25	> 49	<i>Atrophin</i>	12p12–13	AD
Machado–Joseph disease	[CAG]	12–40	> 67	<i>MJD</i>	14q32	AD
Spinobulbar muscular atrophy	[CAG]	11–34	> 40	Androgen receptor	Xq11–12	XL recessive
Non-coding repeat expansion						
Myotonic dystrophy	[CTG]	5–37	> 50	<i>DMPK-3'UTR</i>	19q13	AD
Friedreich's ataxia	[GAA]	7–22	> 200	<i>Frataxin-intronic</i>	9q13	AR
Progressive myoclonic epilepsy	[CCCCGCCCGCG] _{4–6}	2–3	> 25	<i>Cystatin B-5'UTR</i>	21q	AR
Fragile X mental retardation	[CGG]	5–52	> 200	<i>FMR1-5'UTR</i>	Xq27	XL dominant
Fragile site mental retardation 2 (FRAXE)	[GCC]	6–35	> 200	<i>FMR2</i>	Xq28	XL, probably recessive
Note The triplet repeat diseases fall into two major groups: those with disease resulting from expansion of [CAG] _n repeats in coding DNA, resulting in multiple adjacent glutamine residues (polyglutamine tracts), and those with non-coding repeats. The latter tend to be longer. Unaffected parents usually display 'pre-mutation' allele lengths that are just above the normal range. (AD = autosomal dominant; AR = autosomal recessive; UTR = untranslated region; XL = X-linked)						

3.5 Chromosome and contiguous gene disorders

Disease	Locus	Incidence	Clinical features
Numerical chromosomal abnormalities			
Down's syndrome (trisomy 21)	47,XY,+21 or 47,XX,+21	1:800	Characteristic facies, IQ usually < 50, congenital heart disease, reduced life expectancy
Edwards' syndrome (trisomy 18)	47,XY,+18 or 47, XX,+18	1:6000	Early lethality, characteristic skull and facies, frequent malformations of heart, kidney and other organs
Patau's syndrome (trisomy 13)	47,XY,+13 or 47, XX,+13	1:15 000	Early lethality, cleft lip and palate, polydactyly, small head, frequent congenital heart disease
Klinefelter's syndrome	47,XXY	1:1000	Phenotypic male, infertility, gynaecomastia, small testes—p. 763
XYY	47,XYY	1:1000	Usually asymptomatic, some impulse control problems
Triple X syndrome	47,XXX	1:1000	Usually asymptomatic, may have reduced IQ
Turner's syndrome	45,X	1:5000	Phenotypic female, short stature, webbed neck, coarctation of the aorta, primary amenorrhoea—p. 761
Recurrent deletions, microdeletions and contiguous gene defects			
Di George/velocardiofacial syndrome	22q11.2	1 in 4000	Cardiac outflow tract defects, distinctive facial appearance, thymic hypoplasia, cleft palate and hypocalcaemia. Major gene seems to be <i>TBX1</i> (cardiac defects and cleft palate)
Prader–Willi syndrome	15q11–q13	1:15 000	Distinctive facial appearance, hyperphagia, small hands and feet, distinct behavioural phenotype. Imprinted region, deletions on paternal allele in 70% of cases
Angelman's syndrome	15q11–q13	1:15 000	Distinctive facial appearance, absent speech, EEG abnormality, characteristic gait. Imprinted region, deletions on maternal allele in <i>UBE3A</i>
Williams' syndrome	7q11.23	1:10 000	Distinctive facial appearance, supravalvular aortic stenosis, learning disability and infantile hypercalcaemia. Major gene for supravalvular aortic stenosis is <i>elastin</i>
Smith–Magenis syndrome	17p11.2	1 in 25 000	Distinctive facial appearance and behavioural phenotype, self-injury and rapid eye movement (REM) sleep abnormalities. Major gene seems to be <i>RAI1</i>

Fig. 3.9 Chromosomal analysis and structural chromosomal disorders. **A** How chromosome analysis is carried out. Starting with a blood sample, the white cells are stimulated to divide by adding the mitogen phytohaemagglutinin (PHA) and colchicine is used to trap the cells in metaphase, which allows the chromosomes to be seen using light microscopy following staining with Giemsa, resulting in a banding pattern. **B** How structural chromosomal anomalies are described. Human chromosomes can be classed as metacentric if the centromere is near the middle, or acrocentric if the centromere is at the end. The bands of each chromosome are given a number starting at the centromere and working out along the short (p) arm and long (q) arm. Translocations and inversions are balanced structural chromosome anomalies where no genetic material is missing but it is in the wrong order. Translocations can be divided into reciprocal (direct swap of chromosomal material between non-homologous chromosomes) and Robertsonian (fusion of acrocentric chromosomes). Deletions and duplications can also occur due to non-allelic homologous recombination (illustrated in panel C). Deletions are classified as interstitial if they lie within a chromosome and terminal if the terminal region of the chromosome is affected. Duplications can either be in tandem (where the duplicated fragment is orientated in the correct direction) or inverted (where the duplicated fragment is in the wrong direction). (N = normal; A = abnormal) **C** A common error of meiotic recombination, known as non-allelic homologous recombination, can occur (right panel) resulting in a deletion on one chromosome and a duplication in the homologous chromosome. The error is induced by tandem repeats in the DNA sequences (green) which can misalign and bind to each other, thereby 'fooling' the DNA into thinking the pairing prior to recombination is correct.

may contribute to the pathogenesis of complex diseases with a genetic component.

Loss-of-function (LOF) mutations

These mutations cause the normal function of a protein to be reduced or lost. Deletion of the whole gene is the most obvious example but the same phenotype is likely to be seen with a nonsense or frameshift mutation early in the ORF. Missense mutations that alter a critical domain within the protein can also result in LOF. In autosomal recessive diseases, mutations that result in no protein function whatsoever are known as null mutations. If LOF mutations result in an autosomal dominant disease,

the genetic mechanism is known as haplo-insufficiency and indicates that both functional copies of the gene are required for normal cellular function. Mutations in *PKD1* or *PKD2* which cause autosomal dominant adult polycystic kidney disease are mostly LOF.

Gain-of-function mutations

These are usually the result of missense mutations or, occasionally, triplet repeat expansion mutations. In this type of mutation the protein function is altered in a manner that results in a change in the original function of the gene. For example, heterozygous mutations (mutations on one allele in the presence of a wild-type allele)

in *FBN1* cause Marfan's syndrome by the production of a protein with an abnormal amino acid sequence that disrupts the normal assembly of microfibrils. In comparison, complete loss of function of one allele of *FBN1* is usually completely benign. This is an example of how some missense mutations can be worse than 'null' mutations; this is called a 'dominant negative' effect. Constitutive activation of fibroblast growth factor receptors by missense mutation, which causes achondroplasia, is another example of such a mutation.

Polymorphisms

A polymorphism is defined as one that exists with a population frequency of > 1%. Most common polymorphisms are neutral (see below), but some cause subtle changes in gene expression or in protein structure and function (see Box 3.17, p. 65). It is thought that these polymorphisms lead to variations in phenotype within the general population, including variations in susceptibility to common diseases. An example is polymorphism in the gene *SLC2A9* that not only explains a significant proportion of the normal population variation in serum urate concentration but also predisposes 'high-risk' allele carriers to the development of gout. Other examples are listed in Box 3.6.

Neutral variants

The vast majority of variations within the human genome have no discernible effect on the cell or organism. This may be because the variation lies within an intron of a gene or a region of the genome which does not code for a gene or a regulatory element. Also, some variations within the coding regions of a gene do not change the amino acid, typically when the third base of a codon is affected. Some variations that do change the amino acid result in a conservative substitution, which does not change protein function appreciably.

Evolutionary selection

Genetic variants play an important role in evolutionary selection. Some variants can be advantageous to an organism, in which case they will be under positive selection through evolution via improved reproductive fitness. Conversely, other variations that decrease reproductive fitness become less common and are excluded through evolution. Given this simple paradigm, it would be tempting to assume that common mutations are all advantageous and all rare mutations

are pathogenic. Unfortunately, it is often difficult to classify any common mutation as either advantageous or deleterious—or indeed neutral. Mutations that are advantageous in early life and thus enhance reproductive fitness may be deleterious in later life. There may be mutations that are advantageous for survival in particular conditions (for example, famine or pandemic), which may be disadvantageous in more benign circumstances by resulting in a predisposition to obesity or autoimmune disorders. This complexity of balancing selection through evolution is likely to be an important feature of the genetics of common disease.

Constitutional genetic disease

All familial genetic disease is caused by constitutional mutations, which are inherited through the germ line. However, different mutations in the same gene can lead to different consequences, depending on the genetic mechanism underlying that disease. About 1% of the human population carries constitutional mutations that cause disease.

Allelic heterogeneity

Allelic heterogeneity is the term given to the phenomenon whereby several different mutations cause the same phenotype. In familial adenomatous polyposis coli, whole gene deletions, nonsense mutations, frameshift mutations and some missense mutations result in exactly the same phenotype because they all cause loss of function in the *FAP* gene on chromosome 5q. Many other Mendelian disorders show this phenomenon with loss-of-function mutations, including adult polycystic kidney disease (*PKD1*, 16p13; *PKD2*, 4q21). Allelic heterogeneity can also be seen in gain-of-function mutations. In connective tissue disorders, gain-of-function mutations are almost always missense mutations or in-frame deletions or insertions, since the protein has to be made for the disease to manifest. In other diseases, particularly those caused by gain-of-function mutations, allelic heterogeneity is severely restricted. A good example of this is achondroplasia, in which the mutations in *FGFR3* are restricted to a few specific codons which cause constitutive activation of the receptor that is required to cause the disease.

3.6 Examples of recessive diseases caused by common polymorphisms*

Disease	Inheritance	Gene	Genetic variant	Population frequency
Haemochromatosis	AR	<i>HFE</i>	p.Cys282Tyr (p.C282Y; nucleotide c.845G>A) p.His63Asp (p.H63D; nucleotide c.187C>G)	3% 5%
α_1 -antitrypsin deficiency	AR	<i>SERPINA1</i>	p.Glu342Lys (p.E342K, c.1197G>A)	3%
Spinal muscular atrophy	AR	<i>SMN1</i>	Gene deletion by non-allelic homologous recombination	2–3%
Cystic fibrosis	AR	<i>CFTR</i>	p.Phe508del (p.F508del aka Δ F508, c.1521_1523delCTT)	4%

*The genetic variants shown are common in the general population but heterozygotes do not exhibit any evidence of disease. In the homozygous form, however, these variants cause recessive disease due to loss of function of the affected gene.

Locus heterogeneity

Locus heterogeneity is the term given to the phenomenon whereby a similar phenotype results from mutations in several different genes. One of the best examples is retinitis pigmentosa, which can occur as the result of mutations in more than 75 genes, each of which has a different chromosomal location.

De novo mutations

Although the vast majority of constitutional mutations are inherited, each gamete will contain mutations that have occurred as a result of meiosis; these are called de novo mutations. A certain number of de novo mutations in each generation are presumably required for evolution to occur. Such mutations also cause human disease. The best-known examples of de novo mutations cause severe congenital disorders such as thanatophoric dysplasia (*FGFR3* gain-of-function mutation), bilateral anophthalmia (*SOX2* haplo-insufficiency), campomelic dysplasia (*SOX9* loss of function) (see Fig. 3.2, p. 41) and the severe form of osteogenesis imperfecta (dominant negative mutations in *COL1A1* or *COL1A2*).

Somatic genetic disease

Somatic mutations are not inherited but instead occur following meiosis during development or adult life. An example of this phenomenon is polyostotic fibrous dysplasia, in which a somatic mutation in the G_s alpha protein causes constitutive activation of GPCR signalling, resulting in focal lesions in the skeleton and endocrine dysfunction (McCune-Albright syndrome, p. 768).

The most important example of human disease caused by somatic mutations is cancer. Here, mutations occur within genes that are involved in regulating cell division or apoptosis, resulting in abnormal cell growth and tumour formation. Two general types of cancer-causing mutation are recognised: gain-of-function mutations in growth-promoting genes (oncogenes) and loss-of-function mutations in growth-suppressing genes (tumour suppressor genes). Whatever the mechanism, most tumours seem to require an initiating mutation in a single cell that can then escape from normal growth controls. This cell replicates more frequently or fails to undergo programmed death and therefore forms a clone. As the clone of mutated cells expands, one or more cells may be subject to additional mutations which confer further growth advantage, leading to proliferation of these subclones, and ultimately to aggressive metastatic cancer. The cell's complex self-regulating machinery means that more than one mutation is usually required to produce a malignant tumour (see Fig. 11.2, p. 259). For example, if a cell mutates to produce a growth factor for which it already expresses the receptor (autocrine stimulation), that cell will replicate more frequently but will still be subject to cell cycle checkpoints to promote DNA integrity in its progeny. If an additional mutation occurs which overrides a cell cycle checkpoint, that cell and its progeny may go on to accumulate further mutations, some of which may allow it to replicate an unlimited number of times, or to separate from its matrix and cellular attachments without undergoing apoptosis. As deregulated growth continues, cancer cells become increasingly unable to differentiate, fail to respond to the normal local signals in their tissue of origin, and cease

to ensure appropriate chromosomal segregation predivision, generating the classical malignant pathological appearances of disorganised growth, variable levels of differentiation, and gain of additional chromosomes (aneuploidy). Somatic mutations occur more frequently in response to external mutagens, such as those contained in cigarette smoke, or if the cell has defects in DNA repair systems. Cancer is thus a disease that affects the fundamental processes of molecular and cell biology.

In many familial cancer syndromes, somatic mutations interact with inherited mutations to cause a familial increase in the risk of specific cancer. A proportion of familial cancer syndromes are due to loss-of-function mutations in DNA repair enzymes. This increases the rate at which they accumulate somatic mutations, which predisposes to cancer. Autosomal recessive disorders that result in complete loss of specific DNA repair enzymes usually cause a severe multifaceted degenerative disorder with cancer susceptibility as a significant component (e.g. xeroderma pigmentosum, p. 63). Autosomal dominant mutations in genes encoding components of specific DNA repair systems are more common and cause some forms of familial colon cancer and breast cancer (e.g. *BRCA1*).

Other cancer syndromes are caused by loss-of-function mutations in tumour suppressor genes. At the cellular level, loss of one functional copy of a tumour suppressor gene does not have any immediate consequences, since the cell is protected by the remaining normal copy. However, there is a high chance of a somatic mutation developing in the normal allele at some point during life, which leads to tumour development due to complete loss of tumour suppressor activity in the affected cell. This is the so-called Knudsen two-hit hypothesis, which clinically explains why tumours may not develop for many years (or ever) in some members of these cancer-prone families. Yet another group of cancer syndromes are the result of gain-of-function mutations in tumour promoter genes (proto-oncogenes) (see Box 3.13, p. 63).

INVESTIGATION OF GENETIC DISEASE

General principles of diagnosis

Many genetic diseases can be diagnosed by a careful clinical history and examination and an awareness and knowledge of rare disease entities. Although DNA-based diagnostic tools are now widely used, it is important to be aware that not all diagnostic genetic tests involve analysis of DNA. For example, an electrocardiogram (ECG) can establish the diagnosis in long QT syndrome or a renal ultrasound can detect adult polycystic kidney disease. By definition, all genetic testing (whether it is DNA-based or not) has implications both for the patient and for other members of the family. These should be considered before genetic testing is undertaken and systems should be in place to deliver medical information and support to family members and to organise any relevant downstream investigations.

Constructing a family tree

The family tree—or pedigree—is fundamental to the diagnosis of genetic diseases. The basic symbols and nomenclature used in drawing a pedigree are shown

in Figure 3.6 (p. 48). A three-generation family history taken in a routine medical clerking may reveal important genetic information of relevance to the presenting complaint, particularly relating to cancer.

A pedigree must include details from both sides of the family, any history of pregnancy loss or infant death, consanguinity, and details of all medical conditions in family members. Other significant information includes dates of birth and age at death.

It is important to be aware that a diagnosis given by a family member, or even obtained from a death certificate, may be wrong. This is often true in cases of cancer where 'stomach' may mean any part of the bowel, and 'brain' may refer to secondary deposits or be used where the primary site has not been identified.

Polymerase chain reaction (PCR) and DNA sequencing

PCR is a very widely used laboratory technique that amplifies targeted sections of the human genome for analysis. It is the most important technique in DNA diagnostic analysis. Almost any tissue can be used to extract DNA for PCR analysis, but most commonly, a sample of peripheral blood is used. The ability to determine the exact sequence of a fragment of DNA amplified by PCR is also of critical importance in DNA diagnostics. The most widely used DNA sequencing technique is illustrated in Figure 3.10. There are many other laboratory approaches for detecting individual mutations and polymorphisms but they almost all involve PCR at some stage.

Assessing DNA copy number

Visible microscopy of standard metaphase chromosome preparations has been the mainstay of clinical cytogenetic analysis for decades and is very useful for detecting the gain or loss of whole chromosomes or large chromosomal segments (> 4 million bp). Many clinically recognisable syndromes are the result of microdeletions. The specific phenotype associated with individual microdeletion syndromes is the result of loss of one copy of several adjacent genes—a contiguous gene syndrome (see Box 3.5, p. 53). Detection of submicroscopic chromosome anomalies requires special techniques for identification (see Box 3.5). Fluorescent in situ hybridisation (FISH, Fig. 3.11A) and multiplex ligation-dependent probe amplification (MLPA) are two of the most widely used techniques to identify such syndromes. However, the availability of whole-genome microarrays has revolutionised chromosome analysis, as it allows the rapid detection of gain or loss of any segment of DNA throughout the genome (see Box 3.5). These microarrays consist of millions of short sequences of DNA (probes) that are complementary to known sequences in the genome (Fig. 3.11B). Each probe is fixed at a known position on the array (often printed on to a specially coated glass slide). The patient's sample is hybridised to the array, and positive and negative results for each probe are read using a laser scanner that detects fluorescent 'labels' inserted in the DNA. This allows a map of the patient's DNA to be constructed from just one test and missing sequences to be identified.

Non-DNA-based methods of assessment

Although DNA-based diagnostic tools are used in the vast majority of patients with suspected genetic disease,

it may sometimes be more economical or convenient to measure enzyme activity rather than sequencing the coding region of the genes involved. An example of this is the investigation of myopathy thought to be due to defects in mitochondrial complex 1 proteins (Box 3.7). Complex 1 is made up of at least 36 nuclear-encoded and 7 mitochondrial DNA-encoded subunits, and mutations in any of these subunits can cause the disorder, which makes sequence analysis impractical as a first-line clinical test. Conversely, the biochemical measurement of respiratory chain complex I proteins can easily be analysed in muscle biopsies, and this can be diagnostic of a specific mitochondrial cytopathy (see Fig. 3.3, p. 43, and Box 3.1, p. 44).

Genetic testing in pregnancy

Genetic testing may be performed during pregnancy. Invasive tests, such as amniocentesis and chorionic villus sampling, are most often performed to diagnose conditions that result in early infant death or severe disability. Such tests are only offered after careful explanation of the risks involved. Many couples will use the result of such tests to decide about termination of pregnancy. Some indications for testing are listed in Box 3.8; the methods used are summarised in Boxes 3.9 and 3.10. Non-invasive ultrasound scanning is usually offered to all pregnant couples and is particularly important if there is a previous history of serious developmental abnormalities. As the range of tests for genetic diseases increases, demand for prenatal testing is likely to rise. A considerable ethical debate is taking place about the types of disease for which prenatal testing is appropriate.

Genetic testing in children

Ethical issues often arise with regard to genetic testing of children. In childhood-onset conditions for which proven treatments are available or screening is appropriate, it is clearly important to test a child: for example, neonatal testing for cystic fibrosis, when early therapy reduces disease progression (p. 678), or testing a child at risk of developing multiple endocrine neoplasia type 2B (MEN2B), when early thyroidectomy prevents medullary thyroid carcinoma (p. 793). However, testing a healthy child for an adult-onset disorder where no benefit from early intervention exists should be avoided. Instead, the child should be left to make his or her own informed decision as an adult.

Identifying a disease gene in families

For diseases which have a significant genetic contribution but are of unknown cause, the process of attributing an inherited disease to a specific gene typically begins with investigation of the affected family or families. DNA polymorphisms identified in normal populations (p. 51) can be used to track or 'map' disease genes by a technique called genome-wide linkage analysis. There are now techniques that allow > 500 000 SNPs to be typed in a single experiment, and comparison of the segregation of patterns of contiguous SNPs (called haplotypes) in affected and unaffected individuals allows identification

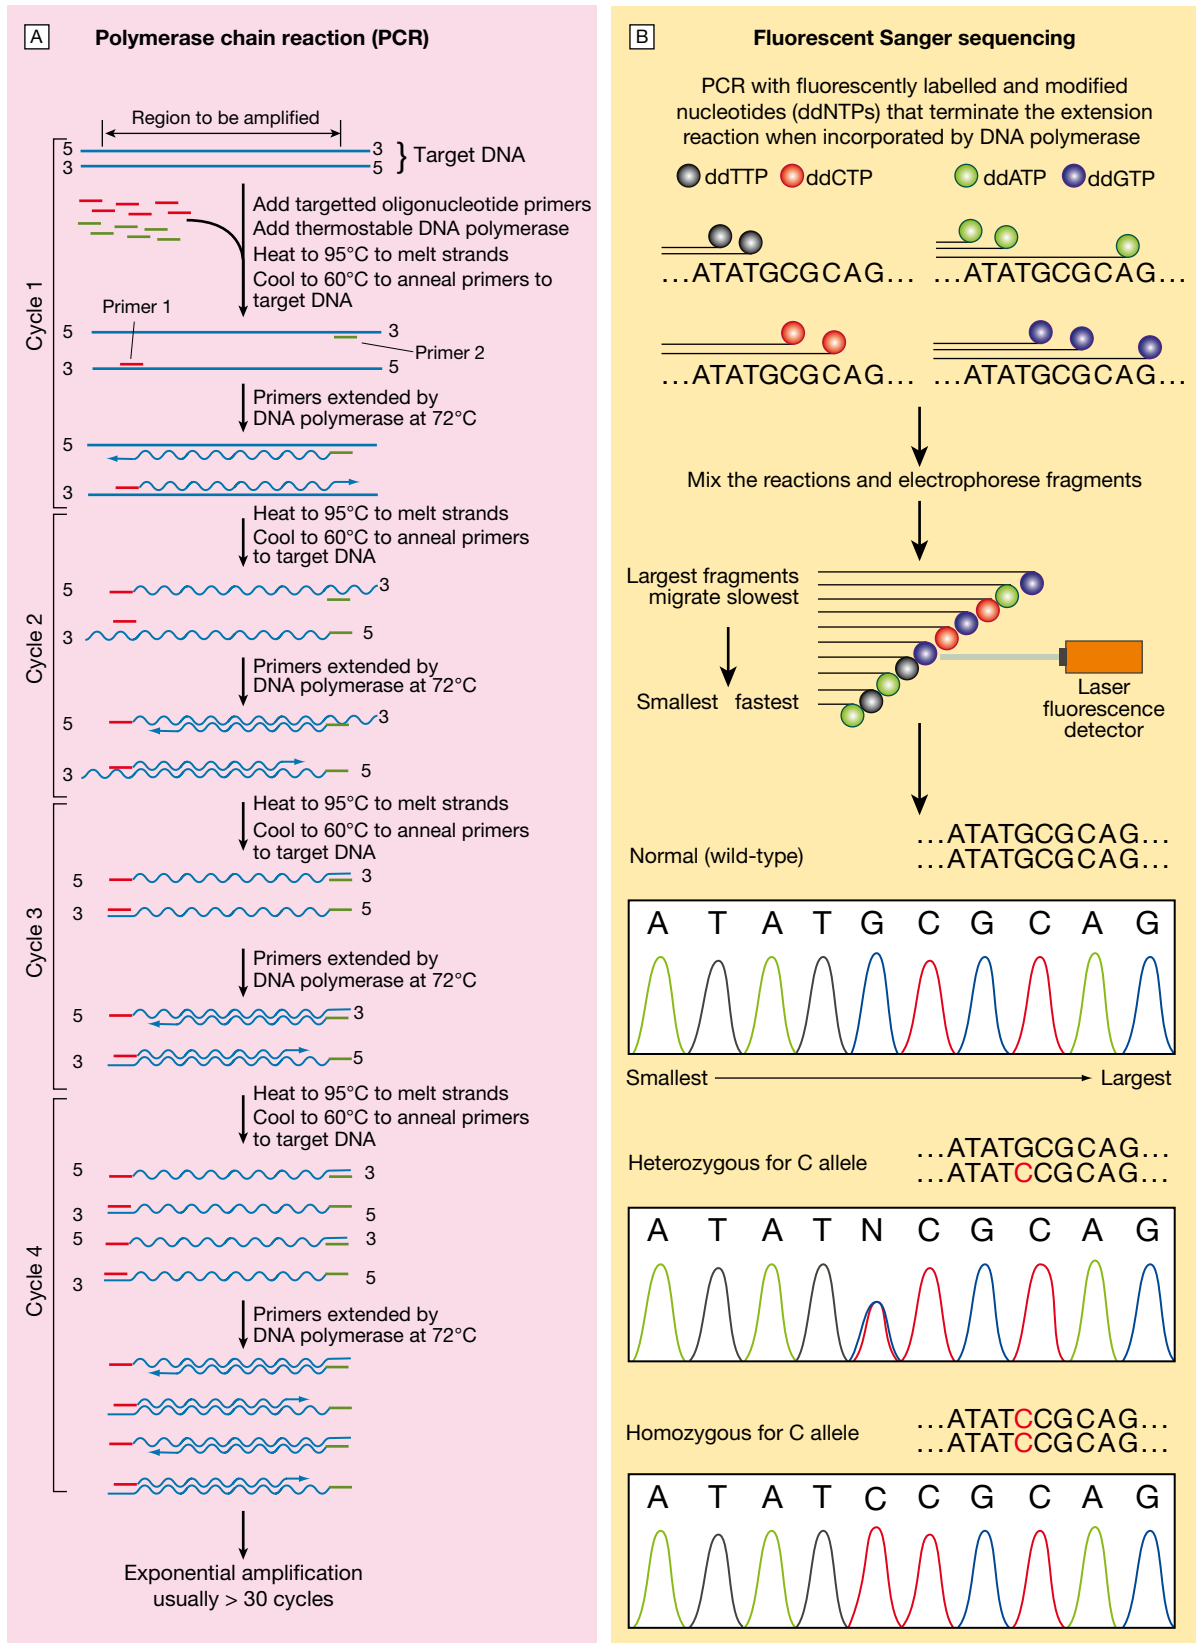

Fig. 3.10 The polymerase chain reaction (PCR) and sequencing. **A** A summary of the steps involved in PCR, which amplifies targeted segments of DNA. **B** Sanger sequencing of DNA, very widely used—together with PCR—in DNA diagnostics.

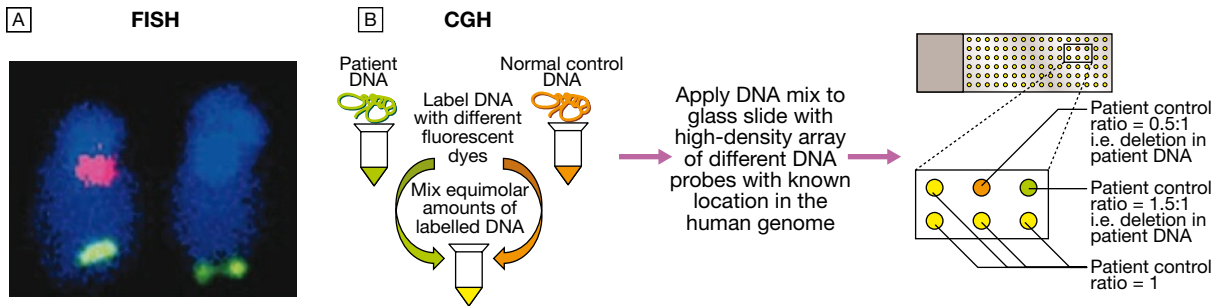

Fig. 3.11 Detection of chromosomal abnormalities by FISH and CGH. **A** An example of FISH analysis showing a pair of homologous metaphase chromosome 22 stained with a blue fluorescent dye. The green spots represent a telomeric probe that has hybridised to both sister chromatids (there are two spots on the right-hand chromosome, whereas on the left the two spots are overlapping). The pink spot shows hybridisation of a probe mapping to band 22q11.2. The left chromosome has a normal signal that is absent on the right. This represents the microdeletion associated with velo-cardio-facial syndrome on the chromosome on the right. **B** Overview of comparative genomic hybridisation (CGH). Deletions and duplications are detected by looking for deviation from the 1:1 ratio of patient and control DNA in a microarray. Ratios in excess of 1 indicate duplications, whereas ratios below 1 indicate deletions.

3.7 Examples of non-DNA-based investigations for common genetic diseases

Disease	Investigation	Page reference
Haemoglobinopathy e.g. sickle-cell disease	Haemoglobin electrophoresis	1027
Coagulation disorders e.g. haemophilia	Clotting factor levels	1046
Immune deficiencies e.g. hypogammaglobulinaemia	Ig levels, complement levels	76
Inborn errors of metabolism e.g. phenylketonuria	Enzyme assays, amino acid levels	447
Endocrine disease e.g. congenital adrenal hyperplasia	Hormone levels, enzyme assays	780
Renal disease e.g. autosomal dominant polycystic kidney disease	Radiology, renal biopsy	506
Myopathy e.g. mitochondrial myopathy	Muscle biopsy, enzyme assay	1234
Skeletal dysplasias e.g. osteogenesis imperfecta	Radiology	1126

3.8 Some indications for prenatal testing

- Advanced maternal age and a high-risk serum screening result
- A previous child with a detectable chromosome abnormality or a parent with a chromosome abnormality such as a balanced translocation
- A parent or child with a genetic disease for which testing is available
- Abnormal antenatal scan

of the 'locus' of DNA where the responsible gene resides. The confidence of association ('linkage') with the disease in question is influenced by the number of subjects studied, the strength of the effect of the gene on the disease, and the closeness of the SNP to the gene in question. The confidence can be expressed as a LoD (logarithm of the odds) score, which is $-\log_{10}$ of the probability (p value) of linkage; by convention a LoD score of > 3 ($p < 0.001$) is taken to be statistically significant. Once a locus has been identified, more detailed mapping within the locus can be undertaken and the relevant mutation confirmed by sequencing the relevant gene.

3.9 Methods used in prenatal testing

Test	Gestation	Comments
Ultrasound	1st trimester onwards	Increased nuchal translucency (an oedematous flap of skin at the base of the neck) for trisomies and Turner's; all major abnormalities such as NTD, congenital heart disease
Chorionic villus biopsy	From 11 weeks	2% risk of miscarriage; used for early chromosomal, DNA and biochemical analysis; a specialised test
Amniocentesis	From 14 weeks	< 1% risk of miscarriage; used for chromosomal and some biochemical analysis, e.g. α -fetoprotein for NTD
Cordocentesis	From 19 weeks	2–3% risk of miscarriage; a highly specialised test; used for chromosomal and DNA analysis

(NTD = neural tube defect)

EBM 3.10 Screening for Down's syndrome

'Antenatal screening in the first and second trimesters identifies fetuses at risk of Down's syndrome. Tests which currently have sensitivity > 60% and specificity > 95% include:

- *First trimester* (11–14 weeks): nuchal translucency; or nuchal translucency, human chorionic gonadotrophin (hCG) and pregnancy-associated plasma protein-A (PAPP-A)
- *Second trimester* (13–20 weeks): triple test (hCG, α -fetoprotein, unconjugated oestriol, uE3)
- Other combinations are available for use from 11–20 weeks.'

For further information:  www.nice.org.uk

Genetic investigation in populations

Genetic screening may be applied to whole populations. The criteria for the use of population screening are well established; they depend on the incidence of specific conditions in individual populations and on whether an intervention is available to ameliorate the effects of the disease. In the UK, examples include screening for phenylketonuria and cystic fibrosis in the newborn, and prenatal screening for neural tube defects and Down's syndrome in pregnant women (see Box 3.10). Screening for carriers of haemoglobinopathies and Tay–Sachs disease is also carried out in some countries where the incidence of these conditions may be high enough to merit screening the entire population (p. 1027).

Predictive genetic testing

In the absence of symptoms or signs of disease in an individual at risk, a genetic test can be used to determine whether that individual carries the disease-causing mutation. This is known as presymptomatic or predictive genetic testing. Predictive tests are usually carried out for adult-onset disorders such as familial cancer syndromes (see Box 3.13) and neurodegenerative disorders such as Huntington's disease (Box 3.11), or when a positive result in children will affect screening and management, such as in familial polyposis coli (pp. 63 and 908). However, many complicated ethical issues arise with testing of children and such tests should only be carried out by clinicians experienced in their use.

Whilst a negative predictive test is clearly a favourable outcome for the individual concerned, a positive test may

**3.11 Predictive testing for Huntington disease**

- Currently, no medical benefit can be derived from knowing presymptomatic genetic status. In this situation, predictive testing is not offered to children but is available to capable adults
- Individuals have several reasonably spaced appointments with a genetic counsellor (or medical geneticist or specialist psychiatrist) prior to testing to ensure the implications of testing are fully understood
- Fully informed patient consent is required prior to testing and individuals must be free to withdraw from testing at any time
- Follow-up support must be available and the result must not be disclosed to any other person without written consent of the tested individual

have significant negative consequences. These should have been explained fully in the counselling process (see below), and include employment discrimination and psychological effects. Providing this is done, current evidence suggests that serious psychological sequelae are uncommon.

PRESENTING PROBLEMS IN GENETIC DISEASE

There are many thousands of known single-gene diseases. Individually, these are rare, but collectively they are relatively common. This diversity makes clinical genetics a fascinating clinical specialty (Box 3.12) but it does mean

**3.12 Common monogenic disorders affecting major organ systems**

System	Disease	Inheritance
Multisystem	Neurofibromatosis	AD
	Tuberous sclerosis	AD
Respiratory	α_1 -antitrypsin deficiency	AR
	Cystic fibrosis	AR
Cardiovascular	Hypertrophic cardiomyopathy	AD
	Long QT syndromes	AD and AR
Renal	Polycystic kidney disease	AD
	Alport's syndrome	XLR
Gastrointestinal	Hereditary pancreatitis	AD
	Familial adenomatous polyposis coli	AD
Hepatic	Gilbert's disease	AD
	Haemochromatosis	AR
	Wilson's disease	AR
Metabolic	Phenylketonuria	AR
	Familial hypercholesterolaemia	AD
	Hypophosphataemic rickets	XLD, AD
Endocrine	Congenital adrenal hyperplasia	AR
	Multiple endocrine neoplasia	AD
	Kallmann's syndrome	XLR or AD
Haematological	Sickle-cell disease	AR
	Alpha- and beta-thalassaemia	AR
	Haemophilia A and B	XLR
Neuromuscular	Duchenne muscular dystrophy	XLR
	Myotonic dystrophy	AD
	Spinal muscular atrophy	AR
CNS	Huntington's disease	AD
	Familial Alzheimer's disease	AD
	Friedreich's ataxia	AR
Musculoskeletal	Ehlers–Danlos syndrome	AD
	Marfan's syndrome	AD
	Osteogenesis imperfecta	AD and AR
Skin	Albinism	AR
	Neurofibromatosis	AD
	Xeroderma pigmentosum	AR
Eye	Retinitis pigmentosa	AR, AD, XLR
	Ocular albinism	XLR

(AD = autosomal dominant; AR = autosomal recessive; XLD = X-linked dominant; XLR = X-linked recessive)

that it is difficult, if not impossible, for any individual clinician to memorise the features associated with all these disorders. It is therefore important to have an awareness of the existence of genetic diseases and some general rules or 'triggers' in mind. Although single-gene disorders can present at any age (see Box 13.15) and affect any tissue or organ system, they share some general characteristics:

- positive family history
- early age of onset
- multisystem involvement
- no obvious non-genetic explanation.

It is important to recognise any unusual clinical presentation and to consider genetic disease in the context of the clinical findings and the family history. Publicly accessible online catalogues of Mendelian diseases can be useful sources of potential diagnoses.

MAJOR CATEGORIES OF GENETIC DISEASE

It would clearly be impossible to discuss all genetic diseases in this chapter. However, the major categories of genetic disease that are commonly encountered by clinical geneticists in adult practice are discussed below.

Inborn errors of metabolism

Inborn errors of metabolism (IEM) are caused by mutations that disrupt the normal function of a biochemical pathway. Most IEM are due to autosomal or X-linked recessive loss-of-function mutations in genes encoding specific enzymes or enzymatic co-factors. Knowledge of the biochemical pathway involved means that specific blocks have predictable consequences, including deficiency of the end product and build-up of intermediary compounds. Many hundreds of different IEM have been identified and these disorders have contributed a great deal to our understanding of human biochemistry. Most IEM are very rare and some are restricted to paediatric practice; however, a growing number may now present during adult life and some of these are discussed below.

Intoxicating IEM

A subgroup of IEM, termed 'intoxicating IEM', can present as a sudden deterioration in a previously well individual. Such deteriorations are usually precipitated by some form of stress, such as infection, pregnancy, exercise or changes in diet. The intoxication is due to the build-up of intermediary, water-soluble compounds, which will vary according to the pathway involved. For example, in urea cycle disorders ammonia is the toxic substance, but in maple syrup urine disease it is branch-chain amino acids. The intoxication is often associated with derangement of the acid-base balance and, if not recognised and treated, will often proceed to multi-organ failure, coma and death. The diagnosis of these disorders requires specialist biochemical analysis of blood and/or urine. Treatment relies on removal of the toxic substance using haemodialysis or chemical conjugation, and prevention of further accumulation by restricting intake of the precursors: total protein restriction in urea cycle disorders and branch-chain amino acid intake in maple syrup urine disease.

Mitochondrial disorders

Disorders of energy production are the most common type of IEM presenting in adult life and some of these disorders have been mentioned in the section on mitochondrial function (see Fig. 3.3, p. 43, and Box 3.1, p. 44). The tissues that are most commonly affected in this group of disorders are those with the highest metabolic energy requirements, such as muscle, heart, retina and brain. Therapy in this group of disorders is based on giving antioxidants and co-factors such as vitamin C and ubiquinone that can improve the function of the respiratory chain.

Storage disorders

Storage disorders are most commonly caused by loss-of-function mutations affecting enzymes involved in lysosomal degradation pathways. The clinical consequences depend on the specific enzyme involved. For example, Fabry disease, an X-linked recessive deficiency of α -galactosidase A, results in abdominal pain, episodic diarrhoea, renal failure and angiokeratoma. Niemann-Pick disease type C is caused by autosomal recessive loss-of-function mutations in either the *NPC1* or *NPC2* gene. This results in hepatosplenomegaly, dysphagia, loss of speech, very early dementia, spasticity and dystonia. An increasing number of storage disorders are treatable with enzyme replacement therapy, making awareness and diagnosis more important.

Neurological disorders

Progressive neurological deterioration is one of the most common presentations of adult genetic disease. These diseases are mostly autosomal dominant and can be grouped into specific neurological syndromes and early-onset forms of well-known non-Mendelian clinical entities. In the latter group the best examples would be early-onset familial forms of dementia, Parkinson's disease and motor neuron disease. The triplet repeat disorders cause an interesting group of syndromes and have specific features that are dealt with below.

Huntington disease

Huntington disease (HD) is the paradigm of triplet repeat disorders. This condition can present with a movement disorder, weight loss or psychiatric symptoms (depression, addiction, psychosis, dementia), or with a combination of all three. The disease is the result of a $[CAG]_n$ triplet repeat expansion mutation in the *HD* gene on chromosome 4. Since CAG is a codon for glutamine and this mutation is positioned in the ORF, this results in an expansion of a polyglutamine tract in the protein. The mutation probably leads to gain of function, as deletions of the gene do not cause HD. The function of the protein encoded by the *HD* gene is not fully understood, but expansion of the repeat to above the normal range of 3–35 results in neurological disease. In general, the severity of disease and age at onset are related to the repeat length. In HD, atrophy of the caudate nuclei and the putamen is obvious on magnetic resonance imaging (MRI) of the brain, and in later stages cerebral atrophy is also apparent. There is currently no therapy that will alter the progression of the disease, which will often be the cause of the patient's death. Within families there is a

tendency for disease severity to increase and age at onset to fall due to further expansion of the repeat, a phenomenon known as anticipation. The mutation is more likely to expand through the male germ line than through female meiosis.

Other triplet repeat disorders

Other progressive neurological disorders caused by triplet repeat expansion mutations in different genes include several forms of autosomal dominant spinocerebellar ataxias, dentatorubral-pallidoluysian atrophy (DRPLA), Machado-Joseph disease, Kennedy disease and myotonic dystrophy. One common feature of the neuropathology of the polyglutamine disorder is the presence of intracellular inclusions in affected cells. It is thought that this accumulation may, in itself, be deleterious and is the result of defective protein degradation.

Connective tissue disorders

Mutations in different types of collagen, fibrillin and elastin make up the majority of connective tissue disorders. The clinical features of these disorders vary, depending on the structural function and tissue distribution of the protein which is mutated. For example, autosomal dominant loss-of-function mutations in the gene encoding elastin cause either supravalvular aortic stenosis, cutis laxa or a combination of both conditions. The most commonly involved systems are:

- *skin* (increased or decreased elasticity, poor wound healing)
- *eyes* (myopia, lens dislocation)
- *blood vessels* (vascular fragility)
- *bones* (osteoporosis, skeletal dysplasia)
- *joints* (hypermobility, dislocation, arthropathy).

Learning disability, dysmorphism and malformations

Congenital global cognitive impairment (also called mental handicap or learning disability) affects about 3% of the population. It is commonly divided into broad categories of mild to moderate (IQ 50–70), moderate to severe (IQ 20–50) and severe to profound (IQ < 20). There are important ‘environmental’ causes of global cognitive impairment, including:

- *teratogen exposure* during pregnancy (alcohol, anticonvulsants)
- *congenital infections* (cytomegalovirus, rubella, toxoplasmosis, syphilis)
- *the sequelae of prematurity* (intraventricular haemorrhage)
- *birth injury* (hypoxic ischaemic encephalopathy).

However, genetic disorders contribute very significantly to the aetiology of global cognitive impairment. Given the complexity of brain development, it is not surprising that global cognitive impairment shows extreme locus heterogeneity. The three most important groups of disorder are reviewed below.

Chromosome disorders

Any significant gain or loss of autosomal chromosomal material (known as aneuploidy) usually results in learn-

ing disability and other phenotypic abnormalities (see Fig. 3.9, p. 54). Down’s syndrome is the most frequently found and best known of these disorders, and is caused by an increased dosage of genes on chromosome 21. Most cases of Down’s syndrome are due to a numerical chromosome abnormality with trisomy of chromosome 21, e.g. 47,XX,+21 or 47,XY,+21. The clinical features are:

- globally delayed development
- short stature
- a significant risk of specific malformations (atrioventricular septal defect, duodenal atresia)
- a predisposition to several late-onset disorders, including hypothyroidism, acute leukaemias and Alzheimer’s disease.

Recent surveys have shown that DNA microarray analysis can identify causative structural chromosome abnormalities in 10–25% of cases of significant learning disability. These deletions and duplications are mostly *de novo* and unique. An interest group of recurrent deletions and duplication due to non-allelic homologous recombination events has been mentioned above. These result in specific microdeletion or microduplication syndromes, such as:

- *velocardiofacial syndrome* due to deletion of 22q11.2 (learning disability, malformations of the cardiac outflow tract, cleft palate, distinctive facial appearance and immune disorders)
- *Williams’ syndrome* due to deletion of 7q11.23 (learning disability, supravalvular aortic stenosis and mild cutis laxa as a result of deletion of the *elastin* gene, distinctive facial appearance and over-friendly, chatty personality).

Dysmorphic syndromes

There are several thousand different dysmorphic syndromes; all are rare but they are characterised by the occurrence of cognitive impairment, malformations and a distinctive facial appearance—or ‘gestalt’—associated with various other clinical features. Making the correct diagnosis is important, as it has profound implications on immediate patient management, detection of future complications and assessment of recurrence risks in the family. Clinical examination remains the mainstay of diagnosis and the patient often needs to be evaluated by a clinician who specialises in the diagnosis of these syndromes. The differential diagnosis in dysmorphic syndromes is often very wide and this has resulted in computer-aided diagnosis becoming an established clinical tool. Dysmorphology databases have been established that are curated catalogues of the many thousands of known syndrome entities which can be searched to identify possible explanations of unusual combinations of clinical features. The clinical diagnosis may then be confirmed by specific genetic investigations, as the genetic basis of a wide range of dysmorphic syndromes has been identified.

X-linked mental handicap

X-linked mental handicap (XLMH) accounts for approximately 10% of cases of moderate to severe learning disability. There are over one hundred genes on the X chromosome that can cause learning disability but the most common disorder is fragile X syndrome, characterised by a distinctive facial appearance, attention deficit, joint hypermobility, macro-orchism (increased testicular size) and a non-staining gap on the X chromosome on

chromosome analysis. Fragile X is caused by a triplet repeat expansion mutation but of a different type from the polyglutamine repeat disorders mentioned above. The repeat in fragile X syndrome is not in the coding region and is a $[CGG]_n$ expansion (see Box 3.4, p. 53). Methylation of the expanded repeat results in silencing of a specific gene called *FMR1*, which encodes an RNA-binding protein.

Familial cancer syndromes

Most cancers are not inherited but occur as the result of an accumulation of somatic mutations, as discussed previously in this chapter. However, it has been recognised for many decades that some families are prone to one or more specific types of cancer (Box 3.13). Affected individuals tend to present with tumours at an early age and are more likely to have multiple primary foci of carcinogenesis.

Retinoblastoma

Patients with autosomal dominant familial retinoblastoma have an inherited mutation in one copy of the *RB* gene, which is a tumour suppressor. This strongly predisposes individuals to the formation of retinoblastoma in one or both eyes. It is possible for more than one primary tumour to form in the same eye and for retinoblastoma to occur in the pineal gland. From a clinical perspective, it is important to screen the eyes and pineal gland of such individuals regularly so that tumours can be treated early and sight preserved. This gene is widely expressed and it is not clear why the retina is the main site of oncogenesis in this syndrome. It is clear that the bone is also sensitive, as there is an increased incidence of osteogenic sarcoma in affected individuals.

Familial adenomatous polyposis coli

Familial adenomatous polyposis coli (FAP) is an autosomal dominant condition due to inactivation mutations in the *FAP* tumour suppressor gene on 5q. The gene product is thought to modulate a specific signalling cascade (Wnt signalling) that regulates cell proliferation.

Mutation carriers usually develop many thousands of intestinal polyps in their second and third decades and have a very high risk of malignant change in the colon. Prophylactic colectomy in the third decade is necessary in most cases. Regular screening for polyps in the upper gastrointestinal tract is also recommended.

Li-Fraumeni syndrome

Heterozygous loss-of-function mutations in the gene encoding p53 cause Li-Fraumeni syndrome. Families with this condition have a very significant increased predisposition to early-onset leukaemias, sarcomas, and breast and brain malignancies. Screening for pre-symptomatic tumours in this condition is very difficult and of unproven benefit, as almost any tissue can be affected.

Hereditary non-polyposis colorectal cancer

Hereditary non-polyposis colorectal cancer (HNPCC) is an autosomal dominant disorder that presents with early-onset familial colon cancer, particularly affecting the proximal colon. Other cancers, such as endometrial cancer, are often observed in affected families. This disorder shows marked locus heterogeneity, as mutations can occur in several different genes encoding proteins involved in DNA mismatch repair.

Familial breast cancer

Familial breast cancer is an autosomal dominant disorder that is most often due to mutations in genes encoding either *BRCA1* or *BRCA2*. Both these proteins are involved in DNA repair. Individuals who carry a *BRCA1* or *BRCA2* mutation are at high risk of early-onset breast and ovarian tumours, and require regular screening for both these conditions. Many affected women will opt for prophylactic bilateral mastectomy and oophorectomy.

Xeroderma pigmentosum

Xeroderma pigmentosum (XP) is the name given to a group of rare disorders in which there are autosomal recessive defects in DNA repair genes which deal primarily with the effects of non-ionising radiation. The skin is particularly involved, and affected patients develop skin cancers with increased frequency.

3.13 Examples of familial cancer syndromes

Disease	Inheritance	Gene	Tumour(s)	Page reference
Retinoblastoma	AD	<i>RB1</i>	Retinoblastoma, osteosarcoma	–
Familial breast/ovarian cancer	AD	<i>BRCA1</i> and <i>BRCA2</i>	Breast, ovary	Ch. 11
Hereditary non-polyposis colorectal cancer (HNPCC)	AD	<i>hMSH2</i> , <i>hMLH1</i> , <i>hPMS1</i> , <i>hPMS2</i>	Colorectal, endometrial, stomach, breast, urinary tract	910
Von Hippel–Lindau disease	AD	<i>VHL</i>	CNS haemangioblastoma, renal, pancreas, pheochromocytoma	1219
Peutz–Jeghers syndrome	AD	<i>STK11</i>	Gastrointestinal, endometrial, breast, ovary	909
Li–Fraumeni syndrome	AD	<i>p53</i>	Sarcoma, brain, breast, leukaemia, adrenal	–

Werner's syndrome

Werner's syndrome is a form of premature ageing (progeria), caused by mutation of one of a series of DNA repair enzymes; it presents with premature skin ageing, degenerative disorders and cancer.

GENETIC COUNSELLING

Genetic counselling is the process of providing information about the medical and family implications of a specific disease in a clear and non-directive manner. Such counselling aims to help individuals make informed decisions about planning a family, taking part in screening programmes and accepting prophylactic therapies. Genetic counselling may be provided by a medical geneticist, a specialist nurse, or a clinician with particular skills in this area, such as an obstetrician or paediatrician (Box 3.14). Perception of genetic risks clearly depends on perceived hazard. For example, a 5% (or 1:20) risk of genetic disease may be perceived as low if the disease is treatable, but unacceptably high if not.

Specific problems encountered in genetic counselling include:

- accurate assessment of genetic risk
- identification of children at risk of genetic disorders
- the increase in genetic risks associated with consanguinity
- non-paternity as an incidental finding in DNA diagnostic tests.

3.14 Clinical genetics services

Component	Role
Medical geneticist	Diagnosis and management of genetic disease, assessment of genetic risk, managing screening programmes, interpretation of genetic test results. Subspecialties include prenatal genetics, dysmorphology (syndrome identification), cancer genetics
Genetic counsellor	Assessing genetic risk, provision of genetic counselling (providing accurate risk information in a comprehensible format), predictive testing for genetic disease and provision of information and support
DNA diagnostic laboratory	Identifying and reporting disease-causing mutations in validated disease genes. Some laboratories also provide linkage analysis to track diseases in families. Laboratories often work in a consortium, as so many different disease genes have now been identified
Cytogenetics laboratory	Identifying pathogenic numerical and structural chromosome anomalies in prenatal, postnatal and oncology samples
Biochemical genetics laboratory	Metabolite and enzymatic-based diagnosis of IEM. Metabolite-based monitoring of treatment of IEM
Newborn screening laboratory	Provision of population-based newborn screening, e.g. PKU, cystic fibrosis, etc.

(IEM = inborn errors of metabolism; PKU = phenylketonuria)

3.15 Genetic disease and counselling in old age

- **Genetic disease:** may present for the first time in elderly patients, e.g. Huntington's disease.
- **Family investigation:** remains essential in the management of genetic disease presenting in old age and referral to clinical genetics services should be considered.

Genetic tests are increasingly used for the diagnosis and prediction of Mendelian disease in a medical context, and such skills will become increasingly important for many clinicians.

Genetic risk is often calculated using Bayes' theorem, which takes prior risk into account to calculate future risk. A simple Bayesian calculation is illustrated here. Consider a woman who is at risk of being a carrier of an X-linked recessive disease. Her grandfather and brother are affected, which makes her mother an obligate gene carrier. Her risk of being a carrier is therefore 50%. However, she has two unaffected sons. This information can be used to modify her risk. The prior probability that she is a carrier is $1/2$ and that she is not a carrier also $1/2$. The conditional probability that she would have two normal sons if she were a carrier is $1/2 \times 1/2 = 1/4$. If she were not a carrier, the probability of having normal sons is 1. From this, the joint probability for each outcome can be calculated (the prior risk \times the conditional risk). This is $1/2 \times 1/4 = 1/8$ for being a carrier and $1/2 \times 1 = 1/2$ for not being a carrier. The final risk, or relative probability, for each outcome can then be obtained by dividing the joint probability for that outcome by the sum of the joint probabilities. Therefore, in this instance, probability that she is a carrier is $1/8 / (1/8 + 1/2) = 1/5$ (20%).

GENETICS OF COMMON DISEASES

Many common disorders, such as diabetes, atherosclerosis, hypertension, cancer, osteoarthritis, inflammatory bowel disease and osteoporosis, have an important genetic component but are not caused by a single mutation. Techniques are now available both to measure the contribution and to identify genes with significant effects. This means that the result of genetic testing is beginning to have an impact on diagnosis, prognosis and therapy for common diseases, and this trend is likely to expand significantly in the years to come. Some of the most useful approaches to clinical interpretation of the genetic aspects of common disorders are outlined below.

Measuring the genetic contribution to complex disease

Genetic contributions to complex disease can be detected and quantified by twin studies and/or by analysing familial clustering. Twin studies use the difference in disease concordance between monozygotic (MZ) and dizygotic (DZ) twins to calculate genetic contribution. MZ twins are genetically identical, whereas DZ twins, like all siblings, are identical for only about 50% of their genetic variation. However, both MZ and DZ twins

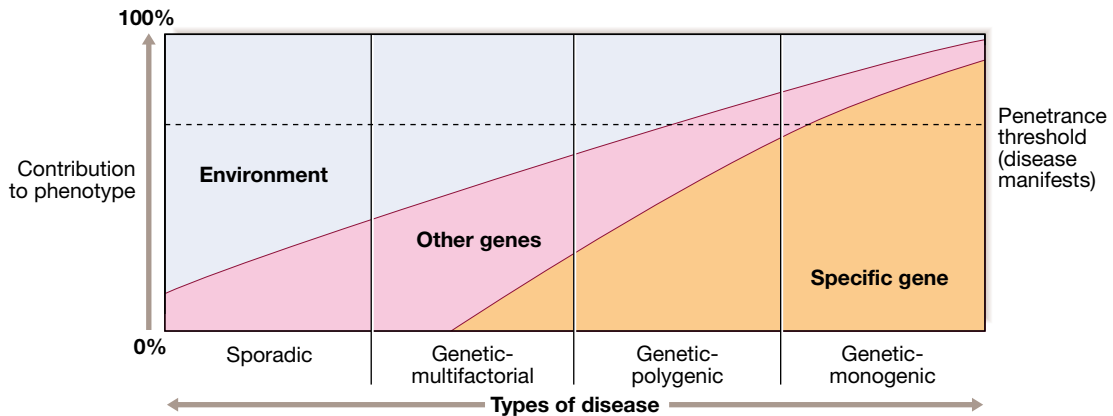

Fig. 3.12 The spectrum of genetic disease: how the genotype influences the phenotype. A particular characteristic or disease in an individual may be due to a specific genetic abnormality (monogenic disease), or may reflect several predisposing genes (polygenic disease). In each case, environmental factors may further influence the phenotype; in their absence, genetic factors alone may be insufficient to allow the disease to develop, resulting in non-penetrance (see text).

share a similar intrauterine environment and similar postnatal environment. Thus, any evidence of a higher concordance of the disease in MZ compared to DZ twins is assumed to be evidence of genetic contribution. Many common diseases and quantitative traits, such as height, weight, blood pressure and bone mineral density, show higher concordance rates in MZ twins compared to DZ twins. Genetic contributions to common diseases can also be assessed by studying the incidence of the disease in first-degree relatives of affected individuals as compared with the general population (Fig. 3.12). The difference in incidence is used to calculate a disease risk, which is measured by the λ_s value (Box 3.16).

Genetic testing in complex disease

Most common diseases are determined by interactions between a number of genes and the environment. In this situation, the genetic contribution to disease is termed polygenic. Until recently, very little progress had been made in identifying the genetic variants that predispose to common diseases, but this has been changed by the advent of genome-wide association studies (GWAS). A GWAS typically involves genotyping between 300 000 and 500 000 genetic markers spread across the genome in a large group of individuals with the disease and controls. By comparing the genotypes in cases and controls, it is possible to identify regions of the genome and candidate genes which contribute to the disease under study. Some of the candidate genes for common diseases identified by this approach are listed in Box 3.17.

Pharmacogenomics

Pharmacogenomics is the science of dissecting the genetic determinants of drug kinetics and effects using information from the human genome. For more than 50 years, it has been appreciated that polymorphic mutations within genes can affect individual responses to some drugs, such as loss-of-function mutations in

3.16 Risk to siblings of affected patients for common polygenic diseases

Disease	λ_s
Type 1 diabetes mellitus	15
Systemic lupus erythematosus	10–20
Multiple sclerosis	20–40
Schizophrenia	10
Ischaemic heart disease	4–12

3.17 Examples of disease-associated polymorphisms

Disease	Inheritance	Gene	Mutation	Population frequency
Breast cancer	Complex	<i>FGFR2</i> (intron 2)	rs1219648	39%
Colorectal cancer	Complex	11q23	rs3802842	24%
Gout	Complex	<i>SLC2A9</i> (intron 3)	rs1014290	23%
Inflammatory bowel disease	Complex	<i>IL23R</i>	rs11465804	93%

CYP2D6 causing hypersensitivity to debrisoquine, an adrenergic-blocking medication formerly used for the treatment of hypertension in 3% of the population. This gene is part of a large family of highly polymorphic genes encoding cytochrome P450 proteins, mostly expressed in the liver, which determine the metabolism of a host of specific drugs. Polymorphisms in the *CYP2D6* gene also determine codeine activation, while those in the *CYP2C9* gene affect warfarin inactivation. Polymorphisms in these and other drug metabolic genes determine the persistence of drugs and, therefore, should provide information about dosages and toxicity. At the present time, genetic testing for assessment of drug response is seldom used routinely, but in the future

Fig. 3.13 Experimental gene and cell therapies. The general approaches to novel gene and stem cell therapies, with their potential or real problems and current limitations. (ES cells = embryonal stem cells)

it may be possible to predict the best specific drugs and dosages for individual patients based on genetic profiling: so-called 'personalised medicine'.

RESEARCH FRONTIERS IN MOLECULAR MEDICINE

Gene therapy

Attempts to replace or repair mutated genes (gene therapy) in humans have met with very limited success so far. Most notable has been replacement of the defective gene in the treatment of severe combined immune deficiency syndrome using retroviral vectors (p. 79). Bone marrow that has been genetically engineered *ex vivo* to express the normal gene product can be returned to the patient. There have been two major problems with the clinical trials of virally delivered gene therapy conducted to date:

- First, the random integration of the retroviral DNA (which contains the replacement gene) into the genome has caused leukaemia in some treated children via activation of proto-oncogenes.
- Second, a severe immune response to the viral vector may be induced. It has not yet been possible to use non-viral means to introduce sufficient numbers of copies of replacement genes to produce significant biological effects.

Other potentially exciting genetic therapies do not involve gene replacement. Several recently identified compounds, including PTC124, can 'force' cells to read through a mutation that results in a premature termination codon in an ORF with the aim of producing a near-normal protein product. The advantage of this type of therapeutic approach is that it can be applied to a subset of patients with any genetic disease where the genetic mechanism is loss of function.

Stem cell therapy and regenerative medicine

The identification of adult stem cells and the ability to purify and maintain such cells *in vitro* offer very exciting therapeutic potential (Fig. 3.13). Indeed, adult stem cell therapy has been in wide use for decades in the form of bone marrow transplantation. The recent discovery that adult fibroblasts can be transdifferentiated to form cells with almost all the characteristics of embryonal

stem cells derived from the early blastocyst has negated much of the controversy surrounding this approach to therapy. In mammalian model species, such cells can be taken and used to regenerate differentiated tissue cells, such as in heart and brain. They have the ability to produce any cell in the body and proliferate rapidly in culture, and so could be used to refashion damaged organs. Such experiments are still in their infancy but are progressing fast.

Pathway medicine

The ability to manipulate pathways that have been altered in genetic disease has tremendous therapeutic potential for Mendelian disease, but a firm understanding of both disease pathogenesis and drug action at a biochemical level is required. An exciting example of this has been the discovery that the vascular pathology associated with Marfan's syndrome is due to the defective fibrillin molecules causing up-regulation of transforming growth factor (TGF)- β signalling in the vessel wall. Losartan is an antihypertensive drug that is marketed as an angiotensin II receptor antagonist. However, it also acts as a partial antagonist of TGF- β signalling and is effective in preventing aortic dilatation in a mouse model of Marfan's syndrome, showing promising effects in early human clinical trials.

The immune system has evolved to protect the host from pathogens while minimising damage to self tissue. Despite the ancient observation that recovery from a disease frequently results in protection against that condition, the existence of the immune system as a functional entity was not recognised until the end of the 19th century. More recently, it has become clear that the immune system not only protects against infection, but also governs the responses that can lead to autoimmune diseases. Dysfunction or deficiency of the immune response leads to a wide variety of diseases, involving every organ system in the body.

The aim of this chapter is to provide a general understanding of immunology and how it contributes to human disease. A review of the key components of the immune response is followed by five sections that illustrate the clinical presentation of the most common forms of immune dysfunction. Clinical immunologists are usually involved in managing patients with allergy and immune deficiency. More detailed discussion of individual conditions can be found in the relevant organ-specific chapters of this book.

FUNCTIONAL ANATOMY AND PHYSIOLOGY OF THE IMMUNE SYSTEM

The immune system consists of an intricately linked network of cells, proteins and lymphoid organs which are strategically placed to ensure maximal protection against infection. Immune defences are normally categorised into the innate immune response, which provides immediate protection against an invading pathogen, and the adaptive or acquired immune response, which takes more time to develop but confers exquisite specificity and long-lasting protection.

The innate immune system

Innate defences against infection include anatomical barriers, phagocytic cells, soluble molecules such as complement and acute phase proteins, and natural killer cells. The innate immune system recognises generic microbial structures present on non-mammalian tissue and can be mobilised within minutes. A specific stimulus will elicit essentially identical responses in different individuals (in contrast with antibody and T-cell responses, which vary greatly between individuals).

Constitutive barriers to infection

The tightly packed, highly keratinised cells of the skin constantly undergo renewal and replacement, which physically limits colonisation by microorganisms. Microbial growth is inhibited by physiological factors such as low pH and low oxygen tension, and sebaceous glands secrete hydrophobic oils that further repel water and microorganisms. Sweat also contains lysozyme, an enzyme that destroys the structural integrity of bacterial cell walls; ammonia, which has antibacterial properties; and several antimicrobial peptides such as defensins. Similarly, the mucous membranes of the respiratory, gastrointestinal and genitourinary tract provide a constitutive barrier to infection. Secreted mucus acts as a physical barrier to trap invading pathogens, and secretory

immunoglobulin A (IgA) prevents bacteria and viruses attaching to and penetrating epithelial cells. As in the skin, lysozyme and antimicrobial peptides within mucosal membranes can directly kill invading pathogens, and additionally lactoferrin acts to starve invading bacteria of iron. Within the respiratory tract, cilia directly trap pathogens and contribute to removal of mucus, assisted by physical manoeuvres such as sneezing and coughing. In the gastrointestinal tract, hydrochloric acid and salivary amylase chemically destroy bacteria, while normal peristalsis and induced vomiting or diarrhoea assist clearance of invading organisms.

Endogenous commensal bacteria provide an additional constitutive defence against infection. Approximately 100 trillion (10^{14}) bacteria normally reside at epithelial surfaces in symbiosis with the human host (p. 134). They compete with pathogenic microorganisms for scarce resources, including space and nutrients. In addition, they produce fatty acids and bactericidins that inhibit the growth of many pathogens. Eradication of the normal flora with broad-spectrum antibiotics commonly results in opportunistic infection by organisms which rapidly colonise an undefended ecological niche.

These constitutive barriers are highly effective, but if external defences are breached by a wound or pathogenic organism, the specific soluble proteins and cells of the innate immune system are activated.

Phagocytes

Phagocytes ('eating cells') are specialised cells which ingest and kill microorganisms, scavenge cellular and infectious debris, and produce inflammatory molecules which regulate other components of the immune system. They include neutrophils, monocytes and macrophages, and are particularly important for defence against bacterial and fungal infections.

Phagocytes express a wide range of surface receptors that allow them to identify microorganisms. These pattern recognition receptors include the Toll-like receptors, NOD (nucleotide-oligomerisation domain protein)-like receptors and mannose receptors. They recognise generic molecular motifs not present on mammalian cells, including bacterial cell wall components, bacterial DNA and viral double-stranded RNA. While phagocytes can recognise microorganisms through pattern recognition receptors alone, engulfment of microorganisms is greatly enhanced by opsonisation. Opsonins include acute phase proteins such as C-reactive protein (CRP), antibodies and complement. They bind both to the pathogen and to phagocyte receptors, acting as a bridge between the two to facilitate phagocytosis (Fig. 4.1).

Neutrophils

Neutrophils, also known as polymorphonuclear leucocytes, are derived from the bone marrow and circulate freely in the blood (Fig. 4.2). They are short-lived cells with a half-life of 6 hours, and are produced at the rate of 10^{11} cells daily. Their functions are to kill microorganisms directly, facilitate the rapid transit of cells through tissues, and non-specifically amplify the immune response. This is mediated by enzymes contained in granules which also provide an intracellular milieu for the killing and degradation of microorganisms.

Two main types of granule are recognised: primary or azurophil granules, and the more numerous secondary or

Fig. 4.1 Opsonisation. Phagocytosis of microbial products may be augmented by several opsonins. **A** C-reactive protein. **B** Antibody. **C** Complement fragments.

Fig. 4.2 Neutrophil function and dysfunction (green boxes).

specific granules. Primary granules contain myeloperoxidase and other enzymes important for killing ingested microbes and digesting their remains. Secondary granules are smaller and contain other enzymes including lysozyme, collagenase and lactoferrin. These can be released into the extracellular space, while the contents of primary granules are released into phagocytic vesicles. Granule staining becomes more intense in response to infection and is termed 'toxic granulation'.

Changes in damaged or infected cells trigger the local production of inflammatory molecules and cytokines. These stimulate the production and maturation of neutrophils in the bone marrow. The neutrophils are recruited to the site by chemotactic agents and by activation of local endothelium. The transit of neutrophils through the blood stream is responsible for the rise in leucocyte count that occurs in early infection. Once within infected tissue, activated neutrophils

seek out and engulf invading microorganisms. These are initially enclosed within membrane-bound vesicles which fuse with cytoplasmic granules to form the phagolysosome. Within this protected compartment, killing of the organism occurs through a combination of oxidative and non-oxidative killing. Oxidative killing, also known as the respiratory burst, is mediated by the NADPH oxidase enzyme complex, which converts oxygen into reactive oxygen species such as hydrogen peroxide and superoxide that are lethal to microorganisms. When combined with myeloperoxidase, hypochlorous ions (HOCl , analogous to bleach) are produced, which are highly effective oxidants and antimicrobial agents. Non-oxidative (oxygen-independent) killing occurs through the release of bactericidal enzymes into the phagolysosome. Each enzyme has a distinct antimicrobial spectrum, providing broad coverage against bacteria and fungi.

The process of phagocytosis depletes neutrophil glycogen reserves and is followed by neutrophil cell death. As the cells die, their contents are released and lysosomal enzymes degrade collagen and other components of the interstitium, causing liquefaction of closely adjacent tissue. The accumulation of dead and dying neutrophils results in the formation of pus which, if extensive, may result in abscess formation.

Monocytes and macrophages

Monocytes are the precursors of tissue macrophages. They are produced in the bone marrow and exported to the circulation, where they constitute about 5% of leucocytes. From the blood stream, they migrate to peripheral tissues where they differentiate into tissue macrophages and reside for long periods. Specialised populations of tissue macrophages include Kupffer cells in the liver, alveolar macrophages in the lung, mesangial cells in the kidney, and microglial cells in the brain. Macrophages, like neutrophils, are capable of phagocytosis and killing of microorganisms but also play an important role in the amplification and regulation of the inflammatory response (Box 4.1). Unlike neutrophils, macrophages do not die after killing pathogens.

Cytokines

Cytokines are small soluble proteins that act as multi-purpose chemical messengers. They are produced by cells involved in innate and adaptive immune responses and by stromal tissue. More than 100 cytokines have been described, with overlapping, complex roles in modifying the immune microenvironment. Subtle differences in cytokine composition, particularly at the initiation of an immune response, may have a major effect on outcome. The most important cytokines are listed in Box 4.2.

<div> <div>i</div> <div>4.2 Important cytokines in regulation of the immune response</div> </div>		
Cytokine	Source	Actions
Interferon-alpha (IFN-α)	T cells and macrophages	Antiviral activity Activates NK cells, CD8 ⁺ T cells and macrophages
Interferon-gamma (IFN-γ)	T cells and NK cells	Increases antimicrobial and antitumour activity of macrophages Determines cytokine production by T cells and macrophages
Tumour necrosis factor alpha (TNF-α)	Macrophages and NK cells	Pro-inflammatory Increases apoptosis and expression of cytokines and adhesion molecules Directly cytotoxic
Interleukin-1 (IL-1)	Macrophages and neutrophils	Acute phase reactant Stimulates neutrophil recruitment, fever, T-cell and macrophage activation, immunoglobulin production
Interleukin-2 (IL-2)	CD4 ⁺ T cells	Stimulates proliferation and differentiation of antigen-specific T lymphocytes
Interleukin-4 (IL-4)	CD4 ⁺ T cells and mast cells	Stimulates maturation of B and T cells, and production of IgE antibody
Interleukin-6 (IL-6)	Monocytes and macrophages	Acute phase reactant Stimulates maturation of B cells into plasma cells
Interleukin-12 (IL-12)	Monocytes and macrophages	Stimulates IFN- γ and TNF- α release by T cells, activates NK cells
(NK = natural killer)		

Complement

The complement system is a group of more than 20 tightly regulated, functionally linked proteins that act to promote inflammation and eliminate invading pathogens. Complement proteins are produced in the liver and are present in the circulation as inactive molecules. When triggered, they enzymatically activate other proteins in a rapidly amplified biological cascade analogous to the coagulation cascade (p. 993).

There are three mechanisms by which the complement cascade may be triggered (Fig. 4.3):

- *The alternative pathway* is triggered directly by binding of C3 to bacterial cell wall components such as lipopolysaccharide of Gram-negative bacteria and teichoic acid of Gram-positive bacteria.
- *The classical pathway* is initiated when two or more IgM or IgG antibody molecules bind to antigen. The associated conformational change exposes binding sites on the antibodies for the first protein in the classical pathway, C1. C1 is a multi-headed molecule which can bind up to six antibody molecules. Once two or more 'heads' of a C1 molecule are bound to antibody, the classical cascade is triggered.

Fig. 4.3 The complement pathway. The activation of C3 is central to complement activation.

- The *lectin pathway* is activated by the direct binding of mannose-binding lectin to microbial cell surface carbohydrates. This mimics the binding of C1 to immune complexes and directly stimulates the classical pathway, bypassing the need for immune complex formation.

Activation of complement by any of these pathways results in activation of C3. This in turn activates the final common pathway, in which the complement proteins C5–C9 assemble together to form the membrane attack complex. This can insert into and puncture target cell walls, leading to osmotic cell lysis. This step is particularly important in the defence against encapsulated bacteria such as *Neisseria* spp. and *Haemophilus influenzae*. Complement fragments generated by activation of the cascade can also act as opsonins, rendering microorganisms more susceptible to phagocytosis by macrophages and neutrophils (see Fig. 4.1). In addition, they are chemotactic agents, promoting leucocyte trafficking to sites of inflammation. Some fragments act as anaphylotoxins, binding to complement receptors on mast cells and triggering release of histamine, which increases vascular permeability. The products of complement activation also help to target immune complexes to antigen-presenting cells, providing a link between the innate and the acquired immune systems. Finally, activated complement products dissolve the immune complexes that triggered the cascade, minimising bystander damage to surrounding tissues.

Mast cells and basophils

Mast cells and basophils are bone marrow-derived cells which play a central role in allergic disorders. Mast cells reside predominantly in tissues exposed to the external environment, such as the skin and gut, while basophils are located in the circulation and are recruited into tissues in response to inflammation. Both contain large cytoplasmic granules which enclose preformed vasoactive substances such as histamine (see Fig. 4.9, p. 87). Mast cells and basophils express IgE receptors

on their cell surface. These bind IgE antibody via the antibody constant region (see Fig. 4.5). On encounter with specific antigen, the cell is triggered to release pre-formed mediators and synthesise additional mediators, including leukotrienes, prostaglandins and cytokines. An inflammatory cascade is initiated which increases local blood flow and vascular permeability, stimulates smooth muscle contraction, and increases secretion at mucosal surfaces.

Natural killer cells

Natural killer (NK) cells are large granular lymphocytes which play a major role in defence against tumours and viruses. They exhibit features of both the adaptive and innate immune systems: they are morphologically similar to lymphocytes and recognise similar ligands, but they are not antigen-specific and cannot generate immunological memory.

NK cells express a variety of cell surface receptors. Some recognise stress signals, while others recognise the absence of human leucocyte antigen (HLA) molecules on cell surfaces (down-regulation of HLA molecules by viruses and tumour cells is an important mechanism by which they evade the T-lymphocyte response). NK cells can also be activated by the binding of antigen-antibody complexes to surface receptors. This physically links the NK cell to its target in a manner analogous to opsonisation and is known as antibody-dependent cellular cytotoxicity (ADCC).

Activated NK cells can kill their targets in various ways. Pore-forming proteins such as perforin induce direct cell lysis, while granzymes are proteolytic enzymes which stimulate apoptosis. In addition, NK cells produce a variety of cytokines such as tumour necrosis factor (TNF)- α and interferon- γ (IFN- γ) which have direct antiviral and antitumour effects.

Dendritic cells

Dendritic cells are present in tissues and sample the environment for foreign particles. They carry microbial

antigens to regional lymph nodes, where they prime adaptive immune responses including B-cell production of antibody and T-cell responses to diverse pathogens.

The adaptive immune system

If the innate immune system fails to provide effective protection against an invading pathogen, the adaptive immune system (Fig. 4.4) is mobilised. This has three key characteristics:

- It has exquisite specificity and is able to discriminate between very small differences in molecular structure.
- It is highly adaptive and can respond to an unlimited number of molecules.
- It possesses immunological memory, being able to recall previous encounter with an antigen and respond more effectively than on the first occasion.

There are two major arms of the adaptive immune response. Humoral immunity involves antibodies that are produced by B lymphocytes; cellular immunity is mediated by T lymphocytes, which synthesise and release cytokines that affect other cells. These interact closely with each other and with the components of the innate immune system, to maximise the effectiveness of the immune response.

Lymphoid organs

- *Primary lymphoid organs.* The primary lymphoid organs are involved in lymphocyte development. They include the bone marrow, where both T and B lymphocytes are derived from haematopoietic stem cells (p. 989) and where B lymphocytes also mature, and the thymus, which is the site of T-cell maturation.
- *Secondary lymphoid organs.* After maturation, lymphocytes migrate to the secondary lymphoid organs. These include the spleen, lymph nodes and mucosa-associated lymphoid tissue. These organs trap and concentrate foreign substances, and are the major sites of interaction between naïve lymphocytes and microorganisms.

The thymus

The thymus is a bilobed structure organised into cortical and medullary areas. The cortex is densely populated with immature T cells, which migrate to the medulla to undergo selection and maturation. The thymus is most active in the fetal and neonatal period, and involutes after puberty. Absence of thymic development is associated with profound T-cell immune deficiency (p. 78), but surgical removal of the thymus in childhood (usually in the context of major cardiac surgery) is not associated with significant immune dysfunction.

The spleen

The spleen is the largest of the secondary lymphoid organs. It is highly effective at filtering blood and is an important site of phagocytosis of senescent erythrocytes, bacteria, immune complexes and other debris. It is also a major site of antibody synthesis. It is particularly important for defence against encapsulated bacteria, and asplenic individuals are at risk of overwhelming *Streptococcus pneumoniae* and *H. influenzae* infection (Box 24.41, p. 1024).

Lymph nodes

Lymph nodes are positioned to maximise exposure to lymph draining from sites of external contact. Their structure is highly organised, as shown in Fig. 4.4B:

- The *cortex* contains primary lymphoid follicles which are the site of B-lymphocyte interactions. When B cells encounter antigen they undergo intense proliferation, forming germinal centres within the cortex.

Fig. 4.4 Anatomy of the adaptive immune system. **A** Macroanatomy. **B** Anatomy of a lymph node.

- The *paracortex* is rich in T lymphocytes and dendritic cells.
- The *medulla* is the major site of antibody-secreting plasma cells.
- Within the medulla there are many *sinuses*, which contain large numbers of macrophages.

Mucosa-associated lymphoid tissue

These tissues have similar structure and function to lymph nodes. They include Peyer's patches in the small intestine, submucosal lymphoid follicles in the appendix, and tonsils in the pharynx.

Lymphatics

The lymphoid tissue is physically connected by lymphatics, which have three major functions: they provide access to lymph nodes, return interstitial fluid to the venous system, and transport fat from the small intestine to the blood stream (see Fig. 16.14, p. 450). The lymphatics begin as blind-ending capillaries, which come together to form lymphatic ducts. These enter and then leave regional lymph nodes as afferent and efferent ducts respectively. They eventually coalesce and drain into the thoracic duct and thence into the left subclavian vein. Lymphatics may be either deep or superficial, and in general follow the distribution of major blood vessels.

Humoral immunity

B lymphocytes

These specialised cells arise from bone marrow stem cells, and their major functions are to produce antibody and interact with T cells. Mature B lymphocytes can be found in the bone marrow, lymphoid tissue, spleen and, to a lesser extent, the blood stream. They express a unique immunoglobulin receptor on their cell surface (the B-cell receptor), which binds to soluble antigen. Encounters with antigen usually occur within the lymph nodes, where, if provided with appropriate signals from nearby T lympho-

Fig. 4.5 The structure of an immunoglobulin (antibody) molecule.

cytes, stimulated antigen-specific B cells respond by rapidly proliferating in a process known as clonal expansion. This is accompanied by a highly complex series of genetic rearrangements which generates B-cell populations that express receptors with greater affinity for antigen than the original. These cells differentiate into either long-lived memory cells, which reside in the lymph nodes, or plasma cells, which produce antibody.

Immunoglobulins

Immunoglobulins (Ig) are soluble proteins made up of two heavy and two light chains (Fig. 4.5). The heavy chain determines the antibody class or isotype, i.e. IgG, IgA, IgM, IgE or IgD. Subclasses of IgG and IgA also occur. The antigen is recognised by the antigen-binding regions (F_{ab}) of both heavy and light chains, while the consequences of antibody-binding are determined by the constant region of the heavy chain (F_c) (Box 4.3).

Antibodies can initiate a number of different actions. They facilitate phagocytosis by acting as opsonins (see Fig. 4.1, p. 71). A similar bridging mechanism facilitates

i

4.3 Classes and properties of antibody

Antibody	Concentration in adult serum	Complement activation*	Opsonisation	Presence in external secretions	Other properties
IgG	8.0–16.0 g/L	IgG1 +++ IgG2 + IgG3 +++	IgG1 ++ IgG3 ++	++	4 subclasses: IgG1, IgG2, IgG3, IgG4 Distributed equally between blood and extracellular fluid, and transported across placenta IgG2 is particularly important in making antibodies against polysaccharides
IgA	1.5–4.0 g/L	–	–	++++	2 subclasses: IgA1, IgA2 Highly effective at neutralising toxins Particularly important at mucosal surfaces
IgM	0.5–2.0 g/L	++++	–	+	Highly effective at agglutinating pathogens
IgE	0.003–0.04 g/L	–	–	–	Majority of IgE is bound to mast cells, basophils and eosinophils Important in allergic disease and defence against parasite infection
IgD	Not detected	–	–	–	Function unknown

*I.e. activation of the classical pathway, also called 'complement fixation'.

cell killing by cytotoxic cells, particularly NK cells (ADCC, p. 73). Binding of antibodies to antigen can trigger activation of the classical complement pathway (see Fig. 4.3). In addition, antibodies may act directly to neutralise the biological activity of their antigen target. This is a particularly important feature of IgA antibodies, which act predominantly at mucosal surfaces.

The humoral immune response is characterised by immunological memory; that is, the antibody response to successive exposures to antigen is qualitatively and quantitatively different from that on first exposure. When a previously unstimulated (naïve) B lymphocyte is activated by antigen, the first antibody to be produced is IgM, which appears in the serum after 5–10 days. Depending on additional stimuli provided by T lymphocytes, other antibody classes (IgG, IgA and IgE) are produced 3–7 days later. If, some time later, a memory B cell is re-exposed to antigen, the lag time between antigen exposure and the production of antibody is decreased (to 2–3 days). In addition, the titre of antibodies produced is greatly increased and the response is dominated by IgG antibodies of high affinity. Furthermore, in contrast to the initial antibody response, secondary antibody responses do not require input from T lymphocytes. This allows the rapid generation of highly specific responses on pathogen re-exposure.

Cellular immunity

T lymphocytes mediate cellular immunity and are important for defence against viruses, fungi and intracellular bacteria. They also play an important immunoregulatory role, orchestrating and regulating the responses of other components of the immune system. T-lymphocyte precursors arise in bone marrow and are exported to the thymus while still immature (see Fig. 4.6). Within the thymus, each cell expresses a T-cell receptor with a unique specificity. These cells undergo a process of stringent selection to ensure that autoreactive T cells are deleted. Mature T lymphocytes leave the thymus and expand to populate other organs of the immune system. It has been estimated that an individual possesses 10^7 – 10^9 T-cell clones, each with a unique T-cell receptor, ensuring at least partial coverage for any antigen encountered.

T cells respond to protein antigens, but they cannot recognise these in their native form. Instead, intact protein must be processed into component peptides which can bind to a structural framework on the cell surface known as HLA (human leucocyte antigen). This process is known as antigen processing and presentation, and it is the peptide/HLA complex which is recognised by individual T cells. While all nucleated cells have the capacity to process and present antigens, specialised antigen-presenting cells include dendritic cells, macrophages and B lymphocytes. HLA molecules exhibit extreme polymorphism; for example, more than 500 different HLA-B alleles have been identified. As each HLA molecule presents a subtly different peptide repertoire to T lymphocytes, this ensures enormous diversity in recognition of antigens within the population.

T lymphocytes can be segregated into two subgroups on the basis of function, recognition of HLA molecules and expression of cell surface proteins. Leucocyte cell surface molecules are named systematically by assigning them a 'cluster of differentiation' (CD) antigen number.

CD8⁺ ('cytotoxic') T lymphocytes

These cells recognise antigenic peptides in association with HLA class I molecules (HLA-A, HLA-B, HLA-C). They kill infected cells directly through the production of pore-forming molecules such as perforin, or by triggering apoptosis of the target cell.

CD4⁺ ('helper') T lymphocytes

These cells recognise peptides presented on HLA class II molecules (HLA-DR, HLA-DP and HLA-DQ) and have mainly immunoregulatory functions. They produce cytokines and provide co-stimulatory signals that support the activation of CD8⁺ T lymphocytes and assist the production of mature antibody by B cells. In addition, their close interaction with phagocytes determines cytokine production by both cell types.

CD4⁺ lymphocytes can be further subdivided into subsets on the basis of the cytokines they produce:

- Typically, Th1 cells produce IL-2, IFN- γ and TNF- α , and support the development of delayed type hypersensitivity responses (p. 86).
- Th2 cells typically secrete IL-4, IL-5 and IL-10, and promote allergic responses (p. 86).
- A further subset of specialised CD4⁺ lymphocytes known as regulatory cells are important in the regulation of other CD4⁺ cells and the prevention of autoimmune disease.

IMMUNE DEFICIENCY

The consequences of deficiencies of the immune system include recurrent infections, autoimmunity and susceptibility to malignancy. Immune deficiency may arise through intrinsic defects in immune function, but is much more commonly due to secondary causes including infection, drug therapy, malignancy and ageing. This chapter gives an overview of the rare primary immune deficiencies. More than a hundred such deficiencies have been described, most of which are genetically determined and usually present in childhood or adolescence. The clinical manifestations are dictated by the component of the immune system involved (Box 4.4). However, there is considerable overlap and redundancy in the immune network, and some diseases do not fall easily into this classification.

Presenting problems in immune deficiency

Recurrent infections

Many patients with an immune deficiency present with recurrent infections. While there is no accepted definition of 'too many' infections, features that may indicate immune deficiency are shown in Box 4.5. Frequent, severe infections or infections caused by unusual organisms or at unusual sites are the most useful indicator.

Baseline investigations include full blood count and white cell differential, acute phase reactants (CRP, see below), renal and liver function tests, urine dipstick and serum immunoglobulins with protein electrophoresis.

4.4 Immune deficiencies and common patterns of infection

	Phagocyte deficiency	Complement deficiency	T-lymphocyte deficiency	Antibody deficiency
Bacteria	<i>Staphylococcus aureus</i> <i>Pseudomonas aeruginosa</i> <i>Serratia marcescens</i> <i>Burkholderia cenocepacia</i> <i>Mycobacterium tuberculosis</i> Atypical mycobacteria	<i>Neisseria meningitidis</i> <i>Neisseria gonorrhoeae</i> <i>Haemophilus influenzae</i> <i>Streptococcus pneumoniae</i>	<i>Mycobacterium tuberculosis</i> Atypical mycobacteria	<i>Haemophilus influenzae</i> <i>Streptococcus pneumoniae</i> <i>Staphylococcus aureus</i>
Fungi	<i>Candida</i> spp. <i>Aspergillus</i> spp.		<i>Candida</i> spp. <i>Aspergillus</i> spp.	
Viruses			Cytomegalovirus (CMV) Enteroviruses Epstein–Barr virus (EBV) Herpes zoster	
Protozoa			<i>Pneumocystis jirovecii</i> <i>Toxoplasma gondii</i> <i>Cryptosporidia</i>	<i>Giardia lamblia</i>

4.5 Warning signs of immune deficiency

- ≥ 8 ear infections within 1 year
- ≥ 2 serious sinus infections within 1 year
- ≥ 2 months on antibiotics with little effect
- ≥ 2 pneumonias within 1 year
- Failure of an infant to gain weight or grow normally
- Recurrent deep skin or organ abscesses
- Persistent thrush in mouth or elsewhere on skin after infancy
- Need for intravenous antibiotics to clear infections
- ≥ 2 deep-seated infections such as sepsis, meningitis or cellulitis
- A family history of primary immune deficiency

Additional microbiological, virological and radiological tests may be appropriate. At this stage it may be clear which category of immune deficiency is being considered, and specific investigation can be undertaken as described below.

If an immune deficiency is suspected but has not yet been formally characterised, patients should not receive live vaccines because of the risk of vaccine-induced disease. Discussion with specialists will help determine whether additional preventative measures, such as prophylactic antibiotics, are indicated.

Primary phagocyte deficiencies

Primary phagocyte deficiencies (see Fig. 4.2, p. 71) usually present with recurrent bacterial and fungal infections which may affect unusual sites. The majority present in childhood but milder forms may present in adults. Affected patients require aggressive management of existing infections, including intravenous antibiotics and surgical drainage of abscesses, and long-term prophylaxis with antifungal agents and trimethoprim-sulfamethoxazole. Specific treatment depends upon the nature of the defect; bone marrow transplantation may be considered (p. 1013).

Leucocyte adhesion deficiencies

These are disorders of phagocyte migration, when failure to express adhesion molecules on vascular endothelium results in the inability of phagocytes to exit the blood stream. They are characterised by recurrent bacterial infections but sites of infection lack pus or neutrophil infiltration. Peripheral blood neutrophil counts may be very high during acute infection because of the failure of mobilised neutrophils to exit blood vessels. Specialised tests show reduced or absent expression of adhesion molecules on neutrophils.

Chronic granulomatous disease

This is caused by mutations in the genes encoding the NADPH oxidase enzymes, which results in failure of oxidative killing. This can be demonstrated with the nitroblue tetrazolium reduction test (NBT). The defect leads to susceptibility to catalase-positive organisms such as *Staphylococcus aureus*, *Burkholderia cenocepacia* and *aspergillus*. Intracellular killing of mycobacteria in macrophages is also impaired. Infections most commonly involve the lungs, lymph nodes, soft tissues, bone, skin and urinary tract, and are characterised histologically by granuloma formation.

Defects in cytokines and cytokine receptors

Defects of cytokines such as IFN- γ , IL-12 or their receptors also result in failure of intracellular killing, and individuals are particularly susceptible to mycobacterial infections. Detailed assessment of cytokine deficiencies is currently only performed in specialised laboratories.

Complement pathway deficiencies

Genetic deficiencies of almost all the complement pathway proteins (see Fig. 4.3, p. 73) have been described. Many can present with recurrent infection with encapsulated bacteria, particularly *Neisseria* species. This reflects

the importance of the membrane attack complex in defence against these bacteria. In addition, genetic deficiencies of the classical complement pathway (C1, C2 and C4) are associated with a high prevalence of autoimmune disease, particularly systemic lupus erythematosus (SLE, p. 1107).

In contrast to other complement deficiencies, mannose-binding lectin deficiency is very common (5% of the population). Individuals with complete mannose-binding lectin deficiency have an increased incidence of bacterial infections if subjected to an additional cause of immune compromise, such as premature birth or chemotherapy. However, the importance of this deficiency in otherwise healthy individuals remains uncertain.

Deficiency of the regulatory protein C1 esterase inhibitor is not associated with recurrent infections but causes recurrent angioedema. This is discussed on page 91.

Investigations and management

Complement C3 and C4 are the only complement components that are routinely measured. Screening for complement deficiencies is performed using more specialised functional tests. The CH50 (classical haemolytic pathway 50, also known as total haemolytic complement (THC)) involves adding the patient's serum to sheep red blood cells (SRBC) which have been coated with anti-SRBC antibody. If the cells lyse, the serum contains all the components of the classical and membrane attack pathways. Absence of lysis indicates a complement deficiency and should be followed by measurement of individual components. However, complement proteins degrade rapidly at room temperature, and the most common cause of an absent CH50 is delay in transportation of the sample to the laboratory. A similar assay is also available for specific measurement of alternative pathway function (AP50).

There is no definitive treatment for complement deficiencies. Patients should be vaccinated with meningococcal, pneumococcal and *H. influenzae* B vaccines in order to boost their adaptive immune responses. Lifelong prophylactic penicillin to prevent meningococcal infection is also recommended. At-risk family members should be screened for complement deficiencies with functional complement assays.

Primary deficiencies of the adaptive immune system

Primary T-lymphocyte deficiencies

These are characterised by recurrent viral, protozoal and fungal infections (see Box 4.4). In addition, many T-cell deficiencies are associated with defective antibody production because of the importance of T cells in providing help for B cells. These disorders generally present in childhood and are illustrated in Figure 4.6.

DiGeorge syndrome

This results from failure of development of the 3rd/4th pharyngeal pouch, usually caused by a deletion of 22q11. It is associated with abnormalities of the aortic arch, hypocalcaemia, tracheo-oesophageal fistulae, cleft lip and palate, and absent thymic development. It is characterised by very low numbers of mature T cells despite normal development in the bone marrow.

Bare lymphocyte syndromes

These are caused by absent expression of HLA molecules within the thymus. If HLA class I molecules are affected, CD8⁺ lymphocytes fail to develop, while absent expression of HLA class II molecules affects CD4⁺ lymphocyte maturation. In addition to recurrent

Fig. 4.6 T-lymphocyte function and dysfunction (green boxes).

infections, failure to express HLA class I is associated with systemic vasculitis caused by uncontrolled activation of natural killer cells.

Autoimmune lymphoproliferative syndrome

This is caused by failure of apoptosis of lymphocytes (p. 47). It is characterised by accumulation of autoreactive cells causing lymphadenopathy, splenomegaly and a variety of autoimmune diseases.

Investigations and management

The principal tests for T-lymphocyte deficiencies are a total lymphocyte count and quantitation of lymphocyte subpopulations by flow cytometry. Serum immunoglobulins should also be quantified. Functional tests of T-cell activation and proliferation may be indicated. Patients in whom T-lymphocyte deficiencies are suspected should be tested for HIV infection (p. 385).

Patients should receive anti-*Pneumocystis* and antifungal prophylaxis, and require aggressive management of specific infections. Immunoglobulin replacement may be indicated if disease is associated with defective antibody production. Stem cell transplantation (p. 1013) may be appropriate in bare lymphocyte syndromes, and thymic transplantation has been used for DiGeorge syndrome.

Combined B- and T-lymphocyte immune deficiencies

Severe combined immune deficiency (SCID) is caused by defects in lymphoid precursors and results in the combined failure of B- and T-cell maturation. The absence of an effective adaptive immune response causes recurrent bacterial, fungal and viral infections soon after birth. Bone marrow transplantation (p. 1013) is the only current treatment option, although specific gene therapy is under investigation.

Primary antibody deficiencies

Primary antibody deficiencies (Fig. 4.7) are characterised by recurrent bacterial infections, particularly of the

respiratory and gastrointestinal tract. The most common causative organisms are bacteria such as *Strep. pneumoniae* and *H. influenzae*. These disorders may present in infancy, when the protective benefit of transferred maternal immunoglobulin has waned. However, three forms of primary antibody deficiency can also present in adulthood:

- *Selective IgA deficiency* is the most common primary immune deficiency, affecting 1:600 northern Europeans. In most patients, low (< 0.05 g/L) or undetectable IgA is an incidental finding with no clinical sequelae. However, 30% of individuals experience recurrent mild respiratory and gastrointestinal infections. In some patients, there is a compensatory increase in serum IgG levels.
- *Common variable immune deficiency (CVID)* is a heterogeneous adult-onset primary immune deficiency of unknown cause. It is characterised by low serum IgG levels and failure to make antibody responses to exogenous pathogens. Paradoxically, antibody-mediated autoimmune diseases such as idiopathic thrombocytopenic purpura and autoimmune haemolytic anaemia are common. CVID is also associated with an increased risk of malignancy, particularly lymphoproliferative disease.
- *Specific antibody deficiency or functional IgG antibody deficiency* is a poorly characterised condition which causes defective antibody responses to polysaccharide antigens. Some patients are deficient in the antibody subclasses IgG2 and IgG4, and this condition was previously called IgG subclass deficiency.

There is overlap between specific antibody deficiency, IgA deficiency and CVID, and some patients may progress to a more global antibody deficiency over time.

Investigations

Serum immunoglobulins (Box 4.6) should be measured in conjunction with protein and urine electrophoresis

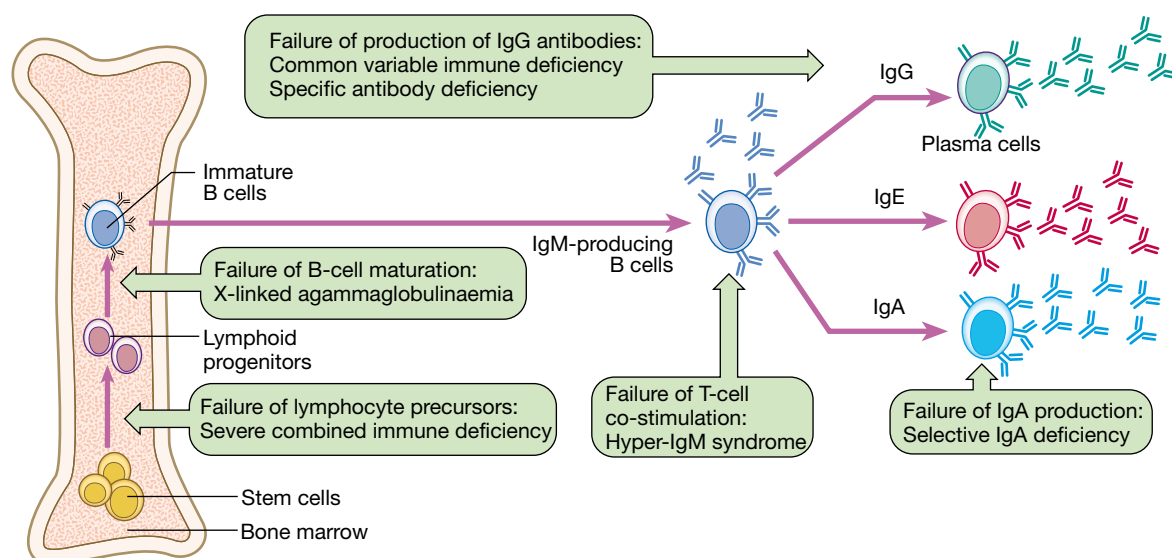

Fig. 4.7 B-lymphocyte function and primary antibody deficiencies (green boxes).

4.6 Investigation of primary antibody deficiencies

	Serum immunoglobulin concentrations				Circulating lymphocyte numbers		Test immunisation
	IgM	IgG	IgA	IgE	B cells	T cells	
Selective IgA deficiency	Normal	Often elevated	Absent	Normal	Normal	Normal	
Common variable immune deficiency	Normal or low	Low	Low or absent	Low or absent	Variable	Variable	No antibody response
Specific antibody deficiency	Normal	Normal	Normal	Normal	Normal	Normal	No antibody response to polysaccharide antigens

to exclude secondary causes of hypogammaglobulinaemia. In addition, specific antibody responses to known pathogens should be assessed by measuring IgG antibodies against tetanus, *H. influenzae* and *Strep. pneumoniae* (most patients will have been exposed to some of these antigens through either infection or immunisation). If specific antibody levels are low, immunisation with the appropriate killed vaccine should be followed by repeat antibody measurement 6–8 weeks later; failure to mount a response indicates a significant defect in antibody production. These functional tests have generally superseded IgG subclass quantitation. Quantitation of B and T lymphocytes by flow cytometry is also useful.

Management

All patients with antibody deficiencies require aggressive treatment of infections and prophylactic antibiotics may be indicated. The mainstay of treatment is immunoglobulin replacement (intravenous immunoglobulin, IVIgG), which is derived from pooled plasma (p. 1007) and contains IgG antibodies to a wide variety of common organisms. IVIgG is usually administered every 3–4 weeks with the aim of maintaining trough IgG levels within the normal adult range. Treatment may be self-administered and is life-long.

With the exception of selective IgA deficiency, immunisation is generally not effective because of the defect in IgG antibody production. As with all primary immune deficiencies, live vaccines should be avoided.

Secondary immune deficiencies

Secondary immune deficiencies are much more common than primary immune deficiencies and occur if the immune system is compromised by external factors (Box 4.7). Common causes include infections, such as HIV and measles, and cytotoxic and immunosuppressive drugs, particularly those used in the management of transplantation, autoimmunity and cancer. Physiological immune deficiency occurs at the extremes of life; the decline of the immune response in the elderly is known as immune senescence (Box 4.8). Management of secondary immune deficiency is described in the relevant chapters on infectious diseases (Ch. 13), HIV (Ch. 14), oncology (Ch. 11) and haematological disorders (Ch. 24).

4.7 Causes of secondary immune deficiency

Physiological

- Ageing
- Prematurity
- Pregnancy

Infection

- HIV
- Measles
- Mycobacterial infection

Iatrogenic

- Immunosuppressive therapy
- Antineoplastic agents
- Corticosteroids
- Stem cell transplantation
- Radiation injury
- Anti-epileptic agents

Malignancy

- B-cell malignancies including leukaemia, lymphoma and myeloma
- Solid tumours
- Thymoma

Biochemical and nutritional disorders

- Malnutrition
- Renal insufficiency/dialysis
- Diabetes mellitus
- Specific mineral deficiencies, e.g. iron, zinc

Other conditions

- Burns
- Asplenia/hyposplenism

4.8 Immune senescence

- **T-cell responses:** decline, with reduced delayed type hypersensitivity responses.
- **Antibody production:** decreased for many exogenous antigens. Although autoantibody production rises, autoimmune disease is less common.
- **Response to vaccination:** reduced, e.g. 30% of healthy older people may not develop protective immunity after influenza vaccination.
- **Allergic disorders and transplant rejection:** less common.
- **Susceptibility to infection:** increased, e.g. community-acquired pneumonia by threefold and urinary tract infection by 20-fold. Latent infections including tuberculosis and herpes zoster, may be reactivated.
- **Manifestations of inflammation:** may be absent, e.g. lack of pyrexia or leucocytosis.

THE INFLAMMATORY RESPONSE

Inflammation is the response of tissues to injury or infection, and is necessary for normal repair and healing. This section focuses on the generic inflammatory response and its multisystem manifestations. The role of inflammation in specific diseases is illustrated in many other chapters of this book.

Physiology and pathology of inflammation

Acute inflammation

Acute inflammation is the result of rapid and complex interplay between the cells and soluble molecules of the innate immune system. The classical external signs include heat, redness, pain and swelling (calor, rubor, dolor and oedema, Fig. 4.8).

The inflammatory process is initiated by local tissue injury or infection. Damaged epithelial cells produce cytokines and antimicrobial peptides, causing early infiltration of phagocytic cells. As a result, there

is production of leukotrienes, prostaglandins, histamine, kinins, anaphylotoxins and inducible nitric oxide synthase within inflamed tissue. The effect is vasodilatation and increased local vascular permeability, which increases flow of fluid and cells to the affected tissue. In addition, pro-inflammatory cytokines produced at the site of injury have profound systemic effects. IL-1, TNF- α and IL-6 act on the hypothalamus to raise the temperature set-point, causing fever, and also stimulate the production of acute phase proteins by the liver.

Acute phase proteins

Acute phase proteins are produced by the liver in response to inflammatory stimuli and have a wide range of activities. C-reactive protein (CRP) and serum amyloid A may be increased 1000-fold, contributing to host defence and stimulating repair and regeneration. Fibrinogen plays an essential role in wound healing, and α_1 -antitrypsin and α_1 -antichymotrypsin control the pro-inflammatory cascade by neutralising the enzymes produced by activated neutrophils, preventing widespread tissue destruction. In addition, antioxidants such as haptoglobin and manganese superoxide dismutase scavenge for oxygen free radicals, while increased levels

4

Fig. 4.8 Clinical features of acute inflammation. In this example, the response is to a penetrating injury and infection of the foot.

of iron-binding proteins such as transferrin, ferritin and lactoferrin decrease the iron available for uptake by bacteria. Immunoglobulins are not acute phase proteins but are often increased in chronic inflammation.

Resolution of inflammation

Resolution of an inflammatory response is crucial for normal healing. This involves active down-modulation of inflammatory stimuli and repair of bystander damage to local tissues. Extravasated neutrophils undergo apoptosis and are phagocytosed by macrophages, along with the remains of microorganisms. Macrophages also synthesise collagenase and elastase, which break down local connective tissue and aid in the removal of debris. Macrophage-derived cytokines, including transforming growth factor (TGF)- β and platelet-derived growth factor, attract fibroblasts and promote the synthesis of new collagen, while angiogenic factors stimulate new vessel formation.

Sepsis and septic shock

Septic shock is the clinical manifestation of overwhelming inflammation (p. 186). Failure of normal inhibitory mechanisms results in excessive production of pro-inflammatory cytokines by macrophages, causing hypotension, hypovolaemia, decreased perfusion and tissue oedema. In addition, uncontrolled neutrophil activation causes release of proteases and oxygen free radicals within blood vessels, damaging the vascular endothelium and further increasing capillary permeability. Direct activation of the coagulation pathway combines with endothelial cell disruption to form clots within the damaged vessels. The clinical consequences include cardiovascular collapse, acute respiratory distress syndrome, disseminated intravascular coagulation, multi-organ failure and often death. Septic shock most frequently results from infection with Gram-negative bacteria, because lipopolysaccharide is particularly effective at activating the inflammatory cascade.

Chronic inflammation

In most instances, the development of an active immune response results in either clearance or control of the inflammatory stimulus with minimal local damage. Failure of elimination may result in chronic inflammation. Persisting microorganisms stimulate the ongoing accumulation of neutrophils, macrophages and activated T lymphocytes. If this is associated with local deposition of fibrous connective tissue, a granuloma may form. Granulomas are characteristic of infections such as tuberculosis and leprosy, in which the microorganism is protected by a robust cell wall which shields it from killing, despite phagocytosis.

Inappropriately vigorous or prolonged immune responses may cause significant bystander tissue damage. These are known as hypersensitivity responses and may involve either antibody- or cell-mediated responses. The Gell and Coombs classification of hypersensitivity responses is discussed on page 86.

Investigations in inflammation

The changes associated with inflammation are reflected in many laboratory investigations. Leucocytosis is

common, and reflects the transit of activated neutrophils and monocytes to the site of infection. The platelet count may also be increased. Chronic inflammation is frequently associated with a normocytic normochromic anaemia of chronic disease (p. 1019). The CRP (see below) is the most widely used clinical measure of acute inflammation, but increased levels of fibrinogen, ferritin and complement components are also associated with the acute phase response, while albumin levels are reduced.

C-reactive protein

C-reactive protein is an acute phase reactant synthesised by the liver, which opsonises invading pathogens. Levels of CRP increase within 6 hours of an inflammatory stimulus and may rise up to 1000-fold. Measurement of CRP provides a direct index of acute inflammation and, because the plasma half-life of CRP is 19 hours, levels fall promptly once the stimulus is removed. Sequential measurement is useful in monitoring disease activity (Box 4.9). For reasons which remain unclear, some diseases are associated with only minor elevations of CRP concentration despite unequivocal evidence of active inflammation. These include SLE, systemic sclerosis, ulcerative colitis and leukaemia. An important practical point is that intercurrent infection does provoke a significant CRP response in these conditions.

Erythrocyte sedimentation rate (ESR)

In contrast to the CRP, the ESR is an indirect measure of the acute phase response. It measures the rate of fall of erythrocytes through plasma, and a major determinant of this is aggregation of red cells. Normally, erythrocytes do not clump together because of their repellent negative charge. Plasma proteins are positively charged and act to neutralise the surface charge of erythrocytes; therefore an increase in plasma proteins, particularly fibrinogen, overcomes the repulsive forces of erythrocytes, causing them to stack together like tyres, or rouleaux. Rouleaux have a higher mass/surface area ratio than single red cells, and therefore sediment faster. Thus the ESR is a composite measure of erythrocyte morphology and of plasma protein composition and concentration.

The most common cause of an increased ESR is an acute phase response, which causes an increase in plasma protein concentration. This is accompanied by a corresponding increase in circulating CRP levels. However, other conditions that do not affect acute phase proteins may alter plasma protein composition and concentration (see Box 4.9). For example, immunoglobulins comprise a significant proportion of plasma proteins, but do not participate in the acute phase response. Thus any condition that causes a monoclonal or polyclonal increase in serum immunoglobulins will increase the ESR without a corresponding increase in CRP. In addition, changes in erythrocyte surface area and density influence sedimentation, and abnormal red cell morphology can make rouleaux formation impossible. For these reasons, an inappropriately low ESR occurs in spherocytosis and sickle cell anaemia.

As CRP is a simpler and more sensitive early indicator of the acute phase response, it is increasingly used in preference to the ESR. If both ESR and CRP are used, any discrepancy should be resolved by assessing the individual determinants of the ESR, i.e. full blood count and film, serum immunoglobulins (IgG, IgA and IgM) and protein

4.9 Conditions commonly associated with abnormal CRP and/or ESR

Condition	Consequence	Effect on CRP ¹	Effect on ESR ²
Acute bacterial, fungal or viral infection	Stimulates acute phase response	Increased (range 50–150 mg/L; in severe infections may be > 300 mg/L)	Increased
Necrotising bacterial infection	Stimulates profound acute inflammatory response	Increased +++ (may be > 300 mg/L)	Increased
Chronic bacterial or fungal infection, e.g. localised abscess, bacterial endocarditis or tuberculosis	Stimulates acute and chronic inflammatory response with polyclonal increase in immunoglobulins as well as increased acute phase proteins	Increased (range 50–150 mg/L)	Increase disproportionate to CRP
Acute inflammatory diseases, e.g. Crohn's disease, polymyalgia rheumatica	Stimulates acute phase response	Increased (range 50–150 mg/L)	Increased
SLE, Sjögren's syndrome	Chronic inflammatory response	Normal (paradoxically)	Increased
Multiple myeloma	Monoclonal increase in serum immunoglobulin without acute inflammation	Normal	Increased
Pregnancy, old age, end-stage renal disease	Increased fibrinogen	Normal	Moderately increased

¹Normal range < 10 mg/L.
²Normal range: adult males < 10 mm/hr, adult females < 20 mm/hr.

electrophoresis. The IgE concentration in plasma is very low and does not contribute significantly to the ESR.

Plasma viscosity

Plasma viscosity is another surrogate measure of plasma protein concentration. Like the ESR, it is affected by the concentration of large plasma proteins, including fibrinogen and immunoglobulins, especially IgM. However, it is not affected by haematocrit variations or by delay in analysis, and is generally considered to be more reliable than the ESR.

Presenting problems in inflammation

In most patients presenting with the manifestations of acute inflammation shown in Figure 4.8, it is possible to identify the source of the problem quickly and to assess the consequences, as discussed in other chapters. Systemic manifestations of inflammation include fever (p. 292), leucocytosis (p. 1000) and shock (p. 186).

Unexplained raised ESR

The ESR should not be used to screen asymptomatic patients for the presence of disease. However, in the era of frequent routine laboratory testing, an unexplained raised ESR is a common problem.

Clinical assessment

A comprehensive history and examination are crucial. Extreme elevations in the ESR (> 100 mm/hr) rarely occur in the absence of significant disease (see Box 4.9).

Investigations

Assessing the CRP, serum immunoglobulins and urine electrophoresis will help determine whether the eleva-

tion in ESR is due to an acute inflammatory process (see Box 4.9).

A full blood count and film may show a normocytic, normochromic anaemia, which occurs in many chronic diseases. Leucocytosis may reflect infection, inflammatory disease or tissue necrosis. Neutrophilia suggests infection or acute inflammation. Atypical lymphocytes may occur in some chronic infections, such as CMV and EBV.

Abnormalities in liver function suggest either a local infective process (hepatitis, hepatic abscess or biliary sepsis) or systemic disease, including malignancy.

Blood and urine cultures should be performed.

Imaging

A chest X-ray and abdominal CT scan may identify a source of unknown infection or malignancy. An abdominal and pelvic ultrasound may identify hepatic lesions, abdominal nodes and local intra-abdominal or pelvic abscesses. An MRI scan is more appropriate for the diagnosis of soft tissue or bone/joint infections. Echocardiography is used to look for vegetations and assess valve function in suspected bacterial endocarditis. White cell scans are rarely indicated but may occasionally be useful in identification of the site of pyogenic infection. An isotope scan may identify evidence of malignancy or focal bone infection.

Periodic fever syndromes

These rare disorders are characterised by recurrent episodes of fever and organ inflammation associated with an elevated acute phase response.

Familial Mediterranean fever (FMF)

This is the most common of the familial periodic fevers, predominantly affecting Mediterranean people, including Arabs, Turks, Sephardic Jews and Armenians. It results from mutations of the *MEFV* gene, which encodes a protein called pyrin. Pyrin regulates neutrophil-mediated inflammation by indirectly suppressing the production of IL-1. FMF is characterised by painful attacks of fever associated with peritonitis, pleuritis and arthritis, and lasts from a few hours to 4 days. During acute episodes, CRP levels are markedly increased. The majority of individuals have their first attack before the age of 20. The major complication of FMF is AA amyloidosis (see below). Colchicine significantly reduces the number of febrile episodes in 90% of patients but is ineffective during acute attacks.

Hyper-IgD syndrome (HIDS)

HIDS is an autosomal recessive disorder that causes recurrent attacks of fever, abdominal pain, diarrhoea, lymphadenopathy, arthralgia, skin lesions and aphthous ulceration. Most patients are from Western Europe, particularly the Netherlands and northern France. The defect is a mutation in the gene for mevalonate kinase, which is involved in the metabolism of cholesterol, but why this causes an inflammatory periodic fever remains unknown. Serum IgD levels are persistently elevated, and CRP levels are increased during acute attacks. No specific treatment is available, although trials of HMG CoA reductase inhibitors are ongoing.

TNF receptor-associated periodic syndrome (TRAPS)

TRAPS, also known as Hibernian fever, is an autosomal dominant syndrome causing recurrent periodic fever, arthralgia, myalgia, serositis and rashes. Attacks may be prolonged (> 1 week). During a typical attack, laboratory findings include neutrophilia, increased CRP and elevated IgA levels. The diagnosis can be confirmed by low serum levels of the soluble type 1 TNF receptor and by analysis of the *TNFRSF1A* gene. As in FMF, the major complication is amyloidosis, and regular screening for proteinuria is advised. TRAPS responds to systemic corticosteroids, and soluble TNF receptor therapy may be effective (p. 1080).

Amyloidosis

The amyloidoses are a group of acquired and hereditary disorders characterised by the extracellular deposition of insoluble proteins. These complex deposits consist of fibrils of the specific protein involved linked to glycosaminoglycans, proteoglycans and serum amyloid P (SAP). Protein accumulation may be localised or systemic, and the clinical manifestations depend upon the organ(s) affected. The diagnosis of amyloidosis should be considered in all cases of unexplained nephrotic syndrome (p. 481), cardiomyopathy (p. 635) and peripheral neuropathy (p. 1225).

Amyloid diseases are classified by aetiology and type of protein deposited (Box 4.10).

4.10 Amyloid disorders			
Disorder	Pathological basis	Predisposing conditions	Other features
Acquired systemic amyloidosis			
Reactive (AA) amyloidosis	Increased production of serum amyloid A as part of prolonged or recurrent acute inflammatory response	Chronic infection (TB, bronchiectasis, chronic abscess, osteomyelitis) Chronic inflammatory diseases (rheumatoid arthritis, FMF)	90% of patients present with non-selective proteinuria or nephrotic syndrome
Light chain amyloidosis (AL)	Increased production of monoclonal light chain	Monoclonal gammopathies, including myeloma, benign gammopathies and plasmacytoma	Restrictive cardiomyopathy, peripheral and autonomic neuropathy, carpal tunnel syndrome, proteinuria, spontaneous purpura, amyloid nodules and plaques. Macroglossia occurs rarely but is pathognomonic. Prognosis is poor
Dialysis-associated (A β 2M) amyloidosis	Accumulation of circulating β_2 -microglobulin due to failure of renal catabolism in kidney failure	Renal dialysis	Carpal tunnel syndrome, chronic arthropathy and pathological fractures secondary to amyloid bone cyst formation. Manifestations occur 5–10 years after the start of dialysis
Senile systemic amyloidosis	Normal transthyretin protein deposited in tissues	Age > 70 yrs	Feature of normal ageing (affects > 90% of 90 year olds). Usually asymptomatic
Hereditary systemic amyloidosis			
> 20 forms of hereditary systemic amyloidosis	Production of protein with an abnormal structure that predisposes to amyloid fibril formation. Most commonly due to mutations in <i>transthyretin</i> gene	Autosomal dominant inheritance	Peripheral and autonomic neuropathy, cardiomyopathy Renal involvement unusual 10% of gene carriers are asymptomatic throughout life

Diagnosis

The diagnosis is established by biopsy, which may be of an affected organ, rectum or subcutaneous fat. The pathognomonic histological feature is apple-green birefringence of amyloid deposits when stained with Congo red dye and viewed under polarised light. Immunohistochemical staining can identify the type of amyloid fibril present. Quantitative scintigraphy with radiolabelled serum amyloid P is a valuable tool in determining the overall load and distribution of amyloid deposits.

Management

The aims of treatment are to support the function of affected organs and, in acquired amyloidosis, to prevent further amyloid deposition through treatment of the primary cause. When the latter is possible, regression of existing amyloid deposits may occur. Liver transplantation may provide definitive treatment in selected patients with hereditary transthyretin amyloidosis.

AUTOIMMUNE DISEASE

Autoimmunity can be defined as the presence of immune responses against self tissue, and is to some extent ubiquitous. It is often a harmless phenomenon, identified only by the presence of low titre autoantibodies or autoreactive T cells. However, autoimmune diseases occur if these responses cause significant organ damage. These are a major cause of chronic morbidity and disability, affecting up to 1 in 30 adults at some time (Box 4.11).

4.11 The spectrum of autoimmune disease

Type	Disease	Page no.
Organ-specific		
Immune response directed against localised antigens	Graves' disease	745
	Hashimoto's thyroiditis	748
	Addison's disease	775
	Pernicious anaemia	1021
	Type 1 diabetes	800
	Sympathetic ophthalmoplegia	1162
	Goodpasture's syndrome	502
	Pemphigus vulgaris	1275
	Bullous pemphigoid	1275
	Idiopathic thrombocytopenic purpura	1045
	Autoimmune haemolytic anaemia	1025
	Myasthenia gravis	1231
	Primary antiphospholipid syndrome	1050
	Rheumatoid arthritis	1088
	Dermatomyositis	1111
	Primary biliary cirrhosis	963
	Autoimmune hepatitis	962
	Sjögren's syndrome	1111
Multisystem		
Immune response directed to widespread target antigens	Systemic sclerosis	1109
	Mixed connective tissue disease	1111
	SLE	1107

Physiology and pathology of autoimmunity

Immunological tolerance

This is the process by which the immune system distinguishes self from foreign tissue, failure of which may result in autoimmune disease.

Central tolerance occurs during lymphocyte development and operates in the thymus and bone marrow. Here, T and B lymphocytes that recognise self antigens are eliminated before they develop into fully immunocompetent cells. This process is most active in fetal life, but continues throughout life as immature lymphocytes are generated.

Some autoreactive cells inevitably evade deletion and escape into the peripheral circulation. These cells are controlled through peripheral tolerance mechanisms. These include the suppression of autoreactive cells by regulatory T cells, and the generation of hyporesponsiveness ('anergy') in lymphocytes which encounter antigen in the absence of the co-stimulatory signals that accompany inflammation. Some tissues such as the eye are not normally patrolled by lymphocytes. Antigens within these 'immunologically privileged' sites are inaccessible to autoreactive cells.

Factors predisposing to autoimmune disease

Both genetic and environmental factors contribute. Autoimmune diseases are much more common in women than in men, for reasons which remain unclear. The most important genetic determinants of autoimmune susceptibility are the HLA genes, reflecting their importance in shaping lymphocyte responses (Box 4.12). Other susceptibility genes include those determining cytokine activity, co-stimulation and cell death.

Several environmental factors can trigger autoimmunity in genetically predisposed individuals. The most widely studied of these is infection, as occurs in acute rheumatic fever following streptococcal infection or reactive arthritis following bacterial infection. A number of mechanisms have been postulated, such as cross-reactivity between the infectious pathogen and self determinants (molecular mimicry), and release of sequestered antigens, which are not usually visible to the immune system, from damaged tissue. Alternatively, infection may result in the production of inflammatory cytokines which overwhelm the normal control mechanisms that prevent bystander damage. Occasionally, the development of autoimmune disease is a side-effect of drug treatment. For example, the metabolic products of

4.12 HLA associations in autoimmune disease

Disease	HLA association	Relative risk
Ankylosing spondylitis	B27	~90:1
Type 1 diabetes	DR3/DR4	~20:1
Rheumatoid arthritis	DR4	~5:1
Graves' disease	DR3	~5:1
Myasthenia gravis	DR3	~3:1

4.13 Gell and Coombs classification of hypersensitivity diseases

Type	Mechanism	Example of disease in response to exogenous agent	Example of autoimmune disease
Type I Immediate hypersensitivity	IgE-mediated mast cell degranulation	Allergic disease	None described
Type II Antibody-mediated	Binding of cytotoxic IgG or IgM antibodies to antigens on cell surface causes cell killing	ABO blood transfusion reaction Hyperacute transplant rejection	Autoimmune haemolytic anaemia Idiopathic thrombocytopenic purpura Goodpasture's disease
Type III Immune complex-mediated	IgG or IgM antibodies bind soluble antigen to form immune complexes which trigger classical complement pathway activation	Serum sickness Farmer's lung	SLE
Type IV Delayed type	Activated T cells, phagocytes and NK cells	Acute cellular transplant rejection Nickel hypersensitivity	Type 1 diabetes Hashimoto's thyroiditis

the anaesthetic agent halothane bind to liver enzymes, resulting in a structurally novel protein. This is recognised as a new (foreign) antigen by the immune system, and the autoantibodies and activated T cells directed against it may cause hepatic necrosis.

Classification of autoimmune diseases

The spectrum of autoimmune diseases is broad. These diseases be classified as organ-specific or multisystem (see Box 4.11), or by the predominant mechanism responsible for tissue damage. The Gell and Coombs classification of hypersensitivity is the most widely used, and distinguishes four types of immune response which result in bystander tissue damage (Box 4.13).

- *Type I hypersensitivity* is relevant in allergy but is not associated with autoimmune disease.
- In *type II hypersensitivity*, injury is localised to a single tissue or organ.
- *Type III hypersensitivity* is a generalised reaction resulting from immune complex deposition in blood vessel walls, skin, joints and glomeruli, where they cause a chronic inflammatory response. This triggers the classical complement cascade as well as recruitment and activation of phagocytes and CD4⁺ lymphocytes. The site of immune complex deposition is determined by the relative amount of antibody, size of the immune complexes, nature of the antigen and local haemodynamics. Generalised deposition of immune complexes gives rise to systemic diseases such as SLE.
- In *type IV hypersensitivity*, activated T cells and macrophages mediate phagocytosis and NK cell recruitment. Autoantibodies may occur but these are not primarily responsible for the tissue damage.

Investigations in autoimmunity

Autoantibodies

An increasing number of autoantibodies can be identified in the laboratory and are useful in disease diagnosis and monitoring, as discussed elsewhere in this book (e.g. p. 1063). Antibody is quantified either by titre (the

minimal dilution at which the antibody can be detected) or by concentration in standardised units.

Cryoglobulins

Cryoglobulins are antibodies directed against other immunoglobulins that form immune complexes which precipitate in the cold. They are classified into three types on the basis of the properties of the immunoglobulin involved (Box 4.14). Testing for cryoglobulins requires the transport of a serum specimen to the laboratory at 37°C. Cryoglobulins should not be confused with cold agglutinins; the latter are autoantibodies specifically directed against the I/i antigen on the surface of red cells, which can cause intravascular haemolysis in the cold (p. 1026).

Measures of complement activation

Quantitation of complement components may be useful in the evaluation of immune complex-mediated diseases. Classical complement pathway activation leads to a decrease in circulating (unactivated) C4, and is often also associated with decreased C3 levels. Serial measurement of C3 and C4 is a useful surrogate measure of immune complex formation.

ALLERGY

Allergic diseases are a common and increasing cause of illness, affecting between 15% and 20% of the population at some time. They comprise a range of disorders from mild to life-threatening, and affect many organs. Atopy is the tendency to produce an exaggerated IgE immune response to otherwise harmless environmental substances, and an allergic disease may be defined as the clinical manifestation of this inappropriate IgE immune response.

Pathology of allergy

Normally, the immune system does not make detectable responses to the many environmental substances to which it is exposed on a daily basis. However, in an allergic reaction, initial exposure to an otherwise harmless

<div> <div>i</div> <div>4.14 Classification of cryoglobulins</div> </div>			
	Type I	Type II	Type III
Immunoglobulin isotype and specificity	Monoclonal IgM paraprotein with no particular specificity	Monoclonal IgM paraprotein directed towards constant region of IgG	Polyclonal IgM or IgG directed towards constant region of IgG
Prevalence	25%	25%	50%
Disease association	Lymphoproliferative disease, especially Waldenström's macroglobulinaemia (p. 1041)	Infection, particularly hepatitis B and hepatitis C; lymphoproliferative disease	Infection, particularly hepatitis B and C; autoimmune disease, including rheumatoid arthritis and SLE

Fig. 4.9 Type I (immediate) hypersensitivity response. **A** After an encounter with allergen, B cells produce IgE antibody against the allergen. **B** Specific IgE antibodies bind to circulating mast cells via high-affinity IgE cell surface receptors. **C** On re-encounter with allergen, the allergen binds to the IgE antibody-coated mast cells. This triggers mast cell activation with release of vasoactive mediators (see Box 4.15).

exogenous substance (known as an allergen) triggers the production of specific IgE antibodies by activated B cells (Fig. 4.9 and Box 4.15). These IgE antibodies bind to the surface of mast cells via high-affinity IgE receptors, a step that is not immediately associated with clinical sequelae. However, upon re-exposure, the allergen binds to membrane-bound IgE which activates the mast cells, releasing a variety of vasoactive mediators (the early phase response) and causing a type I hypersensitivity reaction and the symptoms of allergy. The latter range from sneezing and rhinorrhoea to anaphylaxis (Box 4.16).

Persistent activation of mast cells may result in the recruitment of other cells, and in some patients the early phase response is followed 4–8 hours later by persistent swelling and local inflammation. This is known as the late phase reaction and is mediated by basophils, eosin-

ophils and macrophages. Long-standing or recurrent allergic inflammation may give rise to a chronic inflammatory response characterised by a complex infiltrate of macrophages, eosinophils and T lymphocytes, in addition to mast cells and basophils. Once this has been established, inhibition of mast cell mediators with anti-histamines is clinically ineffective.

Mast cell activation may also be non-specifically triggered through a variety of other signals such as neuro-peptides, anaphylotoxins and bacterial peptides.

Factors influencing susceptibility to allergic diseases

The incidence of allergic diseases is increasing in both industrialised and non-industrialised countries. This trend is largely unexplained but one widely held theory

4.15 Products of mast cell degranulation

Mediator	Biological effects
Preformed and stored within granules	
Histamine	Vasodilatation, chemotaxis, bronchoconstriction and mucus secretion. Increases capillary permeability
Tryptase	Activates complement C3
Eosinophil chemotactic factor	Eosinophil chemotaxis
Neutrophil chemotactic factor	Neutrophil chemotaxis
Synthesised on activation of mast cells	
Leukotrienes	Increase vascular permeability, chemotaxis, mucus secretion and smooth muscle contraction
Prostaglandins	Bronchoconstriction, platelet aggregation and vasodilatation
Thromboxanes	Bronchoconstriction
Platelet-activating factor	Bronchoconstriction, chemotaxis of eosinophils and neutrophils

is the 'hygiene hypothesis'. This proposes that infections in early life bias the immune system against the development of allergies, and that allergy is the penalty for the decreased incidence of infection that has resulted from improvements in sanitation and health care.

A number of other factors contribute to the development of allergic diseases, the strongest of which is a family history. A wide array of genetic determinants of disease susceptibility have been identified, including genes controlling cytokine production, IgE levels and the ability of the epithelial barrier to protect against environmental agents. The expression of a genetic predisposition is governed by environmental factors such as pollutants and cigarette smoke, and the incidence of bacterial and viral infection.

Presenting problems in allergy

A general approach to the allergic patient

Common presentations of allergic disease are shown in Box 4.16. This chapter describes the general principles of the approach to the allergic patient and some of the more severe manifestations of allergy.

Clinical assessment

When assessing possible allergic disease, it is important to identify what the patient means by allergy, as up to 20% of the UK population describe themselves as having a food allergy, although < 1% have an IgE-mediated hypersensitivity reaction confirmed on double blind challenge. The nature of symptoms should be established and specific triggers identified, along with the predictability of a reaction, and the time lag between exposure to a potential allergen and onset of symptoms. An allergic reaction usually occurs within minutes of exposure and provokes predictable symptoms (angioedema, urticaria, wheezing

4.16 Common allergic diseases

• Urticaria	p. 1248
• Angioedema	p. 91
• Atopic dermatitis	p. 1257
• Allergic conjunctivitis	pp. 1094, 1096
• Allergic rhinitis (hayfever)	p. 721
• Allergic asthma	p. 662
• Food allergy	p. 886
• Drug allergy	p. 1286
• Allergy to insect venom	p. 91
• Anaphylaxis	p. 89

and so on). Specific enquiry should be made about other allergic symptoms, past and present, and about family history of allergic disease. Potential allergens in the home and workplace should be identified, and a detailed drug history should always be taken, including compliance, side-effects and the use of complementary therapies.

Investigations

Skin prick tests

Skin prick testing is the 'gold standard' of allergy testing. A droplet of diluted standardised allergen solution is placed on the forearm and the skin is superficially punctured through the droplet with a sterile lancet. After 15 minutes, a positive response is indicated by a local weal and flare response ≥ 2 mm larger than the negative control. A major advantage of skin prick testing is that patients can clearly see the results, which may be useful in gaining compliance with avoidance measures. Disadvantages include the remote risk of a severe allergic reaction, so resuscitation facilities should be available. Results are unreliable in patients with extensive skin disease. Antihistamines inhibit the magnitude of the response and should be discontinued for at least 4 days before testing; corticosteroids do not influence test results.

Specific IgE tests

An alternative to skin prick testing is the quantitation of IgE directed against the putative allergen. The sensitivity and specificity of specific IgE tests (previously known as radioallergosorbent tests, RAST) are lower than skin prick tests. However, IgE tests may be very useful if skin testing is inappropriate: for example, in patients taking antihistamines or those who have severe skin disease or dermatographism. They can also be used to test for cross-reactivity with multiple insect venoms, and post mortem to identify allergens responsible for lethal anaphylaxis.

There is no indication for routine testing of specific IgG antibodies in the investigation of allergic diseases.

Supervised exposure to allergen (challenge test)

Allergen challenges are usually performed in specialist centres, and include bronchial provocation testing, nasal challenge and food challenge. These may be particularly useful in the investigation of occupational asthma or food allergy.

Mast cell tryptase

After a systemic allergic reaction, the circulating level of mast cell mediators increases dramatically. Tryptase is the most stable of these and serum levels peak at 1–2 hours, remaining elevated for 24 hours. Measurement of serum mast cell tryptase is extremely useful in investigating a possible anaphylactic event. Ideally, measurements should be made at the time of the reaction, and 3 hours and 24 hours later.

Non-specific markers of atopic disease: total serum IgE and eosinophilia

Peripheral blood eosinophilia is common in atopic individuals. However, eosinophilia $> 20\%$ or an absolute eosinophil count $> 1.5 \times 10^9/L$ should initiate a search for a non-atopic cause (p. 307).

Atopy is the most common cause of elevated total IgE in developed countries. However, there are many other causes of raised total IgE, including parasite and helminth infections (pp. 364 and 376), lymphoma (p. 1037), drug reactions and Churg–Strauss vasculitis (p. 1114). Moreover, significant allergic disease can occur despite a normal total IgE level. Thus total IgE quantitation is not indicated in the routine investigation of allergic disease.

Management

- *Avoidance of the allergen* should be rigorously attempted, and the advice of specialist dietitians and occupational physicians may be required.
- *Antihistamines* block histamine H_1 tissue receptors, thereby inhibiting the effects of histamine release. Long-acting, non-sedating preparations are particularly useful for prophylaxis against frequent attacks.
- *Corticosteroids* down-regulate pro-inflammatory cytokine production. They are highly effective in allergic disease, and if used topically their adverse effects may be minimised.
- *Sodium cromoglicate* stabilises the mast cell membrane, inhibiting release of vasoactive mediators. It is effective as a prophylactic agent in asthma and allergic rhinitis, but has no role in management of acute attacks. It is poorly absorbed and therefore ineffective in the management of food allergies.
- *Antigen-specific immunotherapy* involves the sequential administration of escalating amounts of dilute allergen over a prolonged period of time. Its mechanism of action is unknown, but it is highly effective in the prevention of insect venom anaphylaxis, and allergic rhinitis secondary to grass pollen (Box 4.17). The traditional route of administration is via subcutaneous injections, which carry a risk of anaphylaxis and should only be performed in specialised centres. More recently, sublingual immunotherapy has been shown to be effective in the management of moderate grass pollen allergy.
- *Omalizumab*, a monoclonal antibody against IgE, inhibits the binding of IgE to mast cells and basophils. It is effective in moderate and severe allergic asthma and rhinitis.
- *Preloaded self-injectable adrenaline (epinephrine)* may be life-saving in the acute management of anaphylaxis.

EBM 4.17 Immunotherapy for allergy

'Immunotherapy is effective for treatment of allergic rhinitis, allergic asthma and stinging insect hypersensitivity. Clinical studies to date do not support the use of allergen immunotherapy for food hypersensitivity, chronic urticaria and/or angioedema.'

- Joint Task Force on Practice Parameters. *Ann Allergy Asthma Immunol* 2003; 90:1–40.

For further information:  www.cochrane.org

Anaphylaxis

Anaphylaxis is a potentially life-threatening, systemic allergic reaction caused by the release of histamine and other vasoactive mediators from mast cells. The risk of death is increased in patients with pre-existing asthma, particularly if this is poorly controlled, and in individuals in whom treatment with adrenaline (epinephrine) is delayed.

Clinical assessment

The clinical features are shown in Figure 4.10. The severity of a reaction should be assessed; the time between allergen exposure and onset of symptoms provides a guide. Enquiry should be made about potential triggers; if these are not immediately obvious, a detailed history of the previous 24 hours may be helpful. The most common allergens are foods, latex, insect venom and drugs (Box 4.18). A history of previous local allergic responses to the offending agent is common. The route of allergen exposure may influence the principal clinical features of a reaction; for example, if an allergen is inhaled,

4.18 Common causes of immediate generalised reactions

Anaphylaxis: IgE-mediated mast cell degranulation

Foods

- Peanuts
- Tree nuts
- Fish and shellfish
- Milk
- Eggs
- Soy products

Insect stings

- Bee venom
- Wasp venom

Chemicals, drugs and other foreign proteins

- Intravenous anaesthetic agents, e.g. suxamethonium, propofol
- Penicillin and other antibiotics
- Latex

Anaphylactoid: non-IgE-mediated mast cell degranulation

Drugs

- Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs)
- Opiates
- Radiocontrast media

Physical

- Exercise
- Cold

Idiopathic

- No cause is identified in 20% of patients with anaphylaxis

Fig. 4.10 Clinical manifestations of anaphylaxis. In this example, the response is to an insect sting containing venom to which the patient is allergic.

the major symptom is frequently wheezing. Features of anaphylaxis may overlap with the direct toxic effects of drugs and venoms (Ch. 9). Potentiating factors such as exercise or alcohol can lower the threshold for an anaphylactic event.

A number of conditions may mimic anaphylaxis (see Fig. 4.10). Anaphylactoid reactions result from the non-specific degranulation of mast cells by drugs, chemicals or other triggers (see Box 4.18), and do not involve IgE antibodies. The clinical presentations are indistinguishable, and in the acute situation discriminating between them is unnecessary. However, this may be important in identifying precipitating factors and appropriate avoidance measures.

Investigations

Measurement of acute and convalescent serum mast cell tryptase concentrations is useful to confirm the diagnosis. Specific IgE tests may be preferable to skin prick tests when investigating patients with a history of anaphylaxis.

Management

Anaphylaxis is an acute medical emergency (Box 4.19).

Individuals who have recovered from an anaphylactic event should be referred for specialist assessment. The aim is to identify the trigger factor, to educate the patient

4.19 Emergency management of anaphylaxis

Prevent further contact with allergen

- e.g. Removal of bee sting

Ensure airway patency

Administer *intramuscular* adrenaline (epinephrine) promptly

- Adult dose: 0.3–1.0 mL 1:1000 solution
- Acts within minutes
- Repeat at 5–10 min intervals if initial response is inadequate

Administer antihistamines

- e.g. Chlorphenamine 10 mg i.m. or slow i.v. injection
- Directly opposes effects of mast cell activation

Administer corticosteroids

- e.g. Hydrocortisone 200 mg i.v.
- Prevents rebound symptoms in severely affected patients

Provide supportive treatments

- e.g. Nebulised β_2 -agonists to decrease bronchoconstriction
- i.v. fluids to restore or maintain blood pressure
- Oxygen

4.20 Prescribing self-injectable adrenaline (epinephrine)

Prescription of an adrenaline auto-injector is usually initiated by a specialist (e.g. immunologist or allergist)

Indications

- Anaphylaxis to allergens which are not easy to avoid, e.g. venom and foods
- Idiopathic anaphylactic reactions
- History of localised reactions with high risk of future anaphylaxis, e.g. reaction to trace allergen or likely repeated exposure to allergen
- History of localised reactions with high risk of adverse outcome, should anaphylaxis occur, e.g. poorly controlled asthma, lack of access to emergency care

Relative contraindications

Risk of arrhythmia or acute coronary syndrome

- Ischaemic heart disease, uncontrolled hypertension
- Tricyclic antidepressants, monoamine oxidase inhibitors, cocaine

Risk of hypertension

Key practice points

Patient and family education

- Know when and how to use the device
- Carry the device at all times
- Seek medical assistance immediately after use
- Wear an alert bracelet or necklace
- Include the school in education for young patients (www.allergyinschools.org.uk)

Prescriptions

- Specify the brand of auto-injector (Epipen® or Anapen®), as they have different triggering mechanisms
- Always prescribe two syringes
- Avoid β -blockers, as they may increase the severity of an anaphylactic reaction and reduce the response to adrenaline

regarding avoidance and management of subsequent episodes, and to identify whether specific treatment such as immunotherapy is indicated. If the trigger factor cannot be identified or cannot be avoided, recurrence is common. Patients who have previously experienced an anaphylactic event should be prescribed self-injectable adrenaline and they and their families or carers should be instructed on its use (Box 4.20). The use of a MedicAlert (or similar) bracelet will increase the likelihood that adrenaline (epinephrine) will be administered in an emergency.

Angioedema

Angioedema is the episodic, localised, non-pitting swelling of submucous or subcutaneous tissues. This most frequently affects the face (Fig. 4.11), extremities and genitalia. Involvement of the larynx or tongue may cause life-threatening respiratory tract obstruction, and oedema of the intestine may cause abdominal pain and distension.

In most cases, the underlying mechanism is degranulation of mast cells. However, angioedema may occasionally be mediated by increased local bradykinin concentration (Box 4.21). Differentiating the mechanism of angioedema is important in determining appropriate investigations and treatment.

A

B

Fig. 4.11 Angioedema. This young man has hereditary angioedema.

A Normal appearance. **B** During an acute attack.

Specific allergies

Insect venom allergy

Local non-IgE-mediated reactions to insect stings are common and may cause extensive swelling around the site lasting as long as 7 days. These usually do not require specific treatment. Toxic reactions to venom after multiple (50–100) simultaneous stings may mimic anaphylaxis. In addition, exposure to large amounts of insect venom frequently stimulates the production of IgE antibodies, and thus may be followed by allergic reactions to single stings. Allergic IgE-mediated reactions vary from mild to life-threatening. Antigen-specific immunotherapy with bee or wasp venom reduces the incidence of recurrent anaphylaxis from 50–60% to 10% after 2 years of treatment (see Box 4.17).

Peanut allergy

Peanut allergy is the most common food-related allergy. More than 50% of patients present before the age of 3 years and some individuals react to their first known exposure to peanuts, possibly because of sensitisation by topical creams. Peanuts are ubiquitous in the Western diet, and every year up to 25% of peanut-allergic individuals will experience a reaction as a result of inadvertent exposure. Peanut allergy only occasionally resolves and life-long avoidance is recommended.

Birch oral allergy syndrome

This syndrome is characterised by birch pollen hayfever, and local angioedema after contact with fresh fruit (especially apples), vegetables and nuts. Cooked fruits and vegetables are tolerated without difficulty. It is due to shared or cross-reactive allergens which are destroyed by cooking or digestion, and can be confirmed by skin prick testing using fresh fruit. Severe allergic reactions are unusual.

C1 inhibitor deficiency

Hereditary angioedema (HAE)

HAE, also known as inherited C1 esterase inhibitor deficiency, is an autosomal dominant disorder caused by

i

4.21 Types of angioedema

	Allergic reaction to specific trigger	Idiopathic angioedema	Hereditary angioedema	ACE-inhibitor associated angioedema
Pathogenesis	IgE-mediated degranulation of mast cells	Non-IgE-mediated degranulation of mast cells	C1 inhibitor deficiency, with resulting increased local bradykinin concentration	Inhibition of breakdown of bradykinin
Key mediator	Histamine	Histamine	Bradykinin	Bradykinin
Prevalence	Common	Common	Rare autosomal dominant disorder	0.1–0.2% of patients treated with ACE inhibitors
Clinical features	Usually associated with urticaria History of other allergies common Follows exposure, e.g. to food, animal dander or insect venom	Usually associated with urticaria May be triggered by physical stimuli such as heat, pressure or exercise Dermatographism common Occasionally associated with underlying infection or thyroid disease	Not associated with urticaria or other features of allergy Does not cause anaphylaxis May cause life-threatening respiratory tract obstruction Can cause severe abdominal pain	Not associated with urticaria Does not cause anaphylaxis Usually affects the head and neck, and may cause life-threatening respiratory tract obstruction Can occur years after the start of treatment
Investigations	Specific IgE tests or skin prick tests	Specific IgE tests and skin prick tests often negative Exclude hypothyroidism	Complement C4 (invariably low in acute attacks) C1 inhibitor levels	No specific investigations
Treatment	Allergen avoidance Antihistamines	Antihistamines are mainstay of treatment and prophylaxis	Unresponsive to antihistamines Attenuated androgens C1 inhibitor concentrate for acute attacks	Discontinue ACE inhibitor Avoid angiotensin II receptor blockers
Associated drug reactions	Specific drug allergies, e.g. penicillin	NSAIDs Opioids Radiocontrast		ACE inhibitors Angiotensin II receptor antagonists

decreased production or activity of C1 inhibitor protein. This complement regulatory protein inhibits spontaneous activation of the classical complement pathway (see Fig. 4.3, p. 73). C1 inhibitor is also a regulatory protein for the kinin cascade, activation of which increases local bradykinin levels and gives rise to local pain and swelling.

In HAE, angioedema may be spontaneous or triggered by local trauma or infection. Multiple parts of the body may be involved, especially the face, extremities, upper airway and gastrointestinal tract. Oedema of the intestinal wall causes severe abdominal pain and many patients with undiagnosed HAE undergo exploratory laparotomy. The most important complication is laryngeal obstruction, often associated with minor dental procedures, which can be fatal. Episodes of angioedema are self-limiting and usually resolve within 48 hours. Patients with HAE generally present in adolescence, but may go undiagnosed for many years. A family history can be identified in 80% of cases. HAE is not associated with allergic diseases and is specifically not associated with urticaria.

Acute episodes are always accompanied by low C4 levels and the diagnosis can be confirmed by C1 inhibitor measurement. Prevention is with modified androgens (e.g. danazol), which increase endogenous production of complement proteins. Severe acute attacks should be treated with infusion of purified C1 inhibitor or fresh frozen plasma.

4.22 Immunological diseases in pregnancy

Allergic disease

- **Maternal dietary restrictions during pregnancy or lactation:** current evidence does not support these for prevention of allergic disease.
- **Breastfeeding for at least 4 months:** prevents or delays the occurrence of atopic dermatitis, cow's milk allergy and wheezing in early childhood, as compared with feeding formula milk containing intact cow's milk protein.

Autoimmune disease

- **Suppressed T cell-mediated immune responses in pregnancy:** may suddenly reactivate post-partum. Autoimmune diseases often improve during pregnancy but flare immediately after delivery. However, an exception is SLE, which is prone to exacerbation in pregnancy.
- **Passive transfer of maternal antibodies:** can mediate autoimmune disease in the fetus and newborn, including SLE, Graves' disease and myasthenia gravis.
- **Antiphospholipid syndrome (p. 1050):** an important cause of fetal loss, intrauterine growth restriction and pre-eclampsia.

Acquired C1 inhibitor deficiency

This rare disorder is clinically indistinguishable from HAE but presents in late adulthood. It is associated with autoimmune and lymphoproliferative diseases. Treatment of the underlying disorder may induce remission of angioedema.

TRANSPLANTATION AND GRAFT REJECTION

Transplantation provides the opportunity for definitive treatment of end-stage organ disease (Box 4.23). The major complications are graft rejection, drug toxicity and infection consequent on immunosuppression. Transplant survival has significantly improved over the last 20 years, as a result of less toxic immunosuppressive agents and increased understanding of the process of transplant rejection.

Bone marrow stem cell transplantation and its complications are discussed on pages 1013–1014.

i 4.23 Number of solid organ transplants in UK per year, 2007–8 ¹		
Organ	Number transplanted	Number waiting ²
Kidney	2282	6790
Liver	660	259
Heart	127	91
Heart and lung	7	18
Lung	116	268
Kidney and pancreas	188	178
¹ From www.uktransplant.org.uk .		
² Patients actively waiting for a transplant on 31 March 2008.		

Transplant rejection

Solid organ transplantation inevitably stimulates an aggressive immune response by the recipient, unless the transplant is between monozygotic twins. The type and severity of the rejection response is determined by the genetic disparity between the donor and recipient, the immune status of the host and the nature of the tissue transplanted (Box 4.24). The most important genetic determinant is the difference between donor and recipient HLA proteins (p. 73). The extensive polymorphism of these proteins means that donor HLA antigens

are almost invariably recognised as foreign by the recipient immune system, unless an active attempt has been made to minimise incompatibility.

- *Acute cellular rejection* is the most common form of graft rejection. It is mediated by activated T lymphocytes and results in deterioration in graft function. If allowed to progress, it may cause fever, pain and tenderness over the graft. It is usually amenable to increased immunosuppressive therapy.
- *Hyperacute rejection* results in rapid and irreversible destruction of the graft. It is mediated by pre-existing recipient antibodies against donor HLA antigens, which arise as a result of previous exposure through transplantation, blood transfusion or pregnancy. It is very rarely seen in clinical practice as the use of screening for anti-HLA antibodies and pre-transplant cross-matching ensures the prior identification of recipients with antibodies against a potential donor.
- *Acute vascular rejection* is mediated by antibody formed de novo after transplantation. It is more curtailed than the hyperacute response because of the use of intercurrent immunosuppression, but it is also associated with reduced graft survival. Aggressive immunosuppressive therapy is indicated, and physical removal of antibody through plasmapheresis may be effective. Not all post-transplant anti-donor antibodies cause graft damage; their consequences are determined by specificity and ability to trigger other immune components such as the complement cascade.
- *Chronic allograft failure*, also known as chronic rejection, is a major cause of graft loss. It is associated with proliferation of transplant vascular smooth muscle, interstitial fibrosis and scarring. The pathogenesis is poorly understood but contributing factors include immunological damage caused by subacute rejection, hypertension, hyperlipidaemia and chronic drug toxicity.

Investigations

Pre-transplantation testing

HLA typing determines an individual's HLA polymorphisms and facilitates donor–recipient matching.

i 4.24 Classification of transplant rejection				
Type	Time	Pathological findings	Mechanism	Treatment
Hyperacute rejection	Minutes to hours	Thrombosis, necrosis	Preformed antibody and complement activation (type II hypersensitivity)	None—irreversible graft loss
Acute vascular rejection	5–30 days	Vasculitis	Antibody and complement activation	Increase immunosuppression
Acute cellular rejection	5–30 days	Cellular infiltration	CD4 ⁺ and CD8 ⁺ T cells (type IV hypersensitivity)	Increase immunosuppression
Chronic allograft failure	> 30 days	Fibrosis, scarring	Immune and non-immune mechanisms	Minimise drug toxicity, control hypertension and hyperlipidaemia

4.25 Immunosuppressive drugs used in transplantation

Drug	Mechanism of action	Major adverse effects
Anti-proliferative agents e.g. azathioprine, mycophenolate mofetil	Inhibit lymphocyte proliferation by blocking DNA synthesis. May be directly cytotoxic at high doses	Increased susceptibility to infection Leucopenia Hepatotoxicity
Calcineurin inhibitors e.g. ciclosporin, tacrolimus	Inhibit T-cell signalling; prevent lymphocyte activation and block cytokine transcription	Increased susceptibility to infection Hypertension Nephrotoxicity Diabetogenic (especially tacrolimus) Gingival hypertrophy, hirsutism (ciclosporin)
Corticosteroids	Decrease phagocytosis and release of proteolytic enzymes; decrease lymphocyte activation and proliferation; decrease cytokine production; decrease antibody production	Increased susceptibility to infection Other complications (p. 774)
Anti-T-cell induction agents e.g. anti-thymocyte globulin (ATG), anti-CD3 monoclonal antibody	Depletion or blockade of T cells by antibodies to cell surface proteins	Profound non-specific immunosuppression Increased susceptibility to infection

Potential transplant recipients are screened for the presence of anti-HLA antibodies using either recombinant HLA proteins or a pool of lymphocytes from individuals with broadly representative HLA types. If antibodies are detected, their specificity is further characterised and the recipient is excluded from receiving a transplant which carries these alleles.

Donor-recipient cross-matching is a functional assay that directly tests whether serum from a recipient (which potentially contains anti-donor antibodies) is able to bind and/or kill donor lymphocytes. It is specific to a prospective donor-recipient pair and is done immediately prior to transplantation. A positive cross-match is a contraindication to transplantation because of the risk of hyperacute rejection.

C4d staining

C4d is a fragment of the complement protein C4 (see Fig. 4.3, p. 73). Deposition of C4d in graft capillaries indicates local activation of the classical complement pathway and provides evidence for antibody-mediated damage. This is useful in the early diagnosis of vascular rejection.

Complications of transplant immunosuppression

The prevention of transplant rejection requires indefinite treatment with immunosuppressive agents. In general, two or more immunosuppressive drugs are used in synergistic combinations in order to minimise drug side-effects (Box 4.25). The major complications of long-term immunosuppression are infection and malignancy.

The risk of some opportunistic infections may be minimised through the use of prophylactic medication (e.g. ganciclovir for CMV prophylaxis and trimethoprim-sulfamethoxazole for *Pneumocystis* prophylaxis). Immunisation with killed vaccines is appropriate, although the immune response may be curtailed. Live vaccines should not be given.

The increased risk of malignancy arises because T-cell suppression results in failure to control viral infections.

Virus-associated tumours include lymphoma (associated with EBV), Kaposi's sarcoma (associated with human herpesvirus 8) and skin tumours (associated with human papillomavirus). Immunosuppression is also associated with a small increase in the incidence of common cancers not associated with viral infection (such as lung, breast and colon cancer), reflecting the importance of T cells in anti-cancer surveillance.

Organ donation

The major problem in transplantation is the shortage of organ donors (see Box 4.23). Cadaveric organ donors are usually previously healthy individuals who experience brain stem death (p. 1158), frequently as a result of road traffic accidents or cerebrovascular events. However, even if organs were obtained from all potential cadaveric donors, their numbers would be insufficient to meet current needs. An alternative is the use of living donors. Altruistic living donation, usually from close relatives, is widely used in renal transplantation. Living organ donation is inevitably associated with some risk to the donor, and it is highly regulated to ensure appropriate appreciation of the risks involved. Because of concerns about coercion and exploitation, non-altruistic organ donation (the sale of organs) is illegal in most countries.

PRINCIPLES AND INVESTIGATION OF ENVIRONMENTAL FACTORS IN DISEASE

Environmental effects on health

Health emerges from a highly complex interaction between factors intrinsic to the patient and his or her environment. Many factors within the environment influence health, including aspects of the physical environment, biological environment (bacteria, viruses), built environment and social environment, but also encompass more distant influences such as the global ecosystem (Fig. 5.1). Environmental changes affect many physiological systems and do not respect boundaries between medical specialties. The specialty of 'public health' in the UK is concerned with the investigation and management of health in communities and populations, but the principles apply in all specialties.

Exposure to infectious agents is a major environmental determinant of health and is described in Chapter 6. This chapter describes the approach to other common environmental factors that influence health.

The hierarchy of systems—from molecules to ecologies

When assessing a patient, a clinician subconsciously considers many levels at which problems may be occurring, including molecular, cellular, tissue, organ and body systems. When the environment's influence on health is being considered, this 'hierarchy of systems' extends beyond the individual to include the family, community, population and ecology. Box 5.1 shows an example of the utility of this concept in describing determinants of coronary heart disease operating at each level of a hierarchy.

Fig. 5.1 Hierarchy of systems that influence population health.

i

5.1 'Hierarchy of systems' applied to ischaemic heart disease

Level in the hierarchy	Example of effect
Molecular	ApoB mutation causing hypercholesterolaemia
Cellular	Foam cells accumulate in vessel wall
Tissue	Atheroma and thrombosis of coronary artery
Organ	Ischaemia and infarction of myocardium
System	Cardiac failure
Person	Limited exercise capacity, impact on employment
Family	Passive smoking, diet
Community	Shops and leisure opportunities
Population	Prevalence of obesity
Society	Policies on smoking, screening for risk factors
Ecology	Agriculture influencing fat content in diet

Interactions between people and their environment

The hierarchy of systems demonstrates that the clinician should not focus too quickly on the disease process without considering the context. Health is an emergent quality of a complex interaction between many determinants, including genetic inheritance, the physical circumstances in which people live (e.g. housing, air quality, working environment), the social environment (e.g. levels of friendship, support and trust), personal behaviour (smoking, diet, exercise), and access to money and the other resources that give people control over their lives. Health care is not the only determinant—and usually not the major determinant—of health status in the population.

These systems do not operate in isolation in separate communities. When one group responds to ill health by manipulating its environment, the consequences may be global. For example, an Afghan farmer who starts growing opium in order to feed his children influences the environment of a teenager in Europe; in turn, drug misuse in Europe has fostered higher prevalence of blood-borne infectious diseases such as human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS); in turn, these have spilled out into sexually transmitted disease. This process contributes to the tragedy of the epidemic of HIV/AIDS.

The life course

The determinants of health operate over the whole lifespan. Values and behaviours acquired during childhood and adolescence have a profound influence on educational outcomes, job prospects and risk of disease. Attributes such as the ability to form empathetic relationships or assess risk have a strong influence on whether a young person takes up damaging behaviour like smoking, risky sexual behaviours and drug misuse. Influences on health can even operate before birth.

Individuals with low birth weight have been shown to have higher prevalence of conditions such as hypertension and type 2 diabetes as young adults and of cardiovascular disease in middle age. It has been suggested that under-nutrition during middle to late gestation permanently 'programmes' cardiovascular and metabolic responses.

This 'life course' perspective highlights the cumulative effect on health of exposures to episodes of illness, adverse environmental conditions and behaviours that damage health. In this way biological and social risk factors at each stage of life link to form pathways to disease and health.

Investigations in environmental health

Incidence and prevalence

The first task is to establish how common a problem is within the population. This is expressed in two ways (Box 5.2).

- If the problem is a continuing condition (e.g. enlarged spleen due to malaria), then prevalence is the appropriate measurement and is calculated by dividing the number of people with the condition at a specified time by the number of people in the population at risk at that time. Prevalence tends to be higher if the problem is common (many new cases) and/or if it is of longer duration.
- If the problem is an event that occurs at a clear point in time (e.g. fever due to malaria), then incidence is used. Incidence is a measure of the rate at which new cases occur (e.g. confirmed pyrexia with malaria parasites on a blood film) in the population at risk during a defined period of time.

Variability by time, person and place

The next task is to establish how the problem varies in terms of time, person and place. The incidence may fluctuate throughout the year; for example, malaria occurs in the wet season but not the dry. Observation over longer

periods establishes whether a problem is becoming more or less common: malaria may re-emerge due to drug resistance. The next question is, who are the victims? Are males or females more commonly affected? What is the age pattern? What are the occupations and social positions of those affected? In this example, symptomatic malaria is more common in poorer, rural-dwelling children. Finally, there is the question of variability by place: the prevalence of malaria is dictated by the distribution of anophelous mosquitoes.

Measuring risk

Epidemiology is also concerned with the numerical estimation of risk. This is best illustrated by a simple example. In a rural African town with a population of 5000, disease 'd' is under investigation. The majority of the cases of disease 'd' (300 out of 360) occurred among women and children who use the river, which recently had its flow of water reduced because of a new irrigation scheme. A formal experiment is established to measure risk. The 1000 women and children who use the river are followed up for 1 year and compared to a cohort with a similar age and sex distribution who use stand pipes as their source of water.

The incidence (new cases) of disease 'd' in the 1000 exposed to risk 'r' (river water) was 300. The incidence (new cases) of disease 'd' in 1000 not exposed to risk 'r' was 60. The relative risk is the incidence in the exposed population (300 per 1000 per year) divided by the incidence in the non-exposed population (60 per 1000 per year). $300/60 = 5$, meaning that those exposed to the river water are 5 times more likely to contract the disease—their relative risk is 5. The attributable risk of exposure 'r' for disease 'd' is the incidence in the exposed population (300) minus the incidence in the non-exposed population (60), which is 240 per 1000 per year. The fraction, or proportion, of the disease in the exposed population which can be attributed to risk (r) is called the attributable fraction, in this case $(300-60)/300 = 0.8$. This means that 80% of the disease can be attributed to exposure to river water.

Establishing cause and effect

Associations between a risk factor and a disease do not prove that the risk factor causes the disease. In the northern hemisphere, both multiple sclerosis and blue eyes are more common but it is implausible that having blue eyes is the cause of multiple sclerosis. Cause and effect can only be proven by more detailed investigation. In the above example, further investigation of the river water for infectious agents will be needed, using the criteria for causation defined in Koch's postulates (p. 132).

Preventive medicine

There are many examples of epidemiological associations defining causative factors in disease, e.g. the association between cigarette smoking and lung cancer (p. 698). However, as illustrated above, the complexity of the interactions between physical, social and economic determinants of health means that successful prevention is often difficult. Moreover, the life course perspective illustrates that it may be necessary to intervene early in life or even before birth, to prevent important disease in

5.2 Calculation of risk using descriptive epidemiology

Prevalence

- The ratio of the number of people with longer-term disease or condition at a specified time, to the number of people in the population who are at risk

Incidence

- The number of events (new cases or episodes) occurring in the population at risk during a defined period of time

Attributable risk

- The difference between the risk (or incidence) of disease in exposed and non-exposed populations

Attributable fraction

- The ratio of the attributable risk to the incidence

Relative risk

- The ratio of the risk (or incidence) in the exposed population to the risk (or incidence) in the non-exposed population

later life. Successful prevention is likely to require many interventions across the life course and at several levels in the hierarchy of systems. The examples below illustrate this principle.

ENVIRONMENTAL DISEASES

The term 'homeostasis' describes the capacity to maintain the internal milieu by adapting to increases or decreases in a given environmental factor. However, there are limits to the coping abilities of any system, at which 'too much' or 'too little' of a given environmental factor will result in ill health. Too many calories lead to obesity while too few lead to malnutrition. Either involuntarily or deliberately, we expose ourselves to many poisons and hazards. Examples discussed elsewhere include industrial/occupational hazards, such as asbestos (p. 712) and other carcinogens (p. 261). 'Social' poisons, such as tobacco, alcohol and drugs of misuse, also need to be considered (p. 237).

Alcohol

Rates of alcohol-related harm have been rising dramatically in the UK, with Scotland (Fig. 5.2) showing the highest rates. Why did Scotland experience a dramatic increase in alcohol deaths from the early 1990s onwards? The most likely explanation is that the environment changed. The price of alcohol fell in real terms and availability increased (more supermarkets sold alcohol and opening times of pubs were extended). Also, the culture changed in a way that fostered higher levels of consumption and more binge drinking. These changes have caused a trebling of male and a doubling of female deaths due to alcohol. Public, professional and governmental concern has now led to increased tax on alcohol, tightening of licensing regulations and curtailment of some promotional activity (e.g. two for one offers in bars). Many experts judge that even more aggressive public health measures will be needed to reverse the levels of harm in the community. The approach for individual patients

Fig. 5.2 Alcohol-related deaths in Scotland by year and sex (1990–2003). Principal ('underlying') and secondary ('contributing') causes of death. (Source: General Register Office (Scotland))

suffering adverse effects of alcohol is described on pages 237 and 246.

Smoking

Smoking tobacco dramatically increases the risk of developing many diseases. It is responsible for a substantial majority of cases of lung cancer and chronic obstructive pulmonary disease, and most smokers die either from these respiratory diseases or from ischaemic heart disease. Smoking also causes cancers of the upper respiratory and gastrointestinal tracts, pancreas, bladder and kidney, and increases risks of peripheral vascular disease, stroke and peptic ulceration. Maternal smoking is an important cause of fetal growth retardation. Moreover, there is increasing evidence that passive (or 'second-hand') smoking has adverse effects on cardiovascular and respiratory health.

When the ill-health effects of smoking were first discovered, doctors imagined that warning people about the dangers of smoking would result in them giving up. However, it also took increased taxation of tobacco, banning of advertising and support for smoking cessation to maintain a decline in smoking rates. In several European countries (including the UK), this has culminated in a complete ban on smoking in all public places—legislation that only became possible as the public became convinced of the dangers of secondhand smoke. However, smoking rates remain high in many poorer areas and are increasing amongst young women. In many developing countries tobacco companies have found new markets and rates are rising. World-wide, there are ~1 billion smokers, and 3 million die prematurely each year as a result of their habit.

In reality, there is a complex hierarchy of systems that interact to cause smokers to initiate and maintain their habit. At the molecular and cellular levels, nicotine acts on the nervous system to create dependence, so that smokers experience unpleasant effects when they attempt to quit. So, even if they know it is harmful, the role of addiction in maintaining the habit is important. Influences at the personal and social level are just as important. Many individuals bolster their denial of the harmful effects of smoking by focusing on someone they knew personally who smoked until he or she was very old and died peacefully in bed. Such strong counter-examples help smokers to maintain internal beliefs that comfort them when presented with statistical evidence. Young female smokers are often motivated more by the desire to 'stay thin' or 'look cool' than to avoid an illness in middle life.

Even if a smoker decides to quit, there are a variety of influences in the wider environment that reduce the chances of sustained success, including peer pressure, cigarette advertising, and finding oneself in circumstances where one previously smoked. The tobacco industry works very hard to maintain and expand the smoking habit, and its advertising budget is much greater than that available to health promoters.

Strategies to help individuals quit smoking are outlined in Boxes 5.3 and 5.4. Although the success rates are modest, these interventions are cost-effective and form an important part of the overall anti-tobacco strategy.

5.3 Methods for smoking cessation

Smokers who are not motivated to try to stop smoking

- Record smoking status at regular intervals
- Anti-smoking advice
- Encourage change in attitude towards smoking to improve motivation

Motivated light smokers (< 10/day)

- Anti-smoking advice
- Anti-smoking support programme

Motivated heavy smokers (10–15/day)

- As above plus nicotine replacement therapy (NRT) (minimum 8 weeks)

Motivated heavy smokers (> 15/day)

- As above plus bupropion if NRT and behavioural support are unsuccessful and patient remains motivated

EBM

5.4 Smoking cessation

'Placebo or will-power alone has a ~2% chance of abstinence for ≥ 6 months. This can be increased by the percentage shown by:

- written self-help materials: 1%
- opportunistic advice from doctor: 2%
- face-to-face behavioural support from specialist: 4–7%
- proactive telephone counselling: 2%
- NRT with limited or intensive behavioural support: 5–12%
- bupropion with intensive behavioural support: 9%.'

• Health Education Board for Scotland, Edinburgh; 2000.

Poverty and affluence

The adverse health and social consequences of poverty are well documented: high birth rates, high death rates and short life expectancy (Box 5.5). Typically, with industrialisation the pattern changes: low birth rates, low death rates and longer life expectancy. Instead of infections, chronic conditions such as heart disease dominate in an older population. Adverse health consequences of excessive affluence are also becoming apparent. Despite experiencing sustained economic growth for the last 50 years, people in many industrialised countries are not growing any happier and the litany of socioeconomic problems—crime, congestion, inequality—persists. Living in societies that give pride of place to economic growth means that there is constant pressure to contribute by performing ever harder at work and by consuming as much as—or more than—we can afford. As a result, people become stressed and may adopt unhealthy strategies to mitigate their discomfort; they overeat, overshop, or use sex or drugs (legal and illegal) as 'pain-killers'. These behaviours often lead to the problems listed in Box 5.5.

Many countries are now experiencing a 'double burden'. They have large populations still living in poverty who are suffering from problems such as diarrhoea and malnutrition, alongside affluent populations (often in cities) who suffer from chronic illness such as diabetes and heart disease. Recent research suggests that uneven distribution of wealth is a more important determinant of health than the absolute level of wealth; countries with a

5.5 Examples of effects of financial resources on health

Poverty

- Respiratory disease exacerbated or caused by air pollution
- Exposure to unnecessary hazards in the workplace or living environment
- Poor hygiene causing diarrhoeal diseases and debilitating intestinal parasitic infections
- Malnutrition
- Cardiovascular disease

Affluence

- Physical inactivity
- Alcohol and drug consumption
- High rates of suicide, depression, anxiety and stress
- Sexually transmitted infection
- Obesity

5.6 Environmental factors in disease in old age

- **Quality of life:** the major goal of public health policy in the young is to prolong lifespan; in old age, quality of life may be more important than its duration.
- **Life course:** the environmental factors that determine life expectancy operate throughout the lifespan and begin before birth.
- **Susceptibility to risk:** decline in many physiological functions increases risks from, for example, extremes of temperature, poverty, pollution and accidents in the home.
- **Reliance on support:** in many societies, financial, family and community support for older people is declining, with increasing risks of social isolation, poverty, malnutrition and neglect.

more even distribution of wealth enjoy longer life expectancies than countries with similar or higher gross domestic products (GDPs) but wider distributions of wealth.

Atmospheric pollution

Emissions from industry, power plants and motor vehicles of sulphur oxides, nitrogen oxides, respirable particles and metals are severely polluting cities and towns in Asia, Africa, Latin America and Eastern Europe. Increased deaths from respiratory and cardiovascular disease occur in vulnerable adults, such as those with established respiratory disease and the elderly, while children experience an increase in bronchitic symptoms. In nations like the UK that have reduced their primary emissions, the new issue of greenhouse gases has emerged. Developing countries also suffer high rates of respiratory disease as a result of indoor pollution caused mainly by heating and cooking combustion.

Carbon dioxide and global warming

Climate change is arguably the world's most important environmental health issue. A combination of increased production of carbon dioxide and habitat destruction, both caused primarily by human activity, seems to be the main cause. The temperature of the globe is rising, climate is being affected, and if the trend continues, sea levels will rise and rainfall patterns will be altered so that both droughts and floods will become more common. These have already claimed millions of lives during

the past 20 years and have adversely affected the lives of many more. The economic costs of property damage and the impact on agriculture, food supplies and prosperity have also been substantial. The health impacts of global warming will also include changes in the geographical range of some vector-borne infectious diseases.

Currently, politicians cannot agree on an effective framework of actions to tackle the problem. Meanwhile, the industrialised world continues with lifestyles and waste that are beyond the planet's limits to sustain. Rapidly growing economies in the world's two most populous states, India and China, are going to be a vital part of the unfolding problem or solution.

Radiation exposure

Radiation includes ionising (Box 5.7) and non-ionising radiations (ultraviolet (UV), visible light, laser, infrared and microwave). Whilst global industrialisation and the generation of fluorocarbons have raised concerns about loss of the ozone layer, leading to an increased exposure to UV rays, and disasters such as the Chernobyl nuclear power station explosion have demonstrated the harm of ionising radiation, it can be harnessed for medical benefit. Ionising radiation is used in X-rays, computed tomography (CT), radionuclide scans and radiotherapy, and non-ionising UV for therapy in skin diseases and laser therapy for diabetic retinopathy.

Types of ionising radiation

These include charged subatomic alpha and beta particles, uncharged neutrons or high-energy electromagnetic radiations such as X-rays and gamma rays. When they interact with atoms, energy is released and the resulting ionisation can lead to molecular damage. The clinical effects of different forms of radiation depend upon their range in air and tissue penetration (see Box 5.7).

Dosage and exposure

The dose of radiation is based upon the energy absorbed by a unit mass of tissue and is measured in grays (Gy), with 1 Gy representing 1 J/kg. To take account of different types of radiation and variations in the sensitivity of various tissues, weighting factors are used to produce a unit of effective dose, measured in sieverts (Sv). This value reflects the absorbed dose weighted for the damaging effects of a particular form of radiation and is most valuable in evaluating the long-term effects of exposure.

i 5.7 Properties of ionising radiations			
	Range in air	Range in tissue	Protection
Alpha particles	Few centimetres	No penetration	Paper
Beta particles	Few metres	Few millimetres	Aluminium sheet
X-rays/gamma rays	Kilometres	Passes through	Lead
Neutrons	Kilometres	Passes through	Concrete or thick polythene

'Background radiation' refers to our exposure to naturally occurring radioactivity (e.g. radon gas and cosmic radiation). This produces an average annual individual dose of approximately 2.6 mSv per year, although this varies according to local geology.

Effects of radiation exposure

Effects on the individual are classified as either deterministic or stochastic.

Deterministic effects

Deterministic (threshold) effects occur with increasing severity as the dose of radiation rises above a threshold level. Tissues with actively dividing cells, such as bone marrow and gastrointestinal mucosa, are particularly sensitive to ionising radiation. Lymphocyte depletion is the most sensitive marker of bone marrow injury, and after exposure to a fatal dose, marrow aplasia is a common cause of death. However, gastrointestinal mucosal toxicity may cause earlier death due to profound diarrhoea, vomiting, dehydration and sepsis. The gonads are highly radiosensitive and radiation may result in temporary or permanent sterility. Eye exposure can result in cataracts and the skin is susceptible to radiation burns. Irradiation of the lung and central nervous system may induce acute inflammatory reactions, pulmonary fibrosis and permanent neurological deficit respectively. Bone necrosis and lymphatic fibrosis are characteristic following regional irradiation, particularly for breast cancer. The thyroid gland is not inherently sensitive but its ability to concentrate iodine makes it susceptible to damage after exposure to relatively low doses of radioactive iodine isotopes, such as were released from Chernobyl.

Stochastic effects

Stochastic (chance) effects occur with increasing probability as the dose of radiation increases. Carcinogenesis represents a stochastic effect. With acute exposures, leukaemias may arise after an interval of around 2–5 years and solid tumours after an interval of about 10–20 years. Thereafter the incidence rises with time. An individual's risk of developing cancer depends on the dose received, the time to accumulate the total dose and the interval following exposure.

Management of radiation exposure

The principal problems after large-dose exposures are maintenance of adequate hydration, control of sepsis and the management of marrow aplasia. Associated injuries such as thermal burns need specialist management within 48 hours of active resuscitation. Internal exposure to radioisotopes should be treated with chelating agents (such as Prussian blue used to chelate ¹³⁷caesium after ingestion). White cell colony stimulation and bone marrow transplantation may need to be considered for marrow aplasia.

Extremes of temperature

Thermoregulation

Body heat is generated by basal metabolic activity and muscle movement, and lost by conduction (which is more effective in water than in air), convection, evaporation and radiation (most important at lower temperatures when other mechanisms conserve heat) (Box 5.8). Body temperature is controlled in the hypothalamus, which is directly sensitive to changes in core temperature and

i

5.8 Thermoregulation: responses to hot and cold environments

	Mechanism	Hot environment	Cold environment
Heat production	Basal metabolic rate	→	↓ in hypothermia
	Muscle activity	↓ by lethargy	↑ by shivering ↓ in severe hypothermia
Heat loss	Conduction*	↑ by vasodilatation	↓ by vasoconstriction ↑↑ in water < 31 °C
	Convection*	↑ by vasodilatation ↓ by lethargy	↓ by vasoconstriction ↑ by wind and movement
	Evaporation*	↑↑ by sweating ↓ by high humidity	↑ by hyperventilation
	Radiation	↑ by vasodilatation	↓ by vasoconstriction (but is the major heat loss in dry cold)

*These losses are dependent on the relative ambient and skin temperatures.

indirectly responds to temperature-sensitive neurons in the skin. The normal 'set-point' of core temperature is tightly regulated within $37 \pm 0.5^\circ\text{C}$, necessary to preserve the normal function of many enzymes and other metabolic processes. The temperature set-point is increased in response to infection (p. 292).

In a cold environment, protective mechanisms include cutaneous vasoconstriction and shivering; however, any muscle activity which involves movement may promote heat loss by increasing convective loss from the skin, and respiratory heat loss by stimulating ventilation. In a hot environment, sweating is the main mechanism for increasing heat loss. This usually occurs when the ambient temperature rises above 32.5°C or during exercise.

Hypothermia

Hypothermia exists when the body's normal thermal regulatory mechanisms are unable to maintain heat in a cold environment and core temperature falls below 35°C (Fig. 5.3).

Whilst infants are susceptible to hypothermia because of their poor thermoregulation and high body surface area to weight ratio, it is the elderly who are at highest risk (Box 5.9). Hypothyroidism is often a contributory factor in old age, while alcohol or other drugs (e.g. phenothiazines) commonly impede the thermoregulatory response in younger people. More rarely, hypothermia is secondary to glucocorticoid insufficiency, stroke, hepatic failure or hypoglycaemia.

Hypothermia also occurs in healthy individuals whose thermoregulatory mechanisms are intact but insufficient to cope with the intensity of the thermal stress. Typical examples include immersion in cold water, when core temperature may fall rapidly (acute hypothermia), exposure to extreme climates such as during hill walking (subacute hypothermia), and slow-onset hypothermia, as develops in an immobilised older individual (subchronic hypothermia). This classification is important, as it determines the method of rewarming.

Clinical features

Diagnosis is dependent on recognition of the environmental circumstances and measurement of core (rectal)

body temperature. Clinical features depend on the degree of hypothermia (see Fig. 5.3).

It is very difficult to diagnose death reliably by clinical means in a cold patient. It has been suggested that, in extreme environmental conditions, irreversible hypothermia is probably present if there is asystole (no carotid pulse for 1 minute), the chest and abdomen are rigid, the core temperature is below 13°C and serum potassium is $> 12\text{ mmol/L}$. However, in general, resuscitative measures should continue until the core temperature is

Fig. 5.3 Clinical features of abnormal core temperature. The hypothalamus normally maintains core temperature at 37°C , but this set-point is altered—for example, in fever (pyrexia, p. 292)—and may be lost in hypothalamic disease (p. 783). In these circumstances the clinical picture at a given core temperature may be different.

5.9 Thermoregulation in old age

- **Age-associated changes:** impairments in vasomotor function, skeletal muscle response and sweating mean that older people react more slowly to changes in temperature.
- **Increased comorbidity:** thermoregulatory problems are more likely in the presence of pathology such as atherosclerosis and hypothyroidism, and medication such as sedatives and hypnotics.
- **Hypothermia:** may arise as a primary event, but more commonly complicates other acute illness, e.g. pneumonia, stroke or fracture.
- **Ambient temperature:** financial pressures and older equipment may result in inadequate heating during cold weather.

normal and only then should a diagnosis of brain death be considered (p. 1158).

Investigations

Blood gases, a full blood count, electrolytes, chest X-ray and electrocardiogram (ECG) are all essential investigations. Haemoconcentration and metabolic acidosis are common, and the ECG may show characteristic J waves which occur at the junction of the QRS complex and the ST segment (Fig. 5.4). Cardiac dysrhythmias, including ventricular fibrillation, may occur. Although the arterial oxygen tension may be normal when measured at room temperature, the arterial PO_2 in the blood falls by 7% for each $1^\circ C$ fall in core temperature. Serum aspartate aminotransferase and creatine kinase may be elevated secondary to muscle damage and the serum amylase is often high due to subclinical pancreatitis. If the cause of hypothermia is not obvious, additional investigations for thyroid and pituitary dysfunction (p. 734), hypoglycaemia (p. 804) and the possibility of drug intoxication (p. 207) should be performed.

Management

Following resuscitation, the objectives of management are to rewarm the patient in a controlled manner while treating associated hypoxia (by oxygenation and ventilation if necessary), fluid and electrolyte disturbance, and cardiovascular abnormalities, particularly dysrhythmias. Careful handling is essential to avoid precipitating the latter. The method of rewarming is dependent not on the absolute core temperature, but on haemodynamic stability and the presence or absence of an effective cardiac output.

Mild hypothermia

Outdoors, continued heat loss is prevented by sheltering the patient from the cold, replacing wet clothing, covering the head and insulating him or her from the ground.

Fig. 5.4 Electrocardiogram showing J waves (arrows) in a hypothermic patient.

Once in hospital, even in the presence of profound hypothermia, if there is an effective cardiac output then forced-air rewarming, heat packs placed in axilla, groin and around the abdomen, inhaled warmed air and correction of fluid and electrolyte disturbances are usually sufficient. Rewarming rates of $1\text{--}2^\circ C$ per hour are effective in leading to a gradual and safe return to physiological normality. Underlying conditions should be treated promptly (e.g. hypothyroidism with triiodothyronine $10\mu g$ i.v. 8-hourly; p. 742).

Severe hypothermia

In the case of severe hypothermia with cardiopulmonary arrest (non-perfusing rhythm), the aim is to restore perfusion, and rapid rewarming at a rate greater than $2^\circ C$ per hour is required. This is best achieved by cardiopulmonary bypass or extracorporeal membrane oxygenation. If these are unavailable, then veno-veno haemofiltration, and pleural, peritoneal, thoracic or bladder lavage with warmed fluids are alternatives. Monitoring of cardiac rhythm and arterial blood gases, including H^+ (pH) is essential. Significant acidosis may require correction (p. 443).

Cold injury

Freezing cold injury (frostbite)

This represents the direct freezing of body tissues and usually affects the extremities: in particular, the fingers, toes, ears and face. Risk factors include smoking, peripheral vascular disease, dehydration and alcohol consumption. The tissues may become anaesthetised before freezing and, as a result, the injury often goes unrecognised at first. Frostbitten tissue is initially pale and doughy to the touch and insensitive to pain (Fig. 5.5). Once frozen, the tissue is hard.

Rewarming should not occur until it can be achieved rapidly in a water bath. Give oxygen and aspirin 300 mg as soon as possible. Frostbitten extremities should be rewarmed in warm water at $40\text{--}42^\circ C$, with antiseptic added. Adequate analgesia is necessary, as rewarming is very painful. Vasodilators such as pentoxifylline (a phosphodiesterase inhibitor) have been shown to improve tissue survival. Once thawed, the injured part must not be re-exposed to cold, and should be dressed and rested. Whilst wound débridement may be neces-

Fig. 5.5 Frostbite in a female Everest sherpa.

sary, amputations should be delayed for 60–90 days, as good recovery may occur over an extended period.

Non-freezing cold injury (trench or immersion foot)

This results from prolonged exposure to cold, damp conditions. The limb (usually the foot) appears cold, ischaemic and numb, but there is no freezing of the tissue. On rewarming, the limb appears mottled and thereafter becomes hyperaemic, swollen and painful. Recovery may take many months, during which there may be chronic pain and sensitivity to cold. The pathology remains uncertain but probably involves endothelial injury. Gradual rewarming is associated with less pain than rapid rewarming. The pain and associated paraesthesia are difficult to control with conventional analgesia and may require amitriptyline (50 mg nocte), best instituted early. The patient is at risk of further damage on subsequent exposure to the cold.

Chilblains

Chilblains are tender, red or purplish skin lesions that occur in the cold and wet. They are often seen in horse riders, cyclists and swimmers, and are more common in women than men. They are short-lived, and although painful, not usually serious.

Heat-related illness

When generation of heat exceeds the body's capacity for heat loss, core temperature rises. Non-exertional heat illness (NEHI) occurs with high environmental temperature in those with attenuated thermoregulatory control mechanisms: the elderly, the young, those with comorbidity or those taking drugs that affect thermoregulation (particularly phenothiazines, diuretics and alcohol). Exertional heat illness (EHI), on the other hand, typically develops in athletes when heat production exceeds the body's ability to dissipate it.

Acclimatisation mechanisms to environmental heat include stimulation of the sweat mechanism with increased sweat volume, reduced sweat sodium content and secondary hyperaldosteronism to maintain body sodium balance. The risk of heat-related illness falls as acclimatisation occurs. Heat illness can be prevented to a large extent by adequate replacement of salt and water, although excessive water intake alone should be avoided because of the risk of dilutional hyponatraemia (p. 435).

A spectrum of illnesses occurs in the heat (see Fig. 5.3). The cause is usually obvious but the differential diagnosis should be considered (Box 5.10).

Heat cramps

These painful muscle contractions occur following vigorous exercise and profuse sweating in hot weather. There is no elevation of core temperature. The mechanism is considered to be extracellular sodium depletion as a result of

persistent sweating, exacerbated by replacement of water but not salt. Symptoms usually respond rapidly to rehydration with oral rehydration salts or intravenous saline.

Heat syncope

This is similar to a vasovagal faint (p. 553) and is related to peripheral vasodilatation in hot weather.

Heat exhaustion

Heat exhaustion occurs with prolonged exertion in hot and humid weather, profuse sweating and inadequate salt and water replacement. There is an elevation in core (rectal) temperature to between 37°C and 40°C, leading to the clinical features shown in Figure 5.3. Blood analyses may show evidence of dehydration with mild elevation of the blood urea, sodium and haematocrit. Treatment involves removal of the patient from the heat, and active evaporative cooling using tepid sprays and fanning (strip-spray-fan). Fluid losses are replaced with either oral rehydration mixtures or intravenous isotonic saline. Up to 5 L positive fluid balance may be required in the first 24 hours. Untreated, heat exhaustion may progress to heat stroke.

Heat stroke

Heat stroke occurs when the core body temperature rises above 40°C and is a life-threatening condition. The symptoms of heat exhaustion progress to include headache, nausea and vomiting. Neurological manifestations include a coarse muscle tremor and confusion, aggression or loss of consciousness. The patient's skin feels very hot, and sweating is often absent due to failure of thermoregulatory mechanisms. Complications include hypovolaemic shock, lactic acidosis, disseminated intravascular coagulation, rhabdomyolysis, hepatic and renal failure, and pulmonary and cerebral oedema.

The patient should be resuscitated with rapid cooling by spraying with water, fanning and ice packs in the axillae and groins. Cold crystalloid intravenous fluids are given but solutions containing potassium should be avoided. Overaggressive fluid replacement must be avoided, as it may precipitate pulmonary oedema or further metabolic disturbance. Appropriate monitoring of fluid balance, including central venous pressure, is important. Investigations for complications include routine haematology and biochemistry, coagulation screen, hepatic transaminases (aspartate aminotransferase and alanine aminotransferase), creatinine kinase and chest X-ray. Once emergency treatment is established, heat stroke patients are best managed in intensive care.

With appropriate treatment, recovery from heat stroke can be rapid (within 1–2 hours) but patients who have had core temperatures higher than 40°C should be monitored carefully for later onset of rhabdomyolysis, renal damage and other complications before discharge from hospital. Clear advice to avoid heat and heavy exercise during recovery is important.

High altitude

The physiological effects of high altitude are significant. On Everest, the barometric pressure of the atmosphere falls from sea level by ~50% at base camp (5400 m) and ~70% at the summit (8848 m). The proportions of oxygen, nitrogen and carbon dioxide in air do not change with the fall in pressure but their partial pressure falls

5.10 Differential diagnosis in patients with elevated core body temperature

- Heat illness (heat exhaustion, heat stroke)
- Sepsis, including meningitis
- Malaria
- Drug overdose
- Malignant hyperpyrexia
- Thyroid storm (p. 741)

in proportion to barometric pressure (Fig. 5.6). Oxygen tension within the pulmonary alveoli is further reduced at altitude because the partial pressure of water vapour is related to body temperature and not barometric pressure, and so is proportionately greater at altitude, accounting for only 6% of barometric pressure at sea level, but 19% at 8848 m.

Physiological effects of high altitude

Reduction in oxygen tension results in a fall in arterial oxygen saturation (see Fig. 5.6). This varies widely between individuals, depending on the shape of the sigmoid oxygen-haemoglobin dissociation curve (see Fig. 8.2, p. 181) and the ventilatory response. Acclimatisation to hypoxaemia at high altitude involves a shift in this dissociation curve (dependent on 2,3-DPG), erythropoiesis, haemoconcentration, and hyperventilation resulting from hypoxic drive (which is then sustained despite hypocapnia by restoration of cerebrospinal fluid pH to normal in prolonged hypoxia). This process takes several days, so travellers need to plan accordingly.

Illnesses at high altitude

Ascent to altitudes up to 2500 m or travel in a pressurised aircraft cabin is harmless to healthy people. Above 2500 m high-altitude illnesses may occur in previously healthy people, and above 3500 m these become common. Sudden ascent to altitudes above 6000 m, as experienced by aviators, balloonists and astronauts, may result in decompression illness with the same clinical features as seen in divers (see below), or even loss of consciousness. However, most altitude illness occurs in travellers and mountaineers.

Fig. 5.6 Change in inspired oxygen tension and blood oxygen saturation at altitude. The blue curve shows changes in oxygen availability at altitude and the red curve shows the typical resultant changes in arterial oxygen saturation in a healthy person. Oxygen saturation varies between individuals according to the shape of the oxygen-haemoglobin dissociation curve and the ventilatory response to hypoxaemia. (To convert kPa to mmHg, multiply by 7.5.)

Acute mountain sickness (AMS)

AMS is a syndrome comprised principally of headache, together with fatigue, anorexia, nausea and vomiting, difficulty sleeping or dizziness. Ataxia and peripheral oedema may be present. Its aetiology is not fully understood but it is thought that hypoxaemia increases cerebral blood flow and hence intracranial pressure. Symptoms occur within 6–12 hours of an ascent and vary in severity from trivial to completely incapacitating. The incidence in travellers to 3000 m may be 40–50%, depending on the rate of ascent.

Treatment of mild cases consists of rest and simple analgesia; symptoms usually resolve after 1–3 days at a stable altitude, but may recur with further ascent. Occasionally there is progression to cerebral oedema. Persistent symptoms indicate the need to descend but may respond to acetazolamide, a carbonic anhydrase inhibitor which induces a metabolic acidosis and stimulates ventilation; acetazolamide may also be used as prophylaxis if a rapid ascent is planned.

High-altitude cerebral oedema (HACE)

The cardinal symptoms of HACE are ataxia and altered consciousness. This is rare, life-threatening and usually preceded by AMS. In addition to features of AMS, the patient suffers confusion, disorientation, visual disturbance, lethargy and ultimately loss of consciousness. Papilloedema and retinal haemorrhages are common, and focal neurological signs may be found.

Treatment is directed at improving oxygenation. Descent is essential and dexamethasone (8 mg immediately and 4 mg 6-hourly) should be given. If descent is impossible, oxygen therapy in a portable pressurised bag may be helpful.

High-altitude pulmonary oedema (HAPE)

This life-threatening condition usually occurs in the first 4 days after ascent above 2500 m. Unlike HACE, HAPE may occur de novo without the preceding signs of AMS. Presentation is with symptoms of dry cough, exertional dyspnoea and extreme fatigue. Later, the cough becomes wet and sputum may be blood-stained. Tachycardia and tachypnoea occur at rest and crepitations may often be heard in both lung fields. There may be profound hypoxaemia, pulmonary hypertension and radiological evidence of diffuse alveolar oedema. It is not known whether the alveolar oedema is a result of mechanical stress on the pulmonary capillaries associated with the high pulmonary arterial pressure, or an effect of hypoxia on capillary permeability. Reduced arterial oxygen saturation is not diagnostic but is a marker for disease progression.

Treatment is directed at reversal of hypoxia with immediate descent and oxygen administration. Nifedipine (20 mg 6-hourly) should be given to reduce pulmonary arterial pressure, and oxygen therapy in a portable pressurised bag should be used if descent is delayed.

Chronic mountain sickness (Monge's disease)

This occurs on prolonged exposure to altitude and has been reported in residents of Colorado, South America and Tibet. Patients present with headache, poor concentration and other signs of polycythaemia. They are cyanosed and often have finger clubbing.

High-altitude retinal haemorrhage

This occurs in over 30% of trekkers at 5000 m. The haemorrhages are usually asymptomatic and resolve spontaneously. Visual defects can occur with haemorrhage involving the macula, but there is no specific treatment.

Venous thrombosis

This has been reported at altitudes over 6000 m. Risk factors include dehydration, inactivity and the cold. The use of the oral contraceptive pill at high altitude should be considered carefully, as this is an additional risk factor.

Refractory cough

A cough at high altitude is common and usually benign. It may be due to breathing dry, cold air and increased mouth breathing, with consequent dry oral mucosa. This may be indistinguishable from the early signs of HAPE.

Air travel

Commercial aircraft usually cruise at 10 000–12 000 m, with the cabin pressurised to an equivalent of around 2400 m. At this altitude, the partial pressure of oxygen is 16 kPa (120 mmHg), leading to a P_{aO_2} in healthy people of 7.0–8.5 kPa (53–64 mmHg). Oxygen saturation is also reduced, but to a lesser degree (see Fig. 5.6). Although well tolerated by healthy people, this degree of hypoxia may be dangerous in patients with respiratory disease.

Advice for patients with respiratory disease

The British Thoracic Society has published guidance on the management of patients with respiratory disease who want to fly. Specialist pre-flight assessment is advised for all patients who have hypoxaemia (oxygen saturation < 95%) at sea level, and includes spirometry and a hypoxic challenge test with 15% oxygen (performed in hospital). Air travel may have to be avoided or undertaken only with inspired oxygen therapy during the flight. Asthmatic patients should be advised to carry their inhalers in their hand baggage. Following pneumothorax, flying should be avoided while air remains in the pleural cavity, but can be considered after proven resolution or definitive (surgical) treatment.

Advice for other patients

Other circumstances in which patients are more susceptible to hypoxia require individual assessment. These include cardiac dysrhythmia, sickle-cell disease and ischaemic heart disease. Most airlines decline to carry pregnant women after the 36th week of gestation. In complicated pregnancies it may be advisable to avoid air travel at an earlier stage. Patients who have had recent abdominal surgery, including laparoscopy, should avoid flying until all intraperitoneal gas is reabsorbed. Divers should not fly for 24 hours after a dive requiring decompression stops.

Ear and sinus pain due to changes in gas volume are common but usually mild, although patients with chronic sinusitis and otitis media may need specialist assessment. A healthy mobile tympanic membrane

visualised during a Valsalva manoeuvre usually suggests a patent Eustachian tube.

On long-haul flights, patients with diabetes mellitus may need to adjust their insulin or oral hypoglycaemic dosing according to the timing of in-flight and subsequent meals (p. 823). Advice is available from Diabetes UK and other websites. Documentary evidence of the need to carry needles and insulin should be carried.

Deep venous thrombosis

Air travellers have an increased risk of venous thrombosis (p. 1004), due to a combination of factors, including loss of venous emptying because of prolonged immobilisation (lack of muscular activity) and reduced barometric pressure on the tissues, together with haemoconcentration as a result of oedema and perhaps a degree of hypoxia-induced diuresis.

Venous thrombosis can probably be prevented by avoiding dehydration and excess alcohol, and exercising muscles during the flight. Without a clear cost-benefit analysis, prophylaxis with aspirin or heparin cannot be recommended routinely, but may be considered in high-risk cases.

Under water

Drowning and near-drowning

Drowning is defined as death due to asphyxiation following immersion in a fluid, whilst near-drowning is defined as survival for longer than 24 hours after suffocation by immersion. Drowning remains a common cause of accidental death throughout the world and is particularly common in young children (Box 5.11). In about 10% of cases no water enters the lungs and death follows intense laryngospasm ('dry' drowning). Prolonged immersion in cold water, with or without water inhalation, results in a rapid fall in core body temperature and hypothermia (p. 101).

Following inhalation of water, there is a rapid onset of ventilation-perfusion imbalance with hypoxaemia, and the development of diffuse pulmonary oedema. Fresh water is hypotonic and, although rapidly absorbed across alveolar membranes, impairs surfactant function, which leads to alveolar collapse and right-to-left shunting of unoxygenated blood. Absorption of large

Older people	
• Domestic baths	

amounts of hypotonic fluid can result in haemolysis. Salt water is hypertonic and inhalation provokes alveolar oedema, but the overall clinical effect is similar to that of freshwater drowning.

Clinical features

Those rescued alive (near-drowning) are often unconscious and not breathing. Hypoxaemia and metabolic acidosis are inevitable features. Acute lung injury usually resolves rapidly over 48–72 hours, unless infection occurs (Fig. 5.7). Complications include dehydration, hypotension, haemoptysis, rhabdomyolysis, renal failure and cardiac dysrhythmias. A small number of patients, mainly the more severely ill, progress to develop the acute respiratory distress syndrome (ARDS; p. 187).

Survival is possible after immersion for periods of up to 30 minutes in very cold water, as the rapid development of hypothermia after immersion may be protective, particularly in children. Long-term outcome depends on the severity of the cerebral hypoxic injury and is predicted by the duration of immersion, delay in resuscitation, intensity of acidosis and the presence of cardiac arrest.

Management

Initial management requires cardiopulmonary resuscitation with administration of oxygen and maintenance of the circulation (p. 556). It is important to clear the airway of foreign bodies and protect the cervical spine. Continuous positive airways pressure (CPAP; p. 194) should be considered for spontaneously breathing patients with oxygen saturations below 94%. Observation is required for a minimum of 24 hours. Prophylactic antibiotics are only required if exposure was to obviously contaminated water.

Fig. 5.7 Near-drowning. Chest X-ray of a 39-year-old farmer, 2 weeks after immersion in a polluted freshwater ditch for 5 minutes before rescue. Airspace consolidation and cavities in the left lower lobe reflect secondary staphylococcal pneumonia and abscess formation.

Diving-related illness

The underwater environment is extremely hostile. Other than drowning, most diving illness is related to changes in barometric pressure and its effect on gas behaviour.

Ambient pressure under water increases by 101 kPa (1 atmosphere) for every 10 metres of seawater (msw) depth. As divers descend, the partial pressures of the gases they are breathing increase (Box 5.12), and the blood and tissue concentrations of dissolved gases rise accordingly. Nitrogen is a weak anaesthetic agent, and if the inspiratory pressure of nitrogen is allowed to increase above ~320 kPa (i.e. a depth of ~30 msw), it produces 'narcosis', resulting in impairment of cognitive function and manual dexterity, not unlike alcohol intoxication. For this reason, compressed air can only be used for shallow diving. Oxygen is also toxic at inspired pressures above ~40 kPa (inducing apprehension, muscle twitching, euphoria, sweating, tinnitus, nausea and vertigo), so 100% oxygen cannot be used as an alternative. For dives deeper than ~30 msw, mixtures of oxygen with nitrogen and/or helium are used.

Whilst drowning remains the most common diving-related cause of death, another important group of disorders usually present once the diver returns to the surface: decompression illness (DCI) and barotrauma.

5.12 Physics of breathing compressed air while diving in sea water

Depth	Lung volume	Barometric pressure	PiO_2	PiN_2
Surface	100%	101 kPa (1 atmos)	21 kPa	79 kPa
10 m	50%	202 kPa (2 atmos)	42 kPa	159 kPa
20 m	33%	303 kPa (3 atmos)	63 kPa	239 kPa
30 m	25%	404 kPa (4 atmos)	84 kPa	319 kPa

Clinical features

Decompression illness

This includes decompression sickness (DCS) and arterial gas embolism (AGE). Whilst the vast majority of symptoms of decompression illness present within 6 hours of a dive, they can also be provoked by flying and thus patients may present to medical services at sites far removed from the dive.

Exposure of individuals to increased partial pressures of nitrogen results in additional nitrogen being dissolved in body tissues; the amount dissolved depends on the depth/pressure and on the duration of the dive. On ascent, the tissues become supersaturated with nitrogen, and this places the diver at risk of producing a critical quantity of gas (bubbles) in tissues if the ascent is too fast. The gas so formed may cause symptoms locally, by bubbles passing through the pulmonary vascular bed (Box 5.13) or by embolisation elsewhere. Arterial embolisation may occur if the gas load in the venous system exceeds the lungs' abilities to excrete nitrogen, or when bubbles pass through a patent foramen ovale (present asymptotically in 25–30% of adults; p. 524). Although DCS and AGE can be indistinguishable, their early treatment is the same.

Barotrauma

During the ascent phase of a dive, the gas in the diver's lungs expands due to the decreasing pressure. The diver

must therefore ascend slowly and breathe regularly; if ascent is rapid or the diver holds his/her breath, the expanding gas may cause lung rupture (pulmonary barotrauma). This can result in pneumomediastinum, pneumothorax or AGE due to gas passing directly into the pulmonary venous system. Other air-filled body cavities may be subject to barotrauma, including the ear and sinuses.

Management

The patient is nursed horizontally and airway, breathing and circulation are assessed. Treatment includes the following:

- High-flow oxygen** is given by a tight-fitting mask using a rebreathing bag. This assists in the washout of excess inert gas (nitrogen) and may reduce the extent of local tissue hypoxia resulting from focal embolic injury.
- Fluid replacement** (oral or intravenous) corrects the intravascular fluid loss from endothelial bubble injury and the dehydration associated with immersion. Maintenance of an adequate peripheral circulation is important for the excretion of excess dissolved gas.
- Recompression** is the definitive therapy. Transfer to a recompression chamber facility may be by surface or air, provided that the altitude remains low (< 300 m) and the patient continues to breathe 100% oxygen. Recompression reduces the volume of gas within tissues and puts nitrogen back into solution.

The majority of patients make a complete recovery with treatment, although a small but significant proportion are left with neurological disability.

PRINCIPLES AND INVESTIGATION OF NUTRITIONAL FACTORS IN DISEASE

Obtaining adequate nutrition is a fundamental requirement for survival of every individual and species. The politics of food provision for humans are complex, and

constitute a prominent factor in wars, natural disasters and the global economy. In recent decades, economic success has been rewarded by plentiful nutrition unknown to previous generations, which has led to a pandemic of obesity and its serious consequences for health. Yet in many parts of the world, famine and under-nutrition still represent a huge burden. Quality, as well as quantity, of food influences health. Inappropriate diets have been linked with diseases such as coronary heart disease and cancer. Deficiencies of simple vitamins or minerals lead to avoidable conditions such as anaemia due to iron deficiency or blindness due to severe vitamin A deficiency. A proper understanding of nutrition is therefore essential in dealing with the needs of individual patients and to inform the planning of public policy.

Physiology of nutrition

Nutrients in the diet can be classified into 'macronutrients', which are eaten in relatively large amounts to provide fuel for energy, and 'micronutrients' (e.g. vitamins and minerals), which do not contribute to energy balance but are required in small amounts because they are not synthesised in the body.

Energy balance

The laws of thermodynamics dictate that energy balance is achieved when energy intake = energy expenditure (Fig. 5.8).

Energy expenditure has several components. The basal metabolic rate (BMR) describes the obligatory energy expenditure required to maintain metabolic functions in tissues and hence sustain life. It is most closely predicted by fat-free mass (i.e. total body mass minus fat mass), which is lower in females and older people (Fig. 5.8B). Extra metabolic energy is consumed during growth, pregnancy and lactation, and when febrile. Metabolic energy is also required for thermal regulation, and expenditure is higher in cold or hot environments. The energy required for digestion of food (diet-induced thermogenesis (DIT); Fig. 5.8C) accounts for approximately 10% of total energy expenditure, with protein requiring more energy than other macronutrients. Another component of energy expenditure is governed by the level of muscular activity, which can vary considerably with occupation and lifestyle (Fig. 5.8D). Physical activity levels are usually defined as multiples of BMR.

Energy intake is determined by the 'macronutrient' content of food. Carbohydrates, fat, protein and alcohol provide fuel for oxidation in the mitochondria to generate energy (as adenosine triphosphate (ATP; p. 42). The energy provided by each differs:

- carbohydrates (16 kJ/g)
- fat (37 kJ/g)
- protein (17 kJ/g)
- alcohol (29 kJ/g).

Regulation of energy balance

Energy intake and expenditure are highly regulated (Fig. 5.9). A link with reproductive function ensures that pregnancy is most likely to occur during times of nutritional plenty when both mother and baby have a better chance of survival. Improved nutrition is thought to be

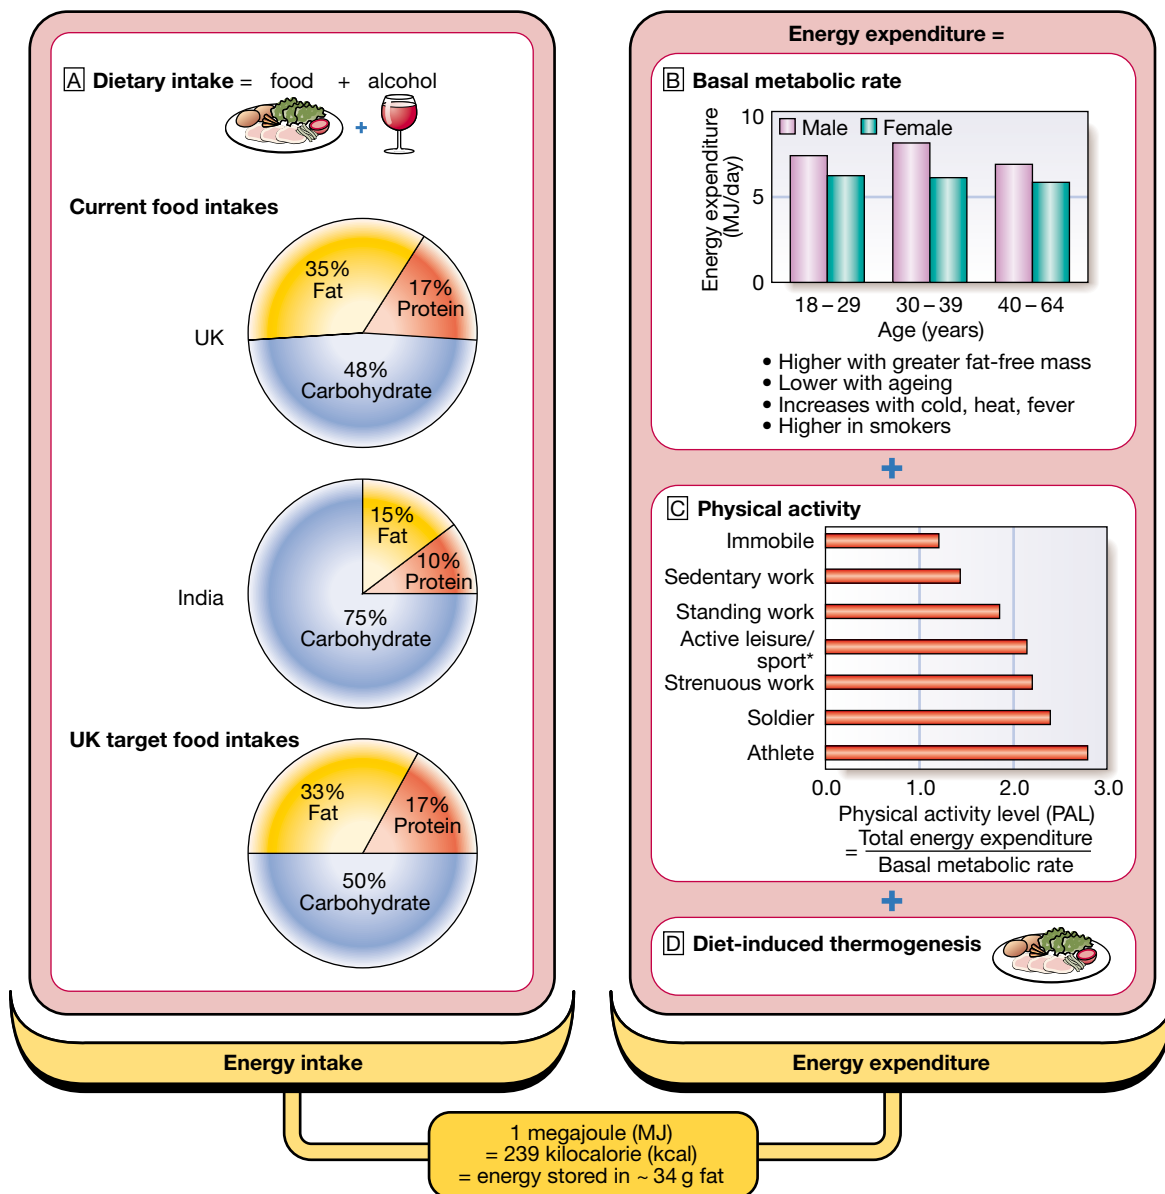

Fig. 5.8 Determinants of energy balance. **A** Energy intake is shown as national averages, highlighting the differences in sources of energy in different countries (but obscuring substantial regional variations). The targets are recommendations as a percentage of food energy only (Source: Dept of Health 1991). For WHO target, see Box 5.17. In the UK it is assumed that 5% of energy intake will be derived from alcohol. **B** Data for normal basal metabolic rate (BMR) were obtained from healthy men and women in various countries. BMR declines from middle age and is lower in women, even after adjustment for body size because of differences in fat-free mass. **C** Energy is required for movement and activity. Physical activity level (PAL) is the multiple of BMR by which total energy expenditure is increased by activity. **D** Energy is consumed in order to digest food. *Leisure or sport activity increases PAL by ~0.3 for each 30–60 minutes of moderate exercise performed 4–5 times per week.

the reason for the increasingly early onset of puberty in many societies. At the other extreme, anorexia nervosa and excessive exercise can lead to amenorrhoea (p. 249).

Regulation of energy balance is coordinated in the hypothalamus, which receives afferent signals that indicate nutritional status in the short term (e.g. the stomach hormone ghrelin, which falls immediately after eating and rises gradually thereafter, to suppress satiety and signal that it is time for the next meal) and the long term (e.g. the adipose hormone leptin, which increases with growing fat mass and stimulates satiety). The hypothal-

amus responds with changes in many local neurotransmitters that alter activity in a number of pathways which influence energy balance (see Fig. 5.9), including hormones acting on the pituitary gland (see Fig. 20.2, p. 743), and neural control circuits which connect with the cerebral cortex and autonomic nervous system.

Responses to under- and over-nutrition

These complex regulatory pathways allow adaptation to variations in nutrition. In response to starvation, reproductive function is suppressed, BMR is reduced, and there are profound psychological effects, including energy

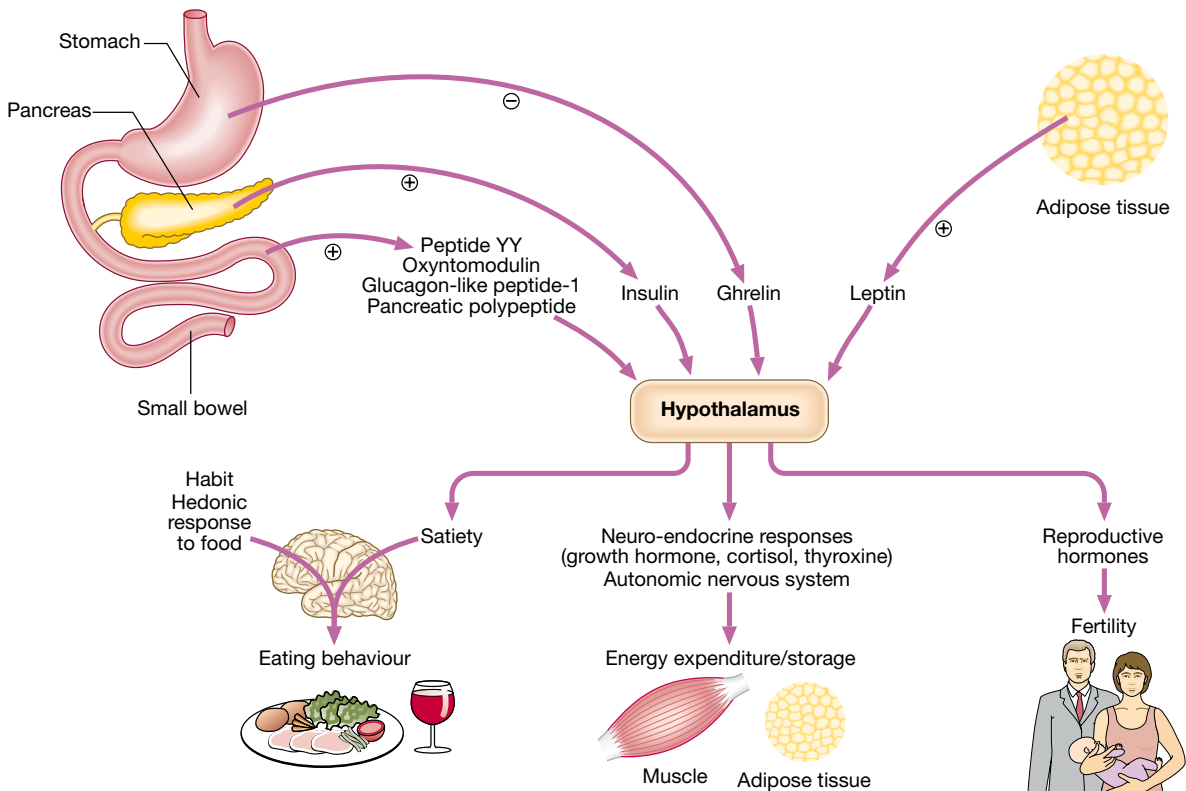

Fig. 5.9 Regulation of energy balance and its link with reproduction. ⊕ indicates factors which are stimulated by eating and induce satiety. ⊖ indicates factors which are suppressed by eating and inhibit satiety.

conservation through lethargy. These adjustments can 'defend' body weight within certain limits. However, in the low-insulin state of starvation (Fig. 21.2, p. 799), fuels are liberated from stores initially in glycogen (in liver and muscle), then in triglyceride (lipolysis in adipose tissue, with excess free fatty acid supply to the liver leading to ketosis) and finally in protein (proteolysis in muscle).

In response to over-nutrition, BMR is increased, and extra energy is consumed in the work of carrying increased fat stores, so that body weight is again 'defended' within certain limits. In the high-insulin state of over-nutrition, excess energy is invested in fatty acids and stored as triglycerides; these are deposited principally in adipose tissue but they may also accumulate in liver (non-alcoholic fatty liver disease; p. 956) and skeletal muscle. In the absence of hypothalamic function (e.g. in those with craniopharyngioma; see Fig. 20.32, p. 792) or in rare patients with mutations in relevant genes (e.g. in leptin or melanocortin-4 receptors), loss of satiety signals, together with loss of adaptive changes in energy expenditure, result in relentless weight gain.

Energy-yielding nutrients (macronutrients)

Carbohydrates

Types of carbohydrate and their dietary sources are listed in Box 5.14. The 'available' carbohydrates (starches and sugars) are broken down to monosaccharides before absorption from the gut (p. 839), and supply over half the energy in a normal, well-balanced diet (see Fig. 5.8A). No individual carbohydrate is an essential nutrient, as car-

bohydrates can be synthesised *de novo* from glycerol or protein. However, if the available carbohydrate intake is less than 100 g per day, increased lipolysis leads to ketosis (see Fig. 21.5, p. 802).

Dietary guidelines do not restrict the intake of intrinsic sugars in fruit and vegetables or the sugars in milk. However, intake of non-milk extrinsic sugars (sucrose, maltose, fructose), which increase the risk of dental caries and diabetes mellitus, should be limited. Starches in cereal foods, root foods and legumes provide the largest proportion of energy in most diets around the world. All starches are polymers of glucose, linked by the same 1–4 glycosidic linkages. However, some starches are digested promptly by salivary and then pancreatic amylase, producing rapid delivery of glucose to the blood. Other starches are digested more slowly, either because they are protected in the structure of the food, because of their crystal structure, or because the molecule is unbranched (amylose). These differences are the basis for the 'glycaemic index' of foods. This is the area under the curve of the rise in blood glucose concentration in the 2 hours following ingestion of 50 g carbohydrate, expressed as a percentage of the response to 50 g anhydrous glucose. There is emerging evidence linking high glycaemic index foods with obesity and type 2 diabetes (p. 803).

Dietary fibre

Dietary fibre is plant food that is not digested by human enzymes in the gastrointestinal tract. Most dietary fibre is known as the 'non-starch polysaccharides' (NSP) (see Box 5.14). A small percentage of 'resistant' dietary starch may also pass unchanged into the large intestine.

Class	Components	Examples	Source
Free sugars	Monosaccharides	Glucose, fructose	Intrinsic: fruits, milks, vegetables
	Disaccharides	Sucrose, lactose, maltose	Extrinsic (extracted, refined): beet or cane sucrose
Short-chain carbohydrates	Oligosaccharides	Maltodextrins, fructo-oligosaccharides	
Starch polysaccharides	Rapidly digestible Slowly digestible Resistant		Cereals (wheat, rice), root vegetables (potato), legumes (lentils, beans, peas)
Non-starch polysaccharides (NSP, dietary fibre)	Fibrous Viscous	Cellulose Hemicellulose Pectins Gums	Plants

Some types of NSP, notably the hemicellulose of wheat, increase the water-holding capacity of colonic contents and the bulk of faeces. They relieve simple constipation, appear to prevent diverticulosis and may reduce the risk of cancer of the colon. Other viscous, indigestible polysaccharides like pectin and guar gum are important in the upper gastrointestinal tract, where they slow gastric emptying, contribute to satiety, and reduce bile salt absorption and hence plasma cholesterol concentration.

Fat has the highest energy density of the macronutrients (37 kJ/g) and excessive consumption may be an insidious cause of obesity (see Fig. 5.8A). Free fatty acids are absorbed in chylomicrons (p. 449), allowing access of complex molecules into the circulation. Fatty acid structures are shown in Figure 5.10. The principal polyunsaturated fatty acid (PUFA) in plant seed oils is linoleic acid (18:2 ω6). This and alpha-linolenic acid (18:3 ω3) are the 'essential' fatty acids, which

Cholesterol is also absorbed directly from food in chylomicrons and is an important substrate for steroid and sterol synthesis, but not an important source of energy.

Proteins are made up of some 20 different amino acids, of which nine are 'essential' (Box 5.15), i.e. they cannot be synthesised in humans but are required for synthesis of important proteins. Another group of five amino acids are termed 'conditionally essential', meaning that they can be synthesised from other amino acids, provided there is an adequate dietary supply. The remaining amino acids can be synthesised in the body by transamination, provided there is a sufficient supply of amino groups.

The nutritive or 'biological' value of different proteins depends on the relative proportions of essential amino acids they contain. Proteins of animal origin, particularly from eggs, milk and meat, are generally of higher biological value than proteins of vegetable origin, which are low in one or more of the essential amino acids. However, when two different vegetable proteins are eaten together (e.g. a cereal and a legume), their

5.15 Amino acids

Essential amino acids

- Tryptophan

- Cysteine: methionine, serine
- Tyrosine: phenylalanine
- Arginine: glutamine/glutamate, aspartate
- Proline: glutamate
- Glycine: serine, choline

amino acid contents are complementary and produce an adequate mix, an important principle in vegan diets.

Dietary recommendations for macronutrients

Recommendations for energy intake (Box 5.16) and proportions of macronutrients (Box 5.17) have been calculated to provide a balance of essential nutrients and minimise the risks of excessive refined sugar (dental caries, high glycaemic index/diabetes mellitus), saturated fat or trans fat (obesity, coronary heart disease). Recommended dietary fibre intake is based on avoiding

5.16 Daily adult energy requirements in health

Circumstances	Requirements	
	Females	Males
At rest	6.7 MJ (1600 kcal)	8.4 MJ (2000 kcal)
Light work	8.4 MJ (2000 kcal)	11.3 MJ (2700 kcal)
Heavy work	9.4 MJ (2250 kcal)	14.6 MJ (3500 kcal)

5.17 WHO recommended population macronutrient goals

Nutrient (% of total energy unless indicated)	Target limits for population average intakes	
	Lower	Upper
Total fat	15	30
Saturated fatty acids	0	10
Polyunsaturated fatty acids	6	10
Trans fatty acids	0	2
Dietary cholesterol (mg/day)	0	300
Total carbohydrate	55	75
Free sugars	0	10
Complex carbohydrate	50	70
Dietary fibre (g/day)		
As non-starch polysaccharides	16	24
As total dietary fibre	27	40
Protein	10	15

risks of colonic disease. The usual recommended protein intake for a healthy man doing light work is 65–100 g/day. The minimum requirement is around 40 g of protein with a high proportion of essential amino acids or a high biological value.

Vitamins

Vitamins are organic substances with key roles in certain metabolic pathways, and are categorised into those that are fat-soluble (vitamins A, D, E and K) and those that are water-soluble (vitamins of the B complex group and vitamin C).

Recommended daily intakes of micronutrients (Box 5.18) vary between countries and the nomenclature has become potentially confusing. In the UK, the 'reference nutrient intake' (RNI) has been calculated as the mean plus two standard deviations (SD) of daily intake in the population, which therefore describes normal intake for 97.5% of the population. The lower reference nutrient intake (LRNI) is the mean minus 2 SD, below which would be considered deficient in most of the population. These dietary reference values (DRV) have superseded the terms RDI (recommended daily intakes) and RDA (recommended daily amounts). Other countries use different terminology. Additional amounts of some micronutrients may be required in pregnancy and lactation (Box 5.19).

Vitamin A (retinol)

Preformed retinol is found only in foods of animal origin. Vitamin A can also be derived from carotenes, which are present in green and coloured vegetables and some fruits. Carotenes provide most of the total vitamin A in the UK, and provide the only supply in vegans. Retinol is converted to several other important molecules:

- *11-cis retinaldehyde* is part of the photoreceptor complex in rods of the retina.
- *Retinoic acid* induces differentiation of epithelial cells by binding to specific nuclear receptors, which induce responsive genes. In vitamin A deficiency, mucus-secreting cells are replaced by keratin-producing cells.
- *Retinoids* are necessary for normal growth, fetal development, fertility, haematopoiesis and immune function.

Vitamin D

The natural form of vitamin D, cholecalciferol or vitamin D₃, is formed in the skin by the action of UV light on 7-dehydrocholesterol, a metabolite of cholesterol. Few foods contain vitamin D naturally and skin exposure to sunlight is the main source. Moving away from the equator, the intensity of UV light decreases, so that at a latitude above 50° (including northern Europe), vitamin D is not synthesised from October to March, and even at > 30° there is seasonal variation. The body store accumulated during the summer is consumed during the winter. Vitamin D is converted in the liver to 25-hydroxy vitamin D (25(OH)D), which is further hydroxylated in the kidneys to 1,25-dihydroxy-vitamin D (1,25(OH)₂D), the active form of the vitamin (see Fig. 20.17, p. 764). 1,25(OH)₂D activates specific intracellular receptors which influence calcium metabolism, bone mineralisation and tissue differentiation. The synthetic form, ergocalciferol or vitamin D₂, is considered to be less effective than the endogenous D₃.

i

5.18 Summary of clinically important vitamins

Vitamin	Sources*	Reference nutrient intake (RNI)
Fat-soluble		
A (retinol)	<i>Rich:</i> liver <i>Important:</i> milk and milk products, eggs, fish oils	700 µg men 600 µg women
D (cholecalciferol)	UV exposure to skin <i>Rich:</i> fish oils <i>Important:</i> egg yolks, margarine, fortified cereals	10 µg if > 65 yrs or no sunlight exposure
E (tocopherol)	<i>Rich:</i> sunflower oil <i>Important:</i> vegetables, nuts, seed oils	No RNI. Safe intake: 4 mg men 3 mg women
K (phylloquinone, menaquinone)	<i>Rich:</i> green vegetables <i>Important:</i> soya oil, menaquinones produced by intestinal bacteria	No RNI. Safe intake: 1 µg/kg
Water-soluble		
B₁ (thiamin)	<i>Rich:</i> pork <i>Important:</i> cereals, grains, beans	0.8 mg per 9.68 MJ (2000 kcal) energy intake
B₂ (riboflavin)	<i>Rich:</i> milk <i>Important:</i> milk and milk products, breakfast cereals, bread	1.3 mg men 1.1 mg women
B₃ (niacin, nicotinic acid, nicotinamide)	<i>Rich:</i> meat, cereals	17 mg men 13 mg women
B₆ (pyridoxine)	<i>Rich:</i> meat, fish, potatoes, bananas <i>Important:</i> vegetables, intestinal microflora synthesis	1.4 mg men 1.2 mg women
Folate	<i>Rich:</i> liver <i>Important:</i> green leafy vegetables, fortified breakfast cereals	200 µg
B₁₂ (Cobalamin)	<i>Rich:</i> animal products <i>Important:</i> bacterial colonisation	1.5 µg
Biotin	<i>Rich:</i> egg yolk <i>Important:</i> intestinal flora	No RNI. Safe intake: 10–200 µg
C (ascorbic acid)	<i>Rich:</i> citrus fruit <i>Important:</i> fresh fruit, fresh and frozen vegetables	40 mg

*Rich sources contain the nutrient in high concentration but are not generally eaten in large amounts; important sources contain less but contribute most because larger amounts are eaten.

Recommended dietary intakes aim to prevent rickets and osteomalacia (p. 1121). There is increasing evidence that vitamin D is important for immune and muscle function, and may reduce falls in the elderly (p. 170). Margarine is fortified with vitamin D in the UK, and milk is fortified in some parts of Europe and in North America.

Vitamin E

There are eight related fat-soluble substances with vitamin E activity. The most important dietary form is α -tocopherol. Vitamin E has many direct metabolic actions:

- It prevents oxidation of polyunsaturated fatty acids in cell membranes by free radicals.
- It helps maintain cell membrane structure.
- It affects DNA synthesis and cell signalling.
- It is involved in the anti-inflammatory and immune systems.

Vitamin K

Vitamin K is supplied in the diet mainly as vitamin K₁ (phylloquinone) in the UK, or as vitamin K₂ (menaquinone) from fermented products in parts of Asia. Vitamin K₂ is also synthesised by bacteria in the colon. Vitamin K is a co-factor for carboxylation reactions: in particular,

the production of γ -carboxyglutamate (gla). Gla residues are found in four of the coagulation factor proteins (II, VII, IX and X; p. 993), conferring their capacity to bind to phospholipid surfaces in the presence of calcium. Other important gla proteins are osteocalcin and matrix gla protein, which are important in bone mineralisation.

Thiamin (vitamin B₁)

Thiamin is widely distributed in foods of both vegetable and animal origin. Thiamin pyrophosphate (TPP) is a co-factor for enzyme reactions involved in the metabolism of macronutrients (carbohydrate, fat and alcohol), including:

- decarboxylation of pyruvate to acetyl-co-enzyme A, which bridges between glycolysis and the tricarboxylic acid (Krebs) cycle
- transketolase activity in the hexose monophosphate shunt pathway
- decarboxylation of α -ketoglutarate to succinate in the Krebs cycle.

Riboflavin (vitamin B₂)

Riboflavin is required for the flavin co-factors involved in oxidation–reduction reactions. It is widely distributed

5.19 Nutrition in pregnancy and lactation

- **Energy requirements:** increased in both the mother and fetus, but can be met through reduced maternal energy expenditure.
- **Micronutrient requirements:** adaptive mechanisms ensure increased uptake of minerals in pregnancy, but extra increments of some are required during lactation (see Box 5.21). Additional increments of some vitamins are recommended during pregnancy and lactation:
 - Vitamin A: for growth and maintenance of the fetus, and to provide some reserve (important in some countries to prevent blindness associated with vitamin A deficiency). Teratogenic in excessive amounts.
 - Vitamin D: to ensure bone and dental development in the infant. Higher incidences of hypocalcaemia, hypoparathyroidism and defective dental enamel have been seen in infants of women not taking vitamin D supplements at > 52° latitude.
 - Folate: to avoid neural tube defects (Box 5.20).
 - Vitamin B₁₂: in lactation only.
 - Thiamin: to meet increased fetal energy demands.
 - Riboflavin: to meet extra demands.
 - Niacin in lactation only.
 - Vitamin C: for the last trimester to maintain maternal stores as fetal demands increase.
 - Iodine: in countries with high consumption of staple foods (e.g. brassicas, maize, bamboo shoots) that contain goitrogens (thiocyanates or perchlorates) which interfere with iodine uptake, supplements prevent infants being born with cretinism.

in animal and vegetable foods. Levels are low in staple cereals but germination increases its content. It is destroyed under alkaline conditions by heat and by exposure to sunlight.

Niacin (vitamin B₃)

Niacin encompasses nicotinic acid and nicotinamide. Nicotinamide is an essential part of the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which play a key role as hydrogen acceptors and donors for many enzymes. Niacin can be synthesised in the body in limited amounts from the amino acid tryptophan.

Pyridoxine (vitamin B₆)

Pyridoxine, pyridoxal and pyridoxamine are different forms of vitamin B₆ which undergo phosphorylation to produce pyridoxal 5-phosphate (PLP). PLP is the co-factor for a large number of enzymes involved in the metabolism of amino acids. Vitamin B₆ is available in most foods.

Folate (folic acid)

Folates exist in many forms. The main circulating form is 5-methyltetrahydrofolate. The natural forms are prone to oxidation. Folic acid is the stable synthetic form. Folate works as a methyl donor for cellular methylation and protein synthesis. It is directly involved in DNA and RNA synthesis, and requirements increase during embryonic development. The UK Department of Health advises that women who have experienced a pregnancy affected by a neural tube defect should take 5mg of folic acid daily from before conception and throughout the first trimester (Box 5.20). All women planning a pregnancy are advised

to include good sources of folate in their diet, and take folate supplements throughout the first trimester. Liver is the richest source of folate but an alternative source (e.g. leafy vegetables) is advised in early pregnancy because of the high vitamin A content of liver (p. 111). In the US, there is mandatory fortification of flour with folic acid and there is voluntary fortification of many foods across Europe. There are now concerns that this may be responsible for the increased incidence of colon cancer through promotion of the growth of polyps.

Hydroxycobalamin (vitamin B₁₂)

Vitamin B₁₂ is a co-factor in folate co-enzyme recycling and nerve myelination. Vitamin B₁₂ and folate are particularly important in DNA synthesis in red blood cells (p. 1020).

Vitamin C (ascorbic acid)

Ascorbic acid is the most active reducing agent in the aqueous phase of living tissues and is involved in intracellular electron transfer. It takes part in the hydroxylation of proline and lysine in procollagen to hydroxyproline and hydroxylysine in mature collagen. It is very easily destroyed by heat, increased pH and light, and is very soluble in water; hence many traditional cooking methods reduce or eliminate it. Claims that high-dose vitamin C improves immune function (including resistance to the common cold) and cholesterol turnover remain unsubstantiated.

Inorganic nutrients

A number of inorganic elements are essential dietary constituents for humans (Box 5.21).

Calcium and phosphorus

Calcium is the most abundant cation in the body and powerful homeostatic mechanisms control circulating ionised calcium levels (p. 763). World Health Organization (WHO) dietary guidelines for calcium differ between countries, with higher intakes usually recommended in places with higher fracture prevalence. Between 20 and 30% of calcium in the diet is absorbed, depending on vitamin D status and food source. Calcium requirements depend on phosphorus intakes with an optimum molar ratio (Ca:P) of 1:1.

EBM 5.20 Periconceptual folate supplementation and neural tube defects

'Folate supplementation in advance of conception and during the first trimester reduces the incidence of neural tube defects by ~70%.'

• Lumley J, et al. (Cochrane Review). Cochrane Library, issue 3, 2005. Oxford: Update Software.

5.21 Summary of clinically important minerals

Mineral	Sources ¹	Reference nutrient intake (RNI)
Calcium	<i>Rich:</i> milk and milk products, tofu <i>Important:</i> milk, boned fish, green vegetables, beans	700 mg ²
Phosphorus	Most foods contain phosphorus <i>Rich:</i> Marmite® and dry-roasted peanuts <i>Important:</i> milk, cereal products, bread and meat	550 mg ²
Magnesium	<i>Rich:</i> whole grains, nuts <i>Important:</i> unprocessed and wholegrain foods	300 mg men 270 mg women ²
Iron	<i>Rich:</i> liver, red meat (haem iron) <i>Important:</i> non-haem iron from vegetables, wholemeal bread	8.7 mg 14.8 mg women < 50 yrs
Zinc	<i>Rich:</i> red meat, seafood <i>Important:</i> dairy produce, wholemeal bread	9.5 mg men 7 mg women ²
Iodine	<i>Rich:</i> edible seaweeds <i>Important:</i> milk and dairy products	140 µg
Selenium	<i>Rich:</i> fish, wheat grown in selenium-rich soils <i>Important:</i> fish	60 µg women ² 75 µg men
Copper	<i>Rich:</i> shellfish, liver <i>Important:</i> bread, cereal products, vegetables	1.2 mg ²
Fluoride	Drinking water, tea	No RNI. Safe intake: 0.5 mg/kg
Potassium	<i>Rich:</i> dried fruit, potatoes, coffee <i>Important:</i> fresh fruit, vegetables, milk	3500 mg
Sodium	<i>Rich:</i> Table salt, anchovies <i>Important:</i> processed foods, bread, bacon	1600 mg

¹Rich sources contain the nutrient in high concentration but are not generally eaten in large amounts; important sources contain less but contribute most because larger amounts are eaten.
²Increased amounts are required in women during lactation.

Excessive phosphorus intakes (e.g. 1–1.5 g/day) with a Ca:P of 1:3 have been shown to cause hypocalcaemia and secondary hyperparathyroidism (p. 765).

Iron

Iron is involved in the synthesis of haemoglobin, and is required for the transport of electrons within cells and in a number of enzyme reactions. Non-haem iron in cereals and vegetables is poorly absorbed, but makes the greater contribution to overall intake, compared to the well-absorbed haem iron from animal products. Fruits and vegetables containing vitamin C enhance iron absorption, while the tannins in tea reduce it. Dietary calcium reduces iron uptake from the same meal, which may precipitate iron deficiency in those with borderline iron stores. There is no physiological mechanism for excretion of iron, so homeostasis depends on the regulation of iron absorption. The normal daily loss of iron is 1 mg, arising from desquamated surface cells and intestinal losses. A regular loss of only 2 mL of blood per day doubles the iron requirement. On average, an additional 20 mg of iron is lost during menstruation, so pre-menopausal women require about twice as much iron as men (and more if menstrual losses are heavy).

Iodine

Iodine is required for synthesis of thyroid hormones (p. 736). It is present in sea fish, seaweed and most plant

foods grown near the sea. The amount of iodine in soil and water influences the iodine content of most foods. Iodine is lacking in the highest mountainous areas of the world (e.g. the Alps and the Himalayas) and in the soil of frequently flooded plains (e.g. Bangladesh).

Zinc

Zinc is present in most foods of vegetable and animal origin. It is an essential component of many enzymes, including carbonic anhydrase, alcohol dehydrogenase and alkaline phosphatase.

Selenium

The family of seleno-enzymes includes glutathione peroxidase, which helps prevent free radical damage to cells, and monodeiodinase, which converts thyroxine to triiodothyronine (p. 736). North American soil has a higher selenium content than European and Asian soil, and the decreasing reliance of Europe on imported American food in recent decades has resulted in a decline in dietary selenium intake.

Fluoride

Fluoride helps prevent dental caries, since it increases the resistance of the enamel to acid attack. It is a component of bone mineral and some studies have shown anti-fracture effects at low doses but excessive intakes may compromise bone structure.

Sodium, potassium and magnesium

The roles of these are discussed in Chapter 16. Western diets are high in sodium due to the sodium chloride (salt) that is added to processed food. In the UK it is suggested that daily salt intakes are kept well below 6 g.

Other essential inorganic nutrients

These include chloride (counter-ion to sodium and potassium), cobalt (required for vitamin B12), sulphur (constituent of methionine and cysteine), manganese (required for or activates many enzymes) and chromium (required for insulin action).

Clinical assessment and investigation of nutritional status

The diverse manifestations of inadequate nutrition dictate that its clinical assessment and investigation involve many systems. Energy balance is reflected in body composition, which is most readily assessed by clinical anthropometric measurements. It can also be tested non-invasively by the measurement of body fat by bioimpedance or dual energy X-ray absorptiometry (DEXA) scanning. Abnormal micronutrient status is commonly manifest in clinical signs in the skin and mucous membranes, or in other systems.

A dietary history provides useful information, especially when obtained by a dietitian. A weighed food diary is considered to be the gold standard dietary assessment but is rarely conducted in clinical practice. Body stores of some micronutrients can be assessed by biochemical tests, although many of these provide indicative rather than definitive results (Box 5.22).

Anthropometric measurements

Body mass index (BMI) is useful for categorising under- and over-nutrition. It is the weight in kilograms divided by the height in metres, squared. For example, an adult weighing 70 kg with a height of 1.75 m has a BMI of $70/1.75^2 = 22.9 \text{ kg/m}^2$. If height cannot be determined (e.g. in older people with kyphosis or in those who cannot stand), a surrogate measure is:

- *the demispan*: measured from the sternal notch to the middle finger; height = $0.73 \times (2 \times \text{demispan}) + 0.43$
- *knee height*:
females (60–80 years): height (cm) = (knee height (cm) $\times 1.91$) – (age (years) $\times 0.17$) + 75.00
males (60–80 years): height (cm) = (knee height (cm) $\times 2.05$) + 59.01.

BMI does not discriminate between fat mass and lean body mass and can be increased by muscle mass (e.g. in athletes). Moreover, there are ethnic differences in body fat content; at the same BMI, Asians have more body fat than Europeans. For optimal health, the BMI should be 18.5–24.9 kg/m².

An indication of the degree of abdominal obesity is the waist circumference, measured at the level of the umbilicus. Hip circumference can be measured at the level of the greater trochanters; waist:hip ratios show whether the distribution of fat is android or gynoid (see below). Skinfold measurements can be used to calculate body fat content, whereas relative loss of muscle and subcutaneous fat can be estimated by measuring mid-arm circumference (at the middle of the humerus) and skinfold thickness over the triceps (using special callipers); muscle mass is estimated by subtracting triceps skinfold thickness from mid-arm circumference.

5.22 Biochemical assessment of vitamin status

Nutrient	Biochemical assessments of deficiency or excess
Vitamin A	Serum retinol may be low in deficiency Serum retinyl esters: when vitamin A toxicity is suspected
Vitamin D	Plasma/serum 25-hydroxy vitamin D (25(OH)D): reflects liver stores Plasma/serum 1,25(OH) ₂ D: difficult to interpret
Vitamin E	Serum tocopherol:cholesterol ratio
Vitamin K	Coagulation assays (e.g. prothrombin time) Plasma vitamin K
Vitamin B₁ (thiamin)	Red blood cell transketolase activity or whole blood vitamin B ₁
Vitamin B₂ (riboflavin)	Red blood cell glutathione reductase activity or whole blood vitamin B ₂
Vitamin B₃ (niacin)	Urinary metabolites: 1-methyl-2-pyridone-5-carboxamide, 1-methylnicotinamide
Vitamin B₆	Plasma pyridoxal phosphate or erythrocyte transaminase activation coefficient
Vitamin B₁₂	Plasma B ₁₂ : poor measure of overall vitamin B ₁₂ status but will detect severe deficiency. Alternatives (methylmalonic acid and holotranscobalamin) are not used routinely
Folate	Red blood cell folate Plasma folate: reflects recent intake but also detects unmetabolised folic acid from foods and supplements
Vitamin C	Leucocyte ascorbic acid: assesses vitamin C tissue stores Plasma ascorbic acid: reflects recent (daily) intake

PRESENTING PROBLEMS OF ALTERED ENERGY BALANCE

Obesity

Obesity is widely regarded as a pandemic, with potentially disastrous consequences for human health. Nearly one-quarter of adults in the UK were obese (i.e. BMI ≥ 30 kg/m²) in 2006, compared with 7% prevalence in 1980 and 16% in 1995. Moreover, almost two-thirds of the UK adult population are overweight (BMI ≥ 25 kg/m²), although there is considerable regional and age group variation. In developing countries, average national rates of obesity are low, but these figures may disguise high rates of obesity in urban communities; for example, nearly one-quarter of women in urban India are overweight.

There is increasing public awareness of the health implications of obesity. Many patients will seek medical help for their obesity, others will present with one of the complications of obesity, and increasing numbers are being identified during health screening examinations.

Complications of obesity

Obesity has adverse effects on both mortality and morbidity (Box 5.23). Changes in mortality are difficult to analyse due to the confounding effects of lower body weight in cigarette smokers. However, it is clear that the lowest mortality rates are seen in Europeans in the BMI range 18.5–24 kg/m² (and at lower BMI in Asians).

5.23 Complications of obesity	
Risk factors	Outcomes
'Metabolic syndrome'	
Type 2 diabetes	Coronary heart disease
Hypertension	Stroke
Hyperlipidaemia	Diabetes complications
Liver fat accumulation	
	Non-alcoholic steatohepatitis
	Cirrhosis
Restricted ventilation	
	Exertional dyspnoea
	Sleep apnoea
	Respiratory failure (Pickwickian syndrome)
Mechanical effects of weight	
	Urinary incontinence
	Osteoarthritis
	Varicose veins
Increased peripheral steroid interconversion in adipose tissue	
	Hormone-dependent cancers (breast, uterus)
	Polycystic ovary syndrome (infertility, hirsutism; p. 760)
Others	
	Psychological morbidity (low self-esteem, depression)
	Socioeconomic disadvantage (lower income, less likely to be promoted)
	Gallstones
	Colorectal cancer
	Skin infections (groin and submammary candidiasis; hidradenitis)

It is suggested that obesity at age 40 years can reduce life expectancy by up to 7 years for non-smokers and by 13 years for smokers. Coronary heart disease (Fig. 5.11) is the major cause of death but cancer rates are also increased in the overweight, especially colorectal cancer in males and cancer of the gallbladder, biliary tract, breast, endometrium and cervix in females. Obesity has little effect on life expectancy at > 70 years, but the obese do spend a greater proportion of their active life disabled. Epidemic obesity has been accompanied by an epidemic of type 2 diabetes (p. 803) and osteoarthritis, particularly of the knee. Although an increased body size results in greater bone density through increased mechanical stress, it is not certain whether this translates to a lower incidence of osteoporotic fractures (p. 1116). Obesity may have profound psychological consequences, compounded by stigmatisation of the obese in many societies.

Body fat distribution

For some complications of obesity, the distribution rather than the absolute amount of excess adipose tissue appears to be important. Increased intra-abdominal fat causes 'central' ('abdominal', 'visceral', 'android' or 'apple-shaped') obesity, which contrasts with subcutaneous fat

Fig. 5.11 Risks of diabetes and cardiovascular disease in overweight and obese women. Data are from the Nurses' Health Study in the USA, mostly of Caucasian women. In some ethnic groups (e.g. South Asians, Native Americans) and in people with higher waist circumference, the metabolic complications are even more severe at a given level of BMI.

accumulation causing 'generalised' ('gynoid' or 'pear-shaped') obesity; the former is more common in men and is more closely associated with type 2 diabetes, the metabolic syndrome and cardiovascular disease (see Box 5.23). The key difference between these depots of fat may lie in their vascular anatomy, with intra-abdominal fat draining into the portal vein and thence directly to the liver. Thus many factors which are associated with adipose tissue (including free fatty acids; 'adipokines', such as tumour necrosis factor- α , adiponectin and resistin; and steroid hormones) may be at higher concentration in the liver and hence induce insulin resistance and promote type 2 diabetes (p. 803).

Aetiology

Accumulation of fat results from a discrepancy between energy consumption and energy expenditure which is too large to be defended by the hypothalamic regulation of BMR. A continuous small daily positive energy balance of only 0.2–0.8 MJ (50–200 kcal; < 10% of intake) would lead to weight gain of 2–20 kg over a period of 4–10 years. Given the cumulative effects of subtle energy excess, body fat content shows 'tracking' with age such that obese children usually become obese adults. Weight tends to increase throughout adult life, as BMR and physical activity decrease (see Fig. 5.8).

The pandemic of obesity reflects changes in both energy intake and energy expenditure (Box 5.24), although both are difficult to measure reliably. The estimated average global daily supply of food energy per person increased from ~9.8 MJ (~2350 kcal) in the 1960s to ~11.7 MJ (~2800 kcal) in the 1990s, but its delivery is unequal. For example, in India it is estimated that 5% of the population receives 40% of the available food energy, leading to obesity in the urban population in parallel with persisting under-nutrition in some rural communities. In affluent societies, a significant proportion of this food supply is discarded. In the US, the average daily energy intake of men reportedly rose from 10.2 MJ (2450 kcal) in 1971 to 11.0 MJ (2618 kcal) in 2000. Portion sizes, particularly of energy-dense foods such as drinks with highly refined sugar content and salty snacks, have increased. However, data in the UK suggest that energy intakes have declined (which may in part be due to deliberate restriction or 'dieting'), but this is apparently insufficient to compensate for the decrease in physical activity levels in recent years. Obesity is correlated positively with the number of hours spent watching television, and inversely with levels of physical activity (e.g. stair climbing). It is suggested that minor activities such as fidgeting

and chewing gum may contribute to energy expenditure and protect against obesity.

Susceptibility to obesity

Susceptibility to obesity and its adverse consequences undoubtedly varies between individuals. It is not true that obese subjects have a 'slow metabolism', since their BMR is higher than that of lean subjects. Twin and adoption studies confirm a genetic influence on obesity. The pattern of inheritance suggests a polygenic disorder, with small contributions from a number of different genes, together accounting for 25–70% of variation in weight. Recent results from 'genome-wide' association studies of polymorphisms in large numbers of people (p. 51) have identified a handful of genes that influence obesity, some of which encode proteins known to be involved in the control of appetite or metabolism and some of which have unknown function. However, these genes account for < 5% of variation in body weight.

A few rare single gene disorders have been identified which lead to severe childhood obesity. These include mutations of the melanocortin-4 receptor (MC4R) that accounts for approximately 5% of severe early-onset obesity; defects in the enzymes processing proopiomelanocortin (POMC, the precursor for adrenocorticotrophic hormone (ACTH)) in the hypothalamus; and mutations in the leptin gene (see Fig. 5.9). The latter can be cured by injected leptin treatment. Additional genetic conditions in which obesity is a feature include the Prader-Willi (see Box 3.3, p. 51) and Lawrence-Moon-Biedl syndromes.

Reversible causes of obesity and weight gain

In a small minority of patients presenting with obesity, specific causal factors can be identified and treated (Box 5.25). These patients are distinguished from those with idiopathic obesity by their short history, with a recent marked change in the trajectory of their adult weight gain.

5.25 Potentially reversible causes of weight gain

Endocrine factors

- Hypothyroidism
- Cushing's syndrome
- Insulinoma
- Hypothalamic tumours or injury

Drug treatments

- Tricyclic antidepressants
- Sulphonylureas
- Oestrogen-containing contraceptive pill
- Corticosteroids
- Sodium valproate
- β -blockers

5.24 Some reasons for the increasing prevalence of obesity—the 'obesogenic' environment

Increasing energy intake

- \uparrow Portion sizes
- \uparrow Snacking and loss of regular meals
- \uparrow Energy-dense food (mainly fat)
- \uparrow Affluence

Decreasing energy expenditure

- \uparrow Car ownership
- \downarrow Walking to school/work
- \uparrow Automation; \downarrow manual labour
- \downarrow Sports in schools
- \uparrow Time spent on computer games and watching TV
- \uparrow Central heating

Clinical assessment and investigations

In assessing an individual presenting with obesity, the aims are to:

- quantify the problem
- exclude an underlying cause
- identify complications
- reach a management plan.

Severity of obesity can be quantified using the BMI (Box 5.26). A waist circumference of > 102 cm in men or > 88 cm in women indicates that the risk of metabolic and cardiovascular complications of obesity is high.

i 5.26 Quantifying obesity with body mass index (weight/height²)		
BMI (kg/m ²)	Classification*	Risk of obesity comorbidity
18.5–24.9	Normal range	Negligible
25.0–29.9	Overweight	Mildly increased
> 30.0	Obese	
30.0–34.9	Class I	Moderate
35.0–39.9	Class II	Severe
> 40.0	Class III	Very severe

*Classification of the World Health Organization (WHO) and International Obesity Task Force. The Western Pacific Region Office of WHO recommends that, amongst Asians, BMI > 23.0 is overweight and > 25.0 is obese.

A dietary history may be helpful in guiding dietary advice, but is notoriously susceptible to under-reporting of food consumption. It is important to consider 'pathological' eating behaviour (such as binge eating, nocturnal eating or bulimia; p. 249), which may be the most important issue to address in some patients. Alcohol is an important source of energy intake and should be considered in detail.

The history of weight gain may help diagnose underlying causes. A patient who has recently gained substantial weight or at a faster rate than previously, and is not taking relevant drugs (see Box 5.25), is more likely to have an underlying disorder such as hypothyroidism (p. 741) or Cushing's syndrome (p. 770). All obese patients should have thyroid function tests performed on one occasion, and an overnight dexamethasone suppression test or 24-hour urine free cortisol if Cushing's syndrome is suspected. Monogenic and 'syndromic' causes of obesity are usually only relevant in children presenting with severe obesity.

Assessment of the diverse complications of obesity (see Box 5.23) requires a thorough history, examination and screening investigations. The impact of obesity on the patient's life and work is a major consideration. Assessment of other cardiovascular risk factors is important. Blood pressure should be measured with a large cuff, if required (p. 605). Associated type 2 diabetes and dyslipidaemia are detected by measuring blood glucose and a serum lipid profile, ideally in a fasting morning sample. Elevated serum transaminases occur in patients with non-alcoholic fatty liver disease (p. 956).

Management

The health risks of obesity are largely reversible. Interventions proven to reduce weight in obese patients also ameliorate cardiovascular risk factors. Lifestyle advice which lowers body weight and increases physical exercise reduces the incidence of type 2 diabetes (p. 818). Given the high prevalence of obesity and the large magnitude of its risks, population strategies to prevent and reverse obesity are high on the priority list for most health organisations. Initiatives include promoting healthy eating in schools, enhancing walking and cycling options for commuters, and liaising with the food industry to reduce energy and fat content and to label foods appropriately. Unfortunately, 'low-fat' foods are often still energy-dense, and current lifestyles with labour-saving devices, sedentary work and passive leisure

activities have much lower energy requirements than the manual labour and household duties of previous generations.

Most patients seeking assistance with obesity are motivated to lose weight but have attempted to do so previously without long-term success. Often weight will have oscillated between periods of successful weight loss and then regain of weight ('recidivism'). They may hold misconceptions that they have an underlying disease, inaccurate perceptions of their energy intake and expenditure, and an unrealistic view of the target weight which they would regard as 'success'. An empathetic explanation of energy balance, which recognises that some individuals are more susceptible to obesity than others and therefore require greater deficits in energy balance in order to lose and sustain body weight, is important. Exclusion of underlying 'hormone imbalance' with simple tests is reassuring and shifts the focus on to consideration of energy balance. Appropriate goals for weight loss should be agreed, recognising that the slope of the relationship between obesity and many of its complications becomes steeper with increasing BMI, so that a given amount of weight loss achieves greater risk reduction at higher levels of BMI. A reasonable goal for most patients is to lose 10% of body weight.

The management plan will vary according to the severity of the obesity (see Box 5.26) and the associated risk factors and complications. It will also be influenced by availability of resources; health-care providers and regulators have generally been careful not to recommend expensive interventions (especially long-term drug therapy and surgery) for everyone who is overweight. Instead, most guidelines focus resources on short-term interventions in those who have high health risks and comorbidities associated with their obesity, and who have demonstrated their capacity to alter their lifestyle to achieve weight loss (Fig. 5.12).

Lifestyle advice

Behavioural modification to avoid some of the effects of the 'obesogenic' environment (see Box 5.24) is the cornerstone of long-term control of weight. Regular eating

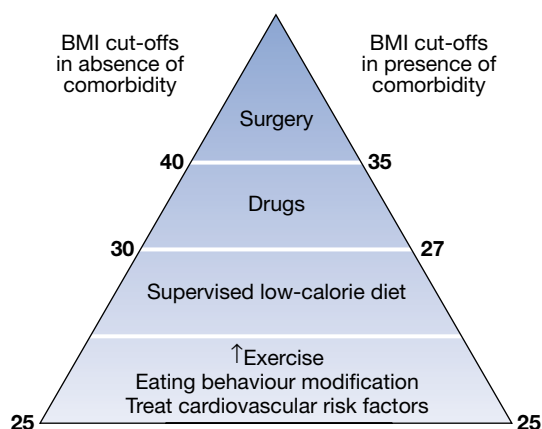

Fig. 5.12 Therapeutic options for obesity. Relevant comorbidities include type 2 diabetes, hypertension, cardiovascular disease, sleep apnoea, and waist circumference > 102 cm in men or 88 cm in women. This is an approximate consensus of the numerous national guidelines which vary slightly in their recommendations and are revised every few years.

5.27 Low-calorie diet therapy for obesity

Diet	% carbohydrate	% fat	% protein	Comment
Normal (typical developed country)	50	30	15	
Moderate fat (e.g. Weight Watchers)	60	25	15	Maintains balance in macronutrients and micronutrients while reducing energy-dense fats
Low carbohydrate (e.g. Atkins)	10	60	30	Induction of ketosis may suppress hunger
High protein (e.g. Zone)	43	30	27	Protein has greater satiety effect than other macronutrients
Low fat (e.g. Ornish)	70	13	17	

patterns and maximising physical activity are advised, with reference to the modest extra activity required to increase PAL ratios (see Fig. 5.8C, p. 108). Where possible, this should be incorporated in the daily routine (e.g. walking rather than driving to work), since this is more likely to be sustained. Alternative exercise (e.g. swimming) may be necessary if musculoskeletal complications prevent walking. Changes in eating behaviour (including food selection, portion size control, avoidance of snacking, regular meals to encourage satiety, and substitution of sugar with artificial sweeteners) should be discussed. Regular support from a dietitian or attendance at a weight loss group may be helpful.

Weight loss diets

In overweight people, adherence to the lifestyle advice above may gradually induce weight loss. In obese patients, more active intervention is usually required to lose weight before conversion to 'weight maintenance' advice above. A significant industry has developed in marketing diets for weight loss. These vary substantially in their balance of macronutrients (Box 5.27), but there is little evidence that they vary in their medium-term (1 year) efficacy. They all involve a reduction of daily total energy intake of ~2.5 MJ (600 kcal) from the patient's normal consumption. The goal is to lose ~0.5 kg/week. Weight loss is highly variable, with patient compliance being the major determinant of success. There is some evidence that weight loss diets are most effective in their early weeks, and that compliance is improved by novelty of the diet; this provides some justification for switching to a different dietary regime when weight loss slows on the first diet. Vitamin supplementation is wise in those diets in which macronutrient balance is markedly disturbed.

In some patients more rapid weight loss is required, e.g. in preparation for surgery. There is no role for starvation diets, which risk profound loss of muscle mass and the development of arrhythmias (and even sudden death) secondary to elevated free fatty acids, ketosis and deranged electrolytes. Very low calorie diets (VLCDs) are recommended for short-term rapid weight loss, producing losses of 1.5–2.5 kg/week compared to 0.5 kg/week on conventional regimes, but require the supervision of an experienced physician and nutritionist. The composition of the diet should ensure a minimum of 50 g of protein each day for men and 40 g for women to minimise muscle degradation. Energy content should be a minimum of 1.65 MJ (400 kcal) for women of height < 1.73 m, and 2.1 MJ (500 kcal) for all men and for women taller than 1.73 m. Side-effects are a problem in the early

stages and include orthostatic hypotension, headache, diarrhoea and nausea.

Drugs

A huge investment has been made by the pharmaceutical industry in finding drugs for obesity. The side-effect profile has limited the use of many agents, but a few drugs are currently licensed (Box 5.28). There is no role for diuretics, or for thyroxine therapy without biochemical evidence of hypothyroidism.

Orlistat inhibits pancreatic and gastric lipases and thereby decreases the hydrolysis of ingested triglycerides, reducing dietary fat absorption by ~30%. The drug is not absorbed and adverse side-effects relate to the effect of the resultant fat malabsorption on the gut: namely, loose stools, oily spotting, faecal urgency, flatulence and the potential for malabsorption of fat-soluble vitamins. Orlistat is taken with each of the three main meals of the day and the dose can be adjusted (60–120 mg) to minimise side-effects. Its efficacy is shown in Box 5.29 and Figure 5.13; these effects may be explained because patients taking orlistat adhere better to low-fat diets in order to avoid unpleasant gastrointestinal side-effects.

Sibutramine reduces food intake through β_1 -adrenoceptor and 5-HT_{2A/2C} (5-hydroxytryptamine,

5.28 Drugs which lower body weight¹

Status	Drugs	Mechanism of action
Not recommended due to toxicity	Amphetamines Fenfluramine, dexfenfluramine Rimonabant ²	Catecholaminergic in CNS and periphery Serotonergic in CNS Cannabinoid receptor antagonist
Not recommended as primary treatment; weight loss a useful minor/temporary effect	Fluoxetine Metformin Exenatide	Serotonergic in CNS Probably inhibits mitochondrial respiratory chain Glucagon-like peptide (GLP)-1 analogue
Currently recommended	Orlistat Sibutramine	Pancreatic lipase inhibitor Serotonergic in CNS

¹ Many other approaches are in development, several of which have reached clinical trials.

² Rimonabant is not licensed in the USA and its licence in Europe is under threat, due to concerns about its effects on mood.

EBM 5.29 Efficacy of anti-obesity drugs

'In a meta-analysis of 30 placebo-controlled RCTs, orlistat reduced body weight by 2.9 kg (95% confidence intervals, 2.5–3.2 kg), sibutramine by 4.2 kg (3.6–4.7 kg), and rimonabant by 4.7 kg (4.1–5.3 kg). Orlistat and rimonabant improved serum lipid profile, blood pressure, and glycaemic control in diabetic patients. However, sibutramine increased blood pressure and rimonabant increased the risk of mood disorders.'

• Rucker D, et al. *British Medical Journal* 2007 335:1194–1199.

serotonin) receptor agonist activity in the central nervous system. Weight loss with sibutramine is 3–5 kg better than placebo with 6 months' therapy and is associated with an improvement in lipid profile (see Box 5.29). Side-effects include dry mouth, constipation and insomnia. Unfortunately, noradrenergic effects of the drug can increase heart rate and blood pressure; these effects are especially undesirable in obese patients. Sibutramine is thus usually second choice after orlistat and cannot be used in those with hypertension or cardiovascular disease. There is insufficient evidence to recommend co-prescription of orlistat and sibutramine.

Rimonabant is a cannabinoid receptor antagonist which acts in the hypothalamus to reduce appetite and may also have beneficial effects in peripheral tissues. Its efficacy in patients with obesity and type 2 diabetes is similar to orlistat (see Box 5.29), including reducing HbA1c by ~1%. However, rimonabant may exacerbate or induce depression and has been associated with a small increased risk of suicide, which has prevented it being licensed in the US and has limited its use in Europe.

Drug therapy is usually reserved for patients with high risk of complications from obesity (see Fig. 5.12), and its optimum timing and duration are controversial. Although life-long therapy is advocated for many drugs which reduce risk on the basis of relatively

short-term research trials (e.g. drugs for hypertension and osteoporosis), patients who continue to take anti-obesity drugs tend to regain weight with time (see Fig. 5.13). This, together with finite health-care resources, has led to the recommendation in some guidelines that anti-obesity drugs are used in the short term to maximise the weight loss achieved with low-calorie diets (so that inevitable regain of weight starts from a lower baseline), but are not used in the long-term maintenance of weight.

Surgery

'Bariatric' surgery to reduce the size of the stomach is by far the most effective long-term treatment for obesity (see Fig. 5.13) and is the only anti-obesity intervention that has been associated with reduced mortality. Several approaches are used (Fig. 5.14) and all can be performed laparoscopically. The mechanism of weight loss may not relate to limiting the stomach or absorptive capacity per se, but rather in disrupting the release of ghrelin from the stomach or of other peptides from the small bowel, thereby enhancing satiety signalling in the hypothalamus. Complications depend upon the approach. Mortality is low in experienced centres, but post-operative respiratory problems, wound infection and dehiscence, staple leaks, stomal stenosis, marginal ulcers and venous thrombosis are common. Additional problems may arise at a later stage, such as pouch and distal oesophageal dilatation, persistent vomiting, 'dumping' (p. 873) and micronutrient deficiencies, particularly of folate, vitamin B₁₂ and iron, which are of concern especially to women contemplating pregnancy.

Bariatric surgery should be contemplated in motivated patients who have very high risks of complications of obesity (see Fig. 5.12), in whom extensive dietary and drug therapy has been inadequately effective. Only experienced specialist surgeons should undertake these procedures.

Fig. 5.13 Effects of orlistat and bariatric surgery on weight loss. [A] Data are from Torgerson JS, et al. *Diabetes Care* 2004; 27:155–161. [B] Data for surgery are from Sjostrom L, et al. *New Engl J Med* 2004; 351:2683–2693. Each obese subject undergoing surgery was matched with a control subject whose obesity was 'treated' by standard non-operative interventions. Note that the maximum weight loss achieved with orlistat was ~11%; surgery achieves much more substantial and prolonged weight loss.

Fig. 5.14 Bariatric surgical procedures. **A** Vertical banded gastroplasty. **B** Laparoscopic banding, with the option of a reservoir band and subcutaneous access to restrict the stomach further after compensatory expansion has occurred. **C** Roux-en-Y gastric bypass.

Cosmetic surgical procedures may be required in obese patients. Apronectomy is usually advocated to remove an overhang of abdominal skin, especially if infected or ulcerated. This operation is of no value for long-term weight reduction if food intake remains unrestricted.

Treatment of additional risk factors

Obesity must not be treated in isolation and other risk factors must be addressed, including smoking, excess alcohol consumption, diabetes mellitus, hyperlipidaemia and hypertension. Treatment of these is discussed in the relevant chapters.

Under-nutrition

Starvation and famine

There remain regions of the world, particularly rural Africa, where under-nutrition due to famine is endemic, the prevalence of BMI < 18.5 kg/m² (Box 5.30) in adults is as high as 20%, and growth retardation due to under-nutrition affects 50% of children.

5.30 Classification of under-nutrition in adults by body mass index (weight/height²)	
BMI (kg/m ²)	Classification
> 20	Adequate nutrition
18.5–20	Marginal
< 18.5	Under-nutrition
17–18.4	Mild
16–17	Moderate
< 16	Severe

WHO reports that under-nutrition is responsible for more than half of all childhood deaths world-wide. Starvation is manifest as marasmus (malnutrition with marked muscle-wasting); or when additional complicating mechanisms, such as oxidative stress, come into play, malnourished children can develop kwashiorkor (malnutrition with oedema). Growth retardation is due to deficiency of key nutrients, e.g. protein, zinc, potassium, phosphorus and sulphur. Treatment of these childhood conditions is not discussed in this adult medicine textbook.

In adults, starvation is the result of chronic under-nutrition, i.e. sustained negative energy (calorie) balance. Causes are shown in Box 5.31. Causes of weight loss are considered further on page 858.

Clinical assessment

In starvation, the severity of malnutrition can be assessed by anthropometric measurements, such as

5.31 Causes of under-nutrition and weight loss in adults	
Decreased energy intake	
<ul style="list-style-type: none"> • Famine • Persistent regurgitation or vomiting • Anorexia, including anorexia nervosa • Malabsorption (e.g. small intestinal disease) • Maldigestion (e.g. pancreatic exocrine insufficiency) 	
Increased energy expenditure	
<ul style="list-style-type: none"> • Increased BMR (thyrotoxicosis, trauma, fever, cancer cachexia) • Excessive physical activity (e.g. marathon runners) • Energy loss (e.g. glycosuria in diabetes) • Impaired energy storage (e.g. Addison's disease, pheochromocytoma) 	

BMI (see Box 5.30). Demispan and mid-arm circumference measurements (p. 115) are most useful in monitoring progress during treatment. The clinical features of severe under-nutrition in adults include:

- weight loss
- thirst, craving for food, weakness and feeling cold
- nocturia, amenorrhoea or impotence
- lax, pale, dry skin with loss of turgor and, occasionally, pigmented patches
- cold and cyanosed extremities, pressure sores
- hair thinning or loss (except in adolescents)
- muscle-wasting, best demonstrated by the loss of the temporalis and periscapular muscles and reduced mid-arm circumference
- loss of subcutaneous fat, reflected in reduced skinfold thickness and mid-arm circumference
- hypothermia, bradycardia, hypotension and small heart
- oedema, which may be present without hypoalbuminaemia ('famine oedema')
- distended abdomen with diarrhoea
- diminished tendon jerks
- apathy, loss of initiative, depression, introversion, aggression if food is nearby
- susceptibility to infections (Box 5.32).

Under-nutrition often leads to vitamin deficiencies, especially of thiamin, folate and vitamin C (see below). Diarrhoea can lead to depletion of sodium, potassium and magnesium. The high mortality rate in famine situations is often due to outbreaks of infection, e.g. typhus or cholera, but the usual signs of infection may not be apparent. In advanced starvation, patients become completely inactive and may assume a flexed, fetal position. In the last stage of starvation, death comes quietly and often quite suddenly. The very old are most vulnerable. All organs are atrophied at necropsy, except the brain, which tends to maintain its weight.

Investigations

In a famine, laboratory investigations may be impractical, but will show that plasma free fatty acids are increased and there is ketosis and a mild metabolic acidosis. Plasma glucose is low but albumin concentration is often maintained because the liver still functions normally. Insulin secretion is diminished, glucagon and cortisol tend to increase, and reverse T_3 replaces normal triiodothyronine (p. 736). The resting metabolic rate falls, partly because of reduced lean body mass and partly because of hypothalamic compensation (see Fig. 5.8, p. 108). The urine has a fixed specific gravity and creatinine excretion becomes low. There may be mild anaemia, leucopenia and thrombocytopenia. The erythrocyte

sedimentation rate is normal unless there is infection. Tests of delayed skin hypersensitivity, e.g. to tuberculin, are falsely negative. The electrocardiogram shows sinus bradycardia and low voltage.

Management

Whether in a famine or in wasting secondary to disease, the severity of under-nutrition is graded according to BMI (see Box 5.30). People with mild starvation are in no danger; those with moderate starvation need extra feeding; those who are severely underweight need hospital care.

In severe starvation, there is atrophy of the intestinal epithelium and of the exocrine pancreas, and the bile is dilute. When food becomes available, it should be given by mouth in small, frequent amounts at first, using a suitable formula preparation (Box 5.33). Individual energy requirements can vary by 30%. During rehabilitation, more concentrated formula can be given with additional food that is palatable and similar to the usual staple meal. Salt should be restricted and micronutrient supplements may be essential (e.g. potassium, magnesium, zinc and multivitamins). Between 6.3 and 8.4 MJ/day (1500–2000 kcal/day) will arrest progressive under-nutrition, but additional energy may be required for regain of weight. During refeeding, a weight gain of 5% body weight per month indicates satisfactory progress. Other care is supportive, and includes attention to the skin, adequate hydration, treatment of infections, and careful monitoring of body temperature since thermoregulation may be impaired.

5.33 WHO recommended diets for refeeding

Nutrient (per 100 mL)	F-75 diet ¹	F-100 diet ²
Energy	315 kJ (75 kcal)	420 kJ (100 kcal)
Protein (g)	0.9	2.9
Lactose (g)	1.3	4.2
Potassium (mmol)	3.6	5.9
Sodium (mmol)	0.9	1.9
Magnesium (mmol)	0.43	0.73
Zinc (mg)	2.0	2.3
Copper (mg)	0.25	0.25
Percentage of energy from		
Protein	5	12
Fat	32	53
Osmolality (osmol/L)	333	419
Dose	170 kJ/kg (40 kcal/kg)	630–920 kJ/kg (150–220 kcal/kg)
Rate of feeding by mouth	2.2 (mL/kg/hr)	Gradual increase in volume, 4-hourly

¹ F-75 is prepared from milk powder (25 g), sugar (70 g), cereal flour (35 g), vegetable oil (27 g), and vitamin and mineral supplements, made up to 1 L with water.

² F-100 (1 L) contains milk powder (80 g), sugar (50 g), vegetable oil (60 g), and vitamin and mineral supplements (no cereal).

5.32 Infections associated with starvation

- Gastroenteritis and Gram-negative septicaemia
- Respiratory infections, especially bronchopneumonia
- Certain viral diseases, especially measles and herpes simplex
- Tuberculosis
- Streptococcal and staphylococcal skin infections
- Helminthic infestations

Circumstances and resources are different in every famine, but many problems are non-medical and concern organisation, infrastructure, liaison, politics, procurement, security and ensuring that food is distributed on the basis of need. Lastly, plans must be made for the future for prevention and/or earlier intervention if similar circumstances prevail.

Under-nutrition in hospital

Under-nutrition is a common problem in the hospital setting. In the UK, approximately one-third of patients are affected by moderate or severe under-nutrition on admission. The elderly are particularly at risk (Box 5.34). Once in hospital, many patients lose weight due to factors such as poor appetite, poor dental health, concurrent illness and even being kept 'nil by mouth' for investigations. Under-nutrition is poorly recognised in hospital and has serious consequences. Physical effects include impaired immunity and muscle weakness, which in turn affect cardiac and respiratory function, and delayed wound healing after surgery with increased risks of post-operative infection. The undernourished patient is often apathetic and withdrawn, which may be mistaken for a depres-

sive illness and can affect cooperation with treatment and rehabilitation.

This can be averted with proper monitoring and involvement of an appropriate multidisciplinary team. As a minimum standard, all patients should be weighed on admission to hospital and at least weekly until discharge. A scoring system for identifying patients at nutritional risk is shown in Figure 5.15.

Nutritional support of the hospital patient

Normal diet

As a first step, patients should be encouraged to eat a normal and adequate diet. This is often neglected and there is evidence of substantial wastage in hospital food. In patients at risk of under-nutrition (see Fig. 5.15) quantities eaten should be recorded on a food chart. Hospital staff must identify and overcome barriers to adequate food intake, such as unpalatability of food, cultural and religious factors influencing acceptability of food, difficulty with hand dexterity (arthritis, stroke), immobility in bed, or poor oral health. Hospital catering departments have an important role in providing acceptable and adequate meals.

Dietary supplements

If sufficient nutritional intake cannot be achieved from normal diet alone, then dietary supplements should be used. These are drinks with high energy and protein content, and are available in cartons as manufactured, flavoured products or made in the hospital kitchen from milk products and egg. They should be prescribed, and administered by nursing staff, to ensure that they are taken regularly. Dietary supplements do not significantly affect the patient's consumption of normal food.

Enteral tube feeding

Patients who are unable to swallow may require artificial nutritional support: for example, after acute stroke or throat surgery or with long-term neurological problems such as motor neuron disease and multiple sclerosis. The enteral route should always be used if possible, since feeding via the gastrointestinal tract preserves the integrity of the mucosal barrier. This prevents bacteraemia

5.34 Energy balance in old age

- **Body composition:** muscle mass is decreased and percentage body fat increased.
- **Energy expenditure:** with the fall in lean body mass, BMR is decreased and energy requirements are reduced.
- **Weight loss:** after weight gain throughout adult life, weight often falls beyond the age of 70 years. This may reflect decreased appetite, loss of smell and taste, and decreased interest in and financial resources for food preparation, especially after loss of a partner.
- **BMI:** less reliable in old age as height is lost (due to kyphosis, osteoporotic crush fractures, loss of intervertebral disc spaces). Alternative measurements include arm demispan and knee height (p. 115), which can be extrapolated to estimate height.

Fig. 5.15 Screening hospitalised patients for risk of malnutrition. Adapted from the British Association of Parenteral and Enteral Nutrition 'Malnutrition Universal Screening Tool' (www.bapen.org.uk).

and, in intensive care patients, reduces the risk of multi-organ failure (p. 199).

If the need for artificial nutritional support is thought to be short-term, then feeding is instituted using a fine-bore nasogastric tube. The position of the tube in the stomach must be confirmed before any fluid is administered, as intrabronchial tube placement is not uncommon and severe respiratory complications can occur if fluid is inadvertently infused into a bronchus. Gastric aspirate has a pH < 4. If there is any doubt about the result of pH testing of the aspirate, then a chest X-ray should be performed to confirm the tube is below the diaphragm. Thereafter, specially prepared liquid feeds are administered either by continuous infusion or using a bolus technique. If the patient fails to absorb the administered feed or vomits it, this may indicate gastric outlet obstruction or gastric stasis, which can be overcome by placing a nasojejunal tube.

If long-term artificial enteral feeding is needed, a percutaneous endoscopic gastrostomy (PEG) should be sited (Fig. 5.16). A PEG tube is more comfortable for the patient, since there is no irritation to the nasal mucosa. The tube is less likely to become displaced or to be pulled out, so the feed can be given more reliably. However, inserting a gastrostomy is an invasive procedure and may be complicated by local infection (30%) and inadvertent puncture of other intra-abdominal organs, causing peritonitis and bleeding. It takes approximately 10 days for a fibrous tract to form around the PEG tube. If the PEG is displaced or removed during that time, there is a high risk of peritonitis. If a problem occurs with food absorption, a jejunal extension can be placed through the PEG tube and liquid feed administered directly into the small bowel.

Parenteral nutrition

Intravenous feeding should only be used when enteral feeding is impossible. Parenteral feeding is expensive and

carries higher risks of complications. There is little benefit if parenteral feeding is required for less than 1 week.

There are a number of possible routes for parenteral nutrition:

- *Peripheral venous cannula*. This can only be used for low-osmolality solutions due to the development of thrombophlebitis, and is unsuitable for patients with high nutritional requirements.
- *Peripherally inserted cannula (PIC)*. A 20 cm cannula is placed in a mid-arm vein. Once again, hyperosmolar solutions cannot be used.
- *Peripherally inserted central catheter (PICC)*. A 60 cm cannula is inserted into a vein in the antecubital fossa. The distal end lies in a central vein, allowing hyperosmolar solutions to be used.
- *Central line*. The subclavian route is preferred to the internal jugular vein, due to lower infection rates. Hyperosmolar solutions can be used without difficulty. Lines need to be handled with strict aseptic technique, and a single lumen tube is preferred, to prevent infection.

If access has been gained to a central vein, nutritional support is usually given as an 'all in one' mixture. The main energy source is provided by carbohydrate, usually as glucose. The solution also contains amino acids, lipid emulsion, electrolytes, trace elements and vitamins. These are mixed as a large bag in a sterile environment, with the constituents adjusted according to the results of regular blood monitoring. Relevant tests include:

- daily: urea and electrolytes, glucose
- twice weekly: liver function tests, calcium, phosphate, magnesium
- weekly: full blood count, zinc, triglycerides
- monthly: copper, selenium, manganese.

If the patient develops fever or other features of septicaemia, it should be assumed to be due to a line infection

Fig. 5.16 Percutaneous endoscopic gastrostomy (PEG) placement. **A** Finger pressure on the anterior abdominal wall is noted by the endoscopist. **B** Following insertion of a cannula through the anterior abdominal wall into the stomach, a guidewire is threaded through the cannula and grasped by the endoscopic forceps or snare. **C** The endoscope is withdrawn with the guidewire. The gastrostomy tube is then attached to the guidewire. **D** The guidewire and tube are pulled back through the mouth, oesophagus and stomach to exit on the anterior abdominal wall, and the endoscope is repassed to confirm the site of placement of the retention device. The latter closely abuts the gastric mucosa; its position is maintained by an external fixation device (see inset). It is also possible to place PEG tubes using fluoroscopic guidance in patients in whom endoscopy is difficult (radiologically inserted gastrostomy (RIG)).

5.35 Ethical and legal considerations in the management of artificial nutritional support*

- Care of the sick involves the duty of providing adequate fluid and nutrients
- Food and fluid should not be withheld from a patient who expresses a desire to eat and drink, unless there is a medical contraindication (e.g. risk of aspiration)
- A treatment plan should include consideration of nutritional issues and should be agreed by all members of the health-care team
- In the situation of palliative care, tube feeding should only be instituted if it is needed to relieve symptoms
- Tube feeding is usually regarded in law as a medical treatment. Like other treatments, the need for such support should be reviewed on a regular basis and changes made in the light of clinical circumstances
- A competent adult patient must give consent for any invasive procedures, including the passage of a nasogastric tube or the insertion of a central venous cannula
- If a patient is unable to give consent, the health-care team should act in that person's best interests, taking into account any previously expressed wishes of the patient and the views of family
- Under certain specified circumstances (e.g. anorexia nervosa), it will be appropriate to provide artificial nutritional support to the unwilling patient

*Based on British Association for Parenteral and Enteral Nutrition guidelines (www.bapen.org.uk).

(p. 189). Blood cultures should be taken, the existing line removed, the tip sent for bacteriological analysis, and a new line inserted.

Refeeding syndrome

When nutritional support is given to an undernourished patient, there is a rapid conversion from a catabolic to an anabolic state. Administration of carbohydrates stimulates release of insulin, leading to cellular uptake of phosphate, potassium and magnesium which may provoke significant falls in serum levels. The resulting electrolyte imbalance can have serious consequences such as cardiac arrhythmias, so careful monitoring is essential. In patients who are thiamin-deficient, Wernicke's encephalopathy can be precipitated by refeeding with carbohydrates (p. 1199); this is prevented by administering thiamin before starting nutritional support.

Legal and ethical aspects of artificial nutritional support

The ability to intervene with artificial nutritional support raises many legal and ethical dilemmas (pp. 9 and 287). Starvation will inevitably lead to death, but inability to eat may be part of the terminal stages of a disease process. Difficult decisions are raised by situations such as strokes which affect swallowing. The instigation of feeding may speed recovery and lead to better functional outcome; on the other hand, feeding might prolong the process of dying in severe stroke. There will be different approaches to these decisions, depending on the local availability of resources as well as legal, cultural and religious influences. Some guidelines are given in Box 5.35.

Cachexia

Cachexia is the weight loss and muscle-wasting associated with chronic illness, which is characteristic of chronic infections such as AIDS, end-stage organ failure and certain cancers (especially of the lung and upper gastrointestinal tract). Although there is decreased energy intake with loss of appetite, the main cause is thought to be increased metabolic rate through the production of key cytokines and other proteolytic factors.

DISEASES OF VITAMINS AND MINERALS

Vitamins

Vitamin deficiency diseases are most prevalent in developing countries but still occur in developed countries. Older people (and alcoholics) are at risk of deficiencies in B vitamins, and vitamins D and C. Nutritional deficiencies in pregnancy can affect either the mother or the developing fetus, and extra increments of vitamins are recommended in the UK (see Boxes 5.19 and 5.20, p. 113). Some nutrient deficiencies are induced by diseases or drugs. Deficiencies of fat-soluble vitamins are seen in conditions of fat malabsorption (e.g. biliary obstruction).

Some vitamins also have pharmacological actions when given at supraphysiological doses, e.g. the use of vitamin A (p. 1268) for acne. Taking vitamin supplements is fashionable in many countries, although there is no evidence of benefit. Toxic effects are most serious with high dosages of vitamins A, B₆ and D.

Investigation of suspected vitamin deficiency or excess may involve biochemical assessment of body stores (see Box 5.22, p. 115). However, measurements in blood should be interpreted carefully in conjunction with the clinical presentation.

Fat-soluble vitamins

Vitamin A

Deficiency

Globally, the most important consequence of vitamin A deficiency is blindness. Each year, approximately 500 000 new cases of blindness occur in young children, mostly in Asia. Adults are not usually at risk because liver stores can supply vitamin A when foods containing vitamin A are unavailable.

Early deficiency causes impaired adaptation to the dark (night blindness). Keratinisation of the cornea (xerophthalmia) causes characteristic Bitot's spots, which progresses to keratomalacia, with corneal ulceration, scarring and irreversible blindness (Fig. 5.17). In countries where vitamin A deficiency is endemic, pregnant

Fig. 5.17 Eye signs of vitamin A deficiency. **[A]** Bitot's spots in xerophthalmia, showing the white triangular plaques (arrows). **[B]** Keratomalacia in a 14-month-old child. There is liquefactive necrosis affecting the greater part of the cornea, with typical sparing of the superior aspect.

women should be advised to eat dark green leafy vegetables and yellow fruits (to build up stores of retinol in the fetal liver), and infants should be fed the same. WHO is giving high priority to prevention in communities where xerophthalmia occurs, with single prophylactic oral doses of 60 mg retinyl palmitate (providing 200 000 U retinol) given to pre-school children. This also reduces mortality from gastroenteritis and respiratory infections.

Toxicity

Repeated moderate or high doses of retinol can cause liver damage, hyperostosis and teratogenicity. Women in countries where deficiency is not endemic are therefore advised not to take vitamin A supplements in pregnancy. Retinol intake may also be restricted in those at risk of osteoporosis. Acute overdose leads to nausea and headache, increased intracranial pressure and skin desquamation. Excessive intake of carotene can cause pigmentation of the skin (hypercarotenosis); this gradually fades when intake is reduced.

Vitamin D

The effects of vitamin D deficiency (calcium deficiency, rickets and osteomalacia) are described on page 1121. An analogue of vitamin D (calcipotriol) is used for treatment of skin conditions such as psoriasis. Excessive doses of cholecalciferol, ergocalciferol or the hydroxylated metabolites cause hypercalcaemia (p. 764).

Vitamin E

Human deficiency is rare and has only been described in premature infants and in malabsorption. It can cause a mild haemolytic anaemia, ataxia and visual scotomas. Vitamin E intakes are considered safe up to 3200 mg/day (1000-fold greater than recommended intakes).

Diets rich in vitamin E are consumed in countries with lower rates of coronary heart disease. However, randomised controlled trials have not demonstrated cardioprotective effects of vitamin E or other antioxidants.

Vitamin K

Vitamin K deficiency leads to delayed coagulation and bleeding. In obstructive jaundice, dietary vitamin K is not absorbed and it is essential to administer the vitamin in parenteral form before surgery. Warfarin and related anticoagulants (p. 993) act by antagonising vitamin K. Vitamin K is given routinely to newborn babies to prevent haemorrhagic disease. Symptoms of excess have been reported only in infants, with synthetic preparations linked to haemolysis and liver damage.

Water-soluble vitamins

Thiamin (vitamin B₁)

In thiamin deficiency, cells cannot metabolise glucose aerobically to generate energy as ATP. Neuronal cells are most vulnerable, since they depend almost exclusively on glucose for energy requirements. Impaired glucose oxidation also causes an accumulation of pyruvic and lactic acids, which produce vasodilatation and increased cardiac output.

Deficiency—*beri-beri*

In the developed world, thiamin deficiency is mainly encountered in chronic alcoholics. Poor diet, impaired absorption, storage and phosphorylation of thiamin in the liver, and the increased requirements for thiamin to metabolise ethanol all contribute. In the developing world, deficiency usually arises as a consequence of a diet based on polished rice. The body has very limited stores of thiamin, so deficiency is manifest after only 1 month on a thiamin-free diet. There are two forms of the disease in adults:

- *Dry (or neurological) beri-beri* manifests with chronic peripheral neuropathy and with wrist and/or foot drop, and may cause Korsakoff's psychosis and Wernicke's encephalopathy (pp. 246 and 1199).
- *Wet (or cardiac) beri-beri* causes generalised oedema due to biventricular heart failure with pulmonary congestion.

In dry beri-beri, response to thiamin administration is not uniformly good. However, multivitamin therapy seems to produce some improvement, suggesting that other vitamin deficiencies may be involved. Wernicke's encephalopathy and wet beri-beri should be treated without delay with intravenous Pabrinex (pp. 247 and 1199). Korsakoff's psychosis is irreversible and does not respond to thiamin treatment.

Riboflavin (vitamin B₂)

Riboflavin deficiency is rare in developed countries. It mainly affects the tongue and lips and manifests as glossitis, angular stomatitis and cheilosis. The genitals may be affected, as well as the skin areas rich in sebaceous

glands, causing nasolabial or facial dyssebacea. Rapid recovery usually follows administration of riboflavin 10 mg daily by mouth.

Niacin (vitamin B₃)

Deficiency—pellagra

Pellagra was formerly endemic among the poor who subsisted chiefly on maize, which contains niacytin, a form of niacin that the body is unable to utilise. Pellagra can develop in only 8 weeks in individuals eating diets that are very deficient in niacin and tryptophan. It remains a problem in parts of Africa, and is occasionally seen in alcoholics and in patients with chronic small intestinal disease in developed countries. Pellagra can occur in Hartnup's disease, a genetic disorder characterised by impaired absorption of several amino acids, including tryptophan. It is also seen occasionally in carcinoid syndrome (p. 782), when tryptophan is consumed in the excessive production of 5-HT.

Pellagra has been called the disease of the three Ds:

- **Dermatitis.** Characteristically, there is erythema resembling severe sunburn, appearing symmetrically over the parts of the body exposed to sunlight, particularly the limbs and especially on the neck, but not the face (Casal's necklace, Fig. 5.18). The skin lesions may progress to vesiculation, cracking, exudation and secondary infection.
- **Diarrhoea.** This is often associated with anorexia, nausea, glossitis and dysphagia, reflecting the presence of a non-infective inflammation that extends throughout the gastrointestinal tract.
- **Dementia.** In severe deficiency, delirium occurs acutely and dementia develops in chronic cases.

Treatment is with nicotinamide, given in a dose of 100 mg 8-hourly by mouth or by the parenteral route. The response is usually rapid. Within 24 hours, the erythema

Fig. 5.18 Dermatitis due to pellagra (niacin deficiency). The lesions appear on those parts of the body exposed to sunlight. The classic 'Casal's necklace' can be seen around the neck and upper chest.

5.36 Vitamin deficiency in old age

- **Requirements:** although energy requirements fall with age, those for micronutrients do not. If dietary intake falls, a vitamin-rich diet is required to compensate.
- **Vitamin D:** levels are commonly low due to reduced dietary intake, decreased sun exposure and less efficient skin conversion. This leads to bone loss and fractures. Supplements should be given to those in institutional care and those with recurrent falls.
- **Vitamin B₁₂ deficiency:** a causal relationship with dementia has not been identified, but it does produce neuropsychiatric effects and should be checked in all those with declining cognitive function.

diminishes, the diarrhoea ceases and a striking improvement occurs in the patient's mental state.

Toxicity

Excessive intakes of niacin may lead to reversible hepatotoxicity. Nicotinic acid is a lipid-lowering agent, but at doses above 200 mg a day gives rise to vasodilatory symptoms ('flushing' and/or hypotension).

Pyridoxine (vitamin B₆)

Vitamin B₆ deficiency is rare. However, certain drugs, such as isoniazid and penicillamine, act as chemical antagonists to pyridoxine. Pyridoxine administration is effective in isoniazid-induced peripheral neuropathy and some cases of sideroblastic anaemia.

Large doses of vitamin B₆ have an antiemetic effect in radiotherapy-induced nausea. Although vitamin B₆ supplements have become popular in the treatment of nausea in pregnancy, carpal tunnel syndrome and premenstrual syndrome, there is no convincing evidence of benefit. Very high doses of vitamin B₆ taken for several months can cause a sensory polyneuropathy.

Biotin

Biotin deficiency results from consuming very large quantities of raw egg whites (> 30% energy intake) because the avidin they contain binds to and inactivates biotin in the intestine. It may also be seen after long periods of total parenteral nutrition. The clinical features of deficiency include scaly dermatitis, alopecia and paraesthesia.

Vitamin B₁₂ and folate

These vitamins and the haematological disorders (macrocytic or megaloblastic anaemias) due to their deficiency are discussed on pages 1020–1022. Vitamin B₁₂, but not folate, is needed for the integrity of myelin, so that vitamin B₁₂ deficiency is also associated with neurological disease (see Box 24.38, p. 1020). Folate deficiency has been associated with heart disease, dementia and cancer.

Neurological consequences of vitamin B₁₂ deficiency

In older people and chronic alcoholics, vitamin B₁₂ deficiency arises from insufficient intake and/or from malabsorption. Several drugs, including neomycin, can render vitamin B₁₂ inactive. Adequate intake of folate maintains erythropoiesis and there is a concern that

Fig. 5.19 Scurvy. [A] Gingival swelling and bleeding. [B] Perifollicular hyperkeratosis.

fortification of foods with folate may mask underlying vitamin B₁₂ deficiency. In severe deficiency there is insidious, diffuse and uneven demyelination. It may be clinically manifest as peripheral neuropathy or spinal cord degeneration affecting both posterior and lateral columns ('subacute combined degeneration of the spinal cord'; p. 1225), or there may be cerebral manifestations (resembling dementia) or optic atrophy. Vitamin B₁₂ therapy improves symptoms in most cases.

Folic acid in the prevention of neural tube defects

Folate deficiency may cause three major birth defects (spina bifida, anencephaly and encephalocele) resulting from imperfect closure of the neural tube, which takes place 3–4 weeks after conception. Maternal supplementation with folate reduces the risk (see Box 5.20, p. 113).

Vitamin C (ascorbic acid)

Deficiency—scurvy

Vitamin C deficiency causes defective formation of collagen with impaired healing of wounds, capillary haemorrhage and reduced platelet adhesiveness (normal platelets are rich in ascorbate) (Fig. 5.19). Precipitants and clinical features of scurvy are shown in Box 5.37. A dose of 250 mg vitamin C 8-hourly by mouth should saturate the tissues quickly. The deficiencies of the patient's diet also need to be corrected and other vitamin supplements given if necessary.

Daily intakes of more than 1 g/day have been reported to cause diarrhoea and the formation of renal oxalate stones.

5.37 Scurvy—vitamin C deficiency

Precipitants

Increased requirement

- Trauma, surgery, burns, infections
- Smoking
- Drugs (corticosteroids, aspirin, indometacin, tetracycline)

Dietary deficiency

- Lack of dietary fruit and vegetables for > 2 months
- Infants fed exclusively on boiled milk

Clinical features

- Swollen gums which bleed easily
- Perifollicular and petechial haemorrhages
- Ecchymoses
- Haemarthrosis
- Gastrointestinal bleeding
- Anaemia
- Poor wound healing

Inorganic nutrients

Deficiency is seen when there is inadequate dietary intake of minerals or excessive loss from the body. Toxic effects have also been observed from self-medication and disordered absorption or excretion. Examples of clinical toxicity include excess of iron (haemochromatosis or haemosiderosis), fluoride (fluorosis; p. 114), copper (Wilson's disease) and selenium (selenosis, seen in parts of China). For most minerals the available biochemical markers do not accurately reflect dietary intake and dietary assessment is required.

Calcium

Calcium absorption may be impaired in vitamin D deficiency (pp. 764 and 1121) and in malabsorption secondary to small intestinal disease. Calcium deficiency causes impaired bone mineralisation and can lead to osteomalacia in adults. The potential benefits of high calcium intake in osteoporosis are discussed on page 1120. Too much calcium can lead to constipation and toxicity has been observed in 'milk alkali syndrome' (p. 765).

Phosphorus

Dietary deficiency of phosphorus is rare (except in older people with limited diets) since it is present in nearly all foods and phosphates are added to a number of processed foods. Phosphate deficiency in adults occurs:

- in patients with renal tubular phosphate loss (p. 447)
- due to prolonged high dosage of aluminium hydroxide (p. 491)
- sometimes when alcoholics are fed with high-carbohydrate foods
- in patients receiving parenteral nutrition if inadequate phosphate is provided.

Deficiency causes hypophosphataemia (p. 447) and muscle weakness secondary to ATP deficiency.

Iron

The major consequence of iron deficiency is anaemia (p. 1017). This is one of the most important nutritional causes of ill health in all parts of the world. In the UK it is estimated that 10% women are iron-deficient. Dietary iron overload is occasionally observed and results in iron accumulation in the liver and, rarely, cirrhosis. Haemochromatosis results from an inherited increase in iron absorption (p. 959).

Iodine

About a billion people in the world are estimated to have an inadequate iodine intake and are hence at risk of iodine deficiency disorder. Goitre is the most common manifestation, affecting about 200 million people (p. 750).

In those areas where most women have endemic goitre, 1% or more of babies are born with cretinism (characterised by mental and physical retardation). There is a higher than usual prevalence of deafness, slowed reflexes and poor learning in the remaining population. The best way of preventing neonatal cretinism is to ensure adequate levels of iodine during pregnancy. This can be achieved by intramuscular injections with 1–2 mL of iodised poppy seed oil (475–950 mg iodine) to women of child-bearing age every 3–5 years, by administration of iodised oil orally at 6-monthly or yearly intervals to adults and children, or by providing iodised salt for cooking.

Zinc

Acute zinc deficiency has been reported in patients receiving prolonged zinc-free parenteral nutrition and causes diarrhoea, mental apathy, a moist eczematoid dermatitis, especially around the mouth, and loss of hair. Chronic zinc deficiency occurs in dietary deficiency, malabsorption syndromes, alcoholism and its associated hepatic cirrhosis. It causes the clinical features seen in the very rare congenital disorder known as acrodermatitis enteropathica (growth retardation, hair loss and chronic diarrhoea). Zinc deficiency is thought to be responsible for one-third of the world's population not reaching their optimal height. In the Middle East, chronic deficiency has been associated with dwarfism and hypogonadism. In starvation, zinc deficiency causes thymic atrophy, and zinc supplements may accelerate the healing of skin lesions, promote general well-being, improve appetite and reduce the morbidity associated with the undernourished state.

Fluoride

If the local water supply contains more than 1 part per million (ppm) of fluoride, the incidence of dental caries is low. Soft waters usually contain no fluoride, whilst very hard waters may contain over 10 ppm. The benefit of fluoride is greatest when it is taken before the permanent teeth erupt, while their enamel is being laid down. The addition of traces of fluoride (at 1 ppm) to public water supplies is now a widespread practice.

Chronic fluoride poisoning is occasionally seen where the water supply contains > 10 ppm fluoride. It can also occur in workers handling cryolite (aluminium sodium fluoride), used in smelting aluminium. Fluoride poisoning is described on page 221. Pitting of teeth is a result of too much fluoride as a child.

Other minerals

Disease states associated with abnormal intakes or disordered metabolism of sodium, potassium and magnesium are discussed in Chapter 16.

Copper metabolism is abnormal in Wilson's disease (p. 960). Deficiency occasionally occurs but only in young children, causing microcytic hypochromic anaemia, neutropenia, retarded growth, skeletal rarefaction and dermatosis.

Selenium deficiency can cause hypothyroidism, cardiomyopathy in children (Keshan's disease) and myopathy in adults. Excess selenium can cause heart disease.

Chromium facilitates the action of insulin. Deficiency presents as hyperglycaemia and has been reported in adults as a rare complication of prolonged parenteral nutrition.

Infection is the establishment of foreign organisms, or 'infectious agents', in or on a human host. This may result in colonisation, if the microorganism exists at an anatomical site without establishing overt tissue injury, or infectious disease, when the interaction between the host and pathogenic organism (or pathogen) induces tissue damage and clinical illness. In clinical practice the term 'infection' is often used interchangeably with 'infectious disease'. Most pathogens are microorganisms, although some are multicellular organisms (parasites).

The interaction between the pathogen and the host is dynamic and complex. Whilst it is rarely in the organism's interest to kill the host (on which it relies for nutrition and protection), the generation of disease manifestations (e.g. diarrhoea, sneezing) may aid its dissemination. Conversely, it is in the host's interests to kill microorganisms likely to cause disease, whilst preserving colonising organisms from which it may derive benefit.

Communicable infectious diseases are caused by organisms transmitted between hosts, whereas endogenous diseases are caused by colonising organisms already established in the host. Opportunistic infections, which may be communicable or endogenous, are those which arise only in individuals with impaired host defence. The chain of infection (Fig. 6.1) describes six essential elements for communicable disease transmission.

Despite dramatic advances in hygiene, immunisation and antimicrobial therapy, infectious diseases are

still responsible for a major global health burden. Key challenges remain in tackling the diversity of infection in developing countries and the emergence of new infectious agents and of antimicrobial-resistant microorganisms. This chapter describes the processes underlying infectious diseases and the general approach to their prevention, diagnosis and treatment. Chapters 13–15 describe specific infectious diseases.

INFECTIOUS AGENTS

The concept of an infectious agent was established by Robert Koch in the late 19th century (Box 6.1). Although fulfilment of 'Koch's postulates' became the standard for the definition of an infectious agent, they do not apply to organisms which cannot be grown in culture (e.g. *Mycobacterium leprae*, *Tropheryma whipplei*) or members of the normal human flora (e.g. *Escherichia coli*, *Candida* spp.). The following groups of infectious agents are now recognised.

Prions

Prions are unique amongst infectious agents in that they are devoid of any nucleic acid. They appear to be transmitted by acquisition of a normal mammalian protein (prion protein, PrP^c) which is in an abnormal conformation (PrP^{Sc}, containing an excess of beta-sheet protein); the abnormal protein inhibits the enzyme proteasome 26S, leading to a vicious circle of further accumulation of abnormally configured PrP^{Sc} protein instead of normally configured PrP^c protein. The result is accumulation of protein forming amyloid in the central nervous system (CNS), causing transmissible spongiform encephalopathies in humans, sheep, cows and cats (see Box 13.38, p. 325 and see p. 1214).

Viruses

Viruses are incapable of independent replication, instead subverting the cellular processes of host cells. A virus that infects a bacterium is a bacteriophage (phage). Viruses contain genetic material (genome), which may be single- or double-stranded DNA or RNA. Some viruses copy their RNA into DNA by reverse transcription (retroviruses). The virus genome is enclosed in an antigenically unique protein coat (capsid); together, these form the nucleocapsid. In many viruses the nucleocapsid is packaged within a lipid envelope. Enveloped viruses are less able to survive in the environment and are spread by respiratory, sexual or blood-borne routes, including arthropod-based transmission. Non-enveloped viruses survive better in the environment

Fig. 6.1 Chain of infection. The infectious agent is the organism that causes the disease. The reservoir is the place where the population of an infectious agent is maintained. The portal of exit is the point from which the infectious agent leaves the reservoir. Transmission is the process by which the infectious agent is transferred from the reservoir to the human host, either directly or via a vector or fomite. The portal of entry is the body site that is first accessed by the infectious agent. Finally, in order for disease to ensue, the person to whom the infectious agent is transmitted must be a susceptible host.

i

6.1 Definition of an infectious agent: Koch's postulates

1. The same organism must be present in every case of the disease
2. The organism must be isolated from the diseased host and grown in pure culture
3. The isolate must cause the disease, when inoculated into a healthy, susceptible animal
4. The organism must be re-isolated from the inoculated, diseased animal

and are predominantly transmitted by faecal-oral or, less often, respiratory routes. The virus life cycle is shown in Figure 6.2.

Prokaryotes: bacteria (including mycobacteria and actinomycetes)

Prokaryotic cells are capable of synthesising their own proteins and nucleic acids, and are able to reproduce autonomously, although they lack a nucleus. The bacterial cell membrane is bounded by a peptidoglycan cell wall, which is thick (20–80 nm) in Gram-positive organisms and thin (5–10 nm) in Gram-negative ones. The Gram-negative cell wall is surrounded by an outer membrane containing lipopolysaccharide (endotoxin). Many bacteria contain extra-chromosomal DNA in the form of plasmids, which can be transferred between organisms. Bacteria may be embedded in a polysaccharide capsule, and motile bacteria are equipped with flagella. Although many prokaryotes are capable of independent existence, some (e.g. *Chlamydia trachomatis*, *Coxiella burnetii*) are obligate intracellular organisms. Bacteria that replicate in artificial culture media are classified and identified

using a range of characteristics (Box 6.2), with examples in Figures 6.3 and 6.4.

Eukaryotes: fungi, protozoa and helminths

Eukaryotes contain functional organelles such as nuclei, mitochondria and Golgi apparatus. Eukaryotes involved in human infection include fungi, protozoa (unicellular eukaryotes with a flexible cell membrane, p. 348) and helminths (multicellular complex organisms including nematodes, trematodes and cestodes, p. 364).

Fungi exist as either moulds (filamentous fungi) or yeasts. Dimorphic fungi exist in either form, depending on environmental conditions (see Fig. 13.55, p. 377). The fungal plasma membrane differs from the human cell membrane in that it contains the sterol, ergosterol. Fungi have a cell wall made up of polysaccharides, chitin and mannoproteins. In most fungi the main structural component of the cell wall is β -1, 3-D-glucan, a glucose polymer.

Protozoa and helminths are often referred to as parasites. Many parasites have complex multi-stage

Fig. 6.2 Virus life cycle. Life cycles vary between viruses. Life cycle components common to most viruses are host cell attachment and penetration, virus uncoating, nucleic acid and protein synthesis, virus assembly and release. Virus release is achieved either by budding, as illustrated, or by lysis of the cell membrane.

life cycles, which involve animal and/or plant hosts in addition to humans.

NORMAL FLORA

Every human is host to an estimated 10^{13} – 10^{14} colonising microorganisms which constitute the normal flora. Resident flora are able to survive and replicate at a body site, whereas transient flora are present only for short periods. Knowledge of non-sterile body sites

Fig. 6.4 Appearances of α - and β -haemolytic streptococci on blood agar. **A** Alpha-haemolytic streptococci. The colonies cause partial haemolysis, which imparts a green tinge to the agar. The organism shown is *Strep. pneumoniae* from the CSF of a patient with meningitis (note also the susceptibility to optochin (O), which is another feature used to identify this organism). **B** Beta-haemolytic streptococci. The colonies cause complete haemolysis, which renders the agar transparent. The organism shown is *Strep. pyogenes* (group A β -haemolytic streptococci) from a superficial wound swab.

and their specific normal flora is required to interpret microbiological culture results (Fig. 6.5).

The relationship between human host and normal flora is symbiotic (the organisms are in close proximity) and may be:

- mutualistic (both organisms benefit)
- commensal (one organism benefits whilst the other derives neither benefit nor harm)
- parasitic (the parasite benefits at the expense of the host, as in infectious disease).

Maintenance of the normal flora is beneficial to health. For example, lower gastrointestinal tract bacteria synthesise and excrete vitamins (e.g. vitamins K and B_{12}); colonisation with normal flora confers 'colonisation resistance' to infection by pathogenic organisms by altering the local environment (e.g. lowering of pH), producing antibacterial agents (such as bacteriocin peptides, fatty acids and metabolic waste products), and inducing host antibodies which may cross-react with pathogenic organisms.

Conversely it is important to exclude infectious agents from sterile body sites. The mucociliary escalator transports environmental material deposited in the respiratory tract to the nasopharynx. The urethral sphincter prevents flow from the non-sterile urethra to the sterile bladder.

Fig. 6.5 Human non-sterile sites and normal flora in health.

Physical barriers, including the skin, lining of the gastrointestinal tract and mucous membranes, maintain sterility of the blood stream, peritoneal and pleural cavities, chambers of the eye, subcutaneous tissue etc.

The normal flora contribute to endogenous infectious disease by either excessive growth (overgrowth) at the 'normal' site, or translocation to a sterile site. Overgrowth is exemplified by 'blind loop' syndrome (see p. 881), dental caries and vaginal thrush, in which external factors favour overgrowth of specific components of the normal flora. Translocation results from spread along a surface or penetration of a closed barrier: for example, in urinary tract infection caused by perineal/enteric flora, and in skin and surgical site infections caused by skin flora such as staphylococci. Normal flora also contributes to disease by cross-infection, in which organisms that are colonising one individual cause disease when transferred to another more susceptible individual.

HOST–PATHOGEN INTERACTIONS

Microorganisms capable of causing disease are termed pathogens. The components of pathogenicity are infectivity (the ability to become established in or on a host)

and virulence (the ability to cause harm once established). Pathogens produce an array of proteins and other factors, termed virulence factors, which interact with host cells to contribute to disease.

- *Primary pathogens* cause disease in a proportion of individuals to whom they are exposed, regardless of their immunological status.
- *Opportunistic pathogens* cause disease only in individuals whose natural host defences are compromised, for example, by genetic susceptibility, immunosuppressive disease or a medical intervention.

Characteristics of successful pathogens

Successful pathogens have a number of attributes. They compete with host cells and colonising flora by various methods including sequestration of nutrients, use of metabolic pathways not used by competing bacteria, or production of bacteriocins (small antimicrobial peptides/proteins that kill closely related bacteria). Motility enables pathogens to reach their site of infection, often in sterile sites that colonising bacteria do not reach, such as the distal airway. Many microorganisms, including

6.3 Exotoxin-mediated bacterial diseases	
Disease	Organism
Antibiotic-associated diarrhoea/pseudo-membranous colitis	<i>Clostridium difficile</i> (p. 304)
Botulism	<i>Clostridium botulinum</i> (p. 1214)
Cholera	<i>Vibrio cholerae</i> (p. 339)
Diphtheria	<i>Corynebacterium diphtheriae</i> (p. 340)
Haemolytic uraemic syndrome	<i>Escherichia coli</i> O157 (and other strains) (p. 498)
Necrotising pneumonia	<i>Staphylococcus aureus</i> (p. 686)
Tetanus	<i>Clostridium tetani</i> (p. 1213)
Toxic shock syndrome	<i>Staphylococcus aureus</i> (p. 326)

viruses, use 'adhesins' to attach to host cells at the site of infection. Other pathogens can invade through tissues.

Pathogens may produce toxins, microbial molecules that cause adverse effects on host cells either at the site of infection or remotely following carriage through the blood stream. Endotoxin is a cell wall component released mainly following bacterial cell damage and has generalised inflammatory effects. Exotoxins are proteins released by living bacteria, which often have specific effects on target organs (Box 6.3.)

Intracellular pathogens, including viruses, bacteria (e.g. *Salmonella* spp., *Listeria monocytogenes* and *Mycobacterium tuberculosis*), parasites (e.g. *Leishmania* spp.) and fungi (e.g. *Histoplasma capsulatum*), have the capacity to survive in intracellular environments, including after phagocytosis by macrophages.

Pathogenic bacteria express different arrays of genes, depending on environmental stress (pH, iron starvation, O₂ starvation etc.) and anatomical location. In quorum sensing, bacteria communicate with one another to adapt their replication or metabolism according to local population density. Bacteria and fungi may respond to the presence of an artificial surface (e.g. prosthetic device, venous catheter) by forming a biofilm, which is a population of organisms encased in a matrix of extracellular molecules. Biofilm-associated organisms are highly resistant to antimicrobial agents.

Genetic diversity enhances the pathogenic capacity of bacteria. Some virulence factor genes are found on plasmids or in phages and are exchanged between different strains or species. The ability to acquire genes from the gene pool of all strains of the species (the 'bacterial supragenome') increases diversity and the potential for pathogenicity. Viruses exploit their rapid reproduction and potential to exchange nucleic acid with host cells to enhance diversity. Once a strain acquires a particularly effective combination of virulence genes, it may become an epidemic strain, accounting for a large subset of infections in a particular region. This phenomenon accounts for influenza pandemics.

The host response

The human host relies on innate and adaptive immune and inflammatory responses to control the normal flora

and respond to pathogens. These responses, and the consequences when they are impaired, are reviewed in Chapter 4.

Pathogenesis of infectious disease

The harmful manifestations of infection are determined by a combination of the virulence factors of the organism and the host response to infection, both of which vary at different stages of disease. Despite the obvious benefits of an intact host response, an excessive response is undesirable. Cytokines and antimicrobial factors contribute to tissue injury at the site of infection, and an excessive inflammatory response may lead to hypotension and organ dysfunction (p. 81). The importance of the immune response in determining disease manifestations is exemplified in immune reconstitution inflammatory syndrome (IRIS, or immune reconstitution disease). In this condition—seen, for example, in HIV infection, neutropenia or tuberculosis (which causes suppression of T-cell function)—there is a paradoxical worsening of the clinical condition as the immune dysfunction is corrected.

The febrile response

Thermoregulation (p. 100) is altered in infectious disease. Microbial pyrogens or the endogenous pyrogens released during tissue necrosis stimulate specialised cells such as monocytes/macrophages to release cytokines including IL-1 β , tumour necrosis factor (TNF)- α , IL-6 and IFN- γ . Cytokine receptors in the pre-optic region of the anterior hypothalamus activate phospholipase A, releasing arachidonic acid as substrate for the cyclo-oxygenase pathway and producing prostaglandin E₂ (PGE₂), which in turn alters the responsiveness of thermosensitive neurons in the thermoregulatory centre. Rigors occur when the body inappropriately attempts to 'reset' core temperature to a higher level by stimulating skeletal muscle activity and shaking.

The role of the febrile response as a defence mechanism requires further study, but there are data to support the hypothesis that raised body temperature interferes with the replication and/or virulence of pathogens.

INVESTIGATION OF INFECTION

Microbiological tests detect either a microorganism (e.g. direct detection and culture) or the host response to the organism (immunological tests) (Box 6.4). They also provide information on responsiveness to antimicrobial therapy. Careful and appropriate sampling increases the chance of useful results (Box 6.5). The results must be interpreted in light of the normal flora in the site from which the sample was obtained and the likely findings in a person without infectious disease. Like all tests, whether a positive test result is diagnostic of disease depends on the specificity and positive predictive value (PPV) of the test (p. 5), and whether a negative test result excludes disease depends on its sensitivity and negative predictive value (NPV). Test sensitivity varies according to the time between infection and testing (there is a 'window of opportunity' during which sensitivity is maximal; see Fig 6.7, p. 140), and the PPV and NPV depend on the prevalence of the condition in the test population.

6.4 Investigation modalities in infectious diseases

Non-microbiological

- e.g. FBC, plasma CRP, cell counts in urine or CSF, CSF protein and glucose

Direct detection

- Microscopy
- Detection of organism components (e.g. antigen, toxin)
- Nucleic acid amplification (e.g. PCR)

Culture

- \pm Antimicrobial sensitivity testing

Immunological tests

- Antibody detection
- T-cell stimulation tests

Microbiological results are therefore interpreted in light of other findings consistent with infectious disease, including the clinical scenario and results of other investigations (e.g. neutrophilia, elevated C-reactive protein (CRP)). Given this complexity, effective two-way communication between the clinician and the microbiologist is a vital component of test interpretation.

Direct detection

Direct detection methods provide rapid results, and may be applied to organisms that cannot be grown easily on

artificial culture media, such as *Chlamydia* spp. They do not usually provide information on antimicrobial susceptibility or the degree to which organisms are related to each other (which is important in the investigation of possible disease outbreaks) unless relevant specific nucleic acid sequences are detected by polymerase chain reaction (PCR).

Detection of whole organisms

Whole organisms are detected by microscopic examination of biological fluids or tissue using a light or electron microscope.

- *Bright field microscopy* (in which the test sample is interposed between the light source and the objective lens) uses stains to enhance visual contrast between the organism and its background. Examples include Gram-staining of bacteria and Ziehl-Neelsen or auramine staining of acid- and alcohol-fast bacilli (AAFB) in tuberculosis. In histopathological examination of tissue samples multiple stains are used to demonstrate not only the presence of microorganisms, but also features of disease pathology.
- *Dark field microscopy* (in which light is scattered to make organisms appear bright on a dark background) is used, for example, to examine genital chancre fluid in suspected syphilis.
- *Electron microscopy* is used to examine stool and vesicle fluid to detect enteric and herpes viruses, respectively.

6.5 How to provide samples for microbiological sampling

Communication

- Discuss samples that may require to be forwarded to another laboratory or processed urgently or by an unusual method with laboratory staff *before* collection
- Communication is the most important requirement for good microbiological sampling. If there is doubt about any aspect of sampling, it is far better to discuss it with laboratory staff beforehand than to risk diagnostic delay by inappropriate sampling or sample handling

Indication

- Screening (e.g. collecting 'routine' urine, i.v. cannulae or sputum) in the absence of clinical evidence of infection is rarely appropriate

Container

- Certain tests (e.g. nucleic acid and antigen detection tests) require proprietary sample collection equipment

Collection

- Follow sample collection instructions precisely (e.g. proper collection of mid-stream, terminal and early morning urine samples, skin decontamination prior to blood culture etc.) to increase diagnostic yield

Labelling

- Label sample containers and request forms according to local policies with demographic identifiers, specimen type and time/date collected
- Include clinical details on request forms
- Identify samples carrying a high risk of infection (e.g. blood liable to contain a blood-borne virus) with a hazard label

Packaging

- Close sample containers tightly and package securely (usually in sealed plastic bags)
- Attach request forms to samples but not in the same compartment (to avoid contamination should leakage occur)

Storage and transport

- Transport samples to the microbiology laboratory as quickly as possible
- If pre-transport storage is required, conditions (e.g. refrigeration, incubation, storage at room temperature) vary with sample type
- Notify the receiving laboratory prior to arrival of samples, to ensure timely processing

Detection of components of organisms

Components of microorganisms that are detected for diagnostic purposes include nucleic acids (DNA and RNA), cell wall molecules, toxins and other antigens. Methods to detect non-nucleic acid antigenic components of microorganisms are described under immunological tests (see below), as they share similar methodology. Examples of antigen detection include *Legionella pneumophila* serogroup 1 antigen in urine, HIV p24 antigen in blood and cryptococcal polysaccharide antigen in cerebrospinal fluid (CSF). Non-immunological methods may also be used, e.g. detection of *Clostridium botulinum* toxin in a mouse bioassay. In toxin-mediated disease, detection of toxin may be of greater relevance than identification of organism (e.g. detection of *C. difficile* toxin in stool).

Nucleic acid amplification tests (NAAT)

Specific sequences of microbial DNA and RNA are identified using a nucleic acid primer which is amplified exponentially by enzymes to generate multiple copies of the specific sequence. The most commonly used amplification method is the polymerase chain reaction (PCR; see Fig. 3.10, p. 58). Reverse transcription (RT) PCR is used to detect RNA from organisms such as hepatitis C virus and HIV-1. In modern amplification systems the use of fluorescent-labelled primers and probes allows 'real-time' detection of amplified DNA. Quantification is based on the principle that the time taken to reach the detection threshold is proportional to the initial number of copies of the target nucleic acid sequence.

Determination of nucleic acid sequence is also used to assign microorganisms to specific strains according to their genotype, which may be relevant to treatment and/or prognosis (e.g. in hepatitis C infection, p. 953). Nucleic acid sequences that are relevant to pathogenicity (such as toxin genes) or antimicrobial resistance can also be detected. For example, detection of the *mecA* gene is used to screen for methicillin-resistant *Staphylococcus aureus* (MRSA).

Nucleic acid amplification provides the most sensitive direct detection methods, but their extreme sensitivity can produce false positive results from contamination. PCR techniques are particularly useful when a rapid diagnosis is required. They are used widely in virology, where the possibility of false positive results from colonising or contaminating organisms is remote, and are applied to blood, respiratory samples, stool and urine. In bacteriology, PCR is used mainly to examine samples from normally sterile sites, such as CSF, blood and, increasingly, tissue. The role of PCR in mycology and parasitology is not yet established.

Culture

Organisms in samples of tissue, swabs and body fluids may replicate in culture, allowing their detection and characterisation.

- *In vivo culture* (in a living organism) is not used in routine diagnostic microbiology.
- *Ex vivo culture* (tissue culture) was widely used in the isolation of viruses, but is being gradually supplanted by nucleic acid amplification techniques.

- *In vitro culture* (in artificial culture media) of bacteria and fungi is used for definitive identification, to test for antimicrobial susceptibility and to subtype the organism for epidemiological purposes.

However, culture has its limitations. Results are not immediate, even for organisms which are easy to grow, and negative culture rarely excludes infection completely. Organisms such as *M. tuberculosis* are inherently slow-growing, typically taking 2 weeks to be detectable in the most specialised systems (liquid culture with constant monitoring) and longer when grown on solid media. Certain organisms, such as *M. leprae* and *Tropheryma whippelii*, cannot be cultivated on artificial media, and others (e.g. *Chlamydia* spp. and viruses) grow only in *ex vivo* systems, which are slow and labour-intensive to use.

Blood culture

Rapid microbiological diagnosis is required for bloodstream infection (BSI). To diagnose BSI, a liquid culture medium is inoculated with freshly drawn blood (Fig. 6.6). Bacterial growth can be detected by serial subculture or the detection of radio-labelled CO₂ produced by bacteria on breakdown of radio-labelled carbon sources provided in the growth media. Modern blood culture systems allow constant monitoring of liquid media for products of microbial respiration (mainly CO₂) using fluorescence. It is likely that constant-monitoring systems will be replaced or enhanced by nucleic acid amplification-based techniques.

Immunological tests

Immunological tests detect the host response to a specific microorganism and can be used to diagnose infection with organisms that are difficult to detect by other methods or are no longer present in the host. The term 'serological' describes tests carried out on serum, and includes both antigen and antibody detection. Immunological tests can also be performed on fluids other than blood (e.g. CSF, urine). Immunological tests require a functional host immune system, and often provide only a retrospective diagnosis.

The diagnostic opportunities afforded by methods that detect organism components and antibodies are illustrated in Figure 6.7.

Antibody detection

Detection of antibodies specific to the antigens of microorganisms is applied mainly to blood (Fig. 6.7). Results are typically expressed as titres: that is, the reciprocal of the highest dilution of the serum at which antibody is detectable (for example, detection at serum dilution of 1:64 gives a titre of 64). 'Seroconversion' is defined as either a change from negative to positive detection or a fourfold rise in titre between acute and convalescent serum samples. An acute sample is usually taken during the first week of disease and the convalescent sample 2–4 weeks later. Earlier diagnosis can be achieved by detection of IgM antibodies, which are produced early in infection (p. 75). Many immunological tests may be adapted to detect antigens instead of antibodies.

1 Patient sampling

Contamination of blood culture bottles should be minimised by using careful aseptic technique and following local guidelines

2 Sample handling

Local instructions should be followed, including safety instructions, labelling requirements, submission of paired vs. single bottles and use of multiple sets of blood cultures

3 Specimen transport

Specimens should be transported to the laboratory as quickly as possible. If there is a delay, the sample must be stored in conditions specified by the manufacturer of the blood culture system in use

4 Incubation

The specimen is incubated at 35–37°C for 5–7 days. If there has been no growth at this time, it is reported as negative and discarded

5 Growth detection

In most systems microbial growth is detected by constant automatic monitoring of CO₂ in the bottle. For significant bacteraemias this usually takes 12–24 hrs. Time to positivity (TTP) may be shorter in overwhelming sepsis and longer with fastidious organisms (e.g. *Brucella* spp.)

6 Preliminary results

If growth is detected, a Gram film is made from the blood culture medium. The results are communicated immediately to the clinician and used to guide antibiotic therapy

7 Incubation

A small amount of the medium is incubated on a range of appropriate culture media. Preliminary susceptibility testing may also be carried out

8 Culture results

After incubation, presumptive identification and preliminary susceptibility results are communicated to the clinician

9 Definitive results

For most organisms definitive identification requires a further overnight incubation to enable confirmatory and/or further biochemical tests. Definitive susceptibility testing may also require further incubation with a range of antimicrobials

10 Reporting

A final summary of the results is released when all testing is complete. For purposes of clinical care, liaison of the interim results (e.g. Gram film, presumptive identification and susceptibility) is usually more important than release of the final result. Effective clinical-laboratory communication is vital

Overnight incubation required

Urgent communication required

Fig. 6.6 An overview of the processing of blood cultures.

Fig. 6.7 Detection of antigen, nucleic acid and antibody in infectious disease. The acute sample is usually taken during the first week of illness, and the convalescent sample 2–4 weeks later. Detection limits and duration of detectability vary between tests and diseases, although in most diseases IgM is detectable within the first 1–2 weeks.

Enzyme-linked immunosorbent assay (ELISA, EIA)

The principles of ELISA are illustrated in Figure 6.8. These assays rely on linking an antibody with an enzyme which generates a colour change on exposure to a chromogenic substrate. Various configurations allow detection of antigens or specific subclasses of immunoglobulin (e.g. IgG, IgM, IgA). ELISA may also be adapted to detect PCR products, using immobilised oligonucleotide hybridisation probe and various detection systems.

Immunoblot (Western blot)

Microbial proteins are separated according to molecular weight by polyacrylamide gel electrophoresis (PAGE)

and transferred (blotted) on to a nitrocellulose membrane, which is incubated with patient serum. Binding of specific antibody is detected with an enzyme-anti-immunoglobulin conjugate similar to that used in ELISA, and specificity is confirmed by its location on the membrane. Immunoblotting is a highly specific test, which may be used to confirm the results of less specific tests, such as ELISA.

Immunofluorescence assays (IFA)

IFAs are highly specific. In indirect immunofluorescence a serum sample is incubated with immobilised antigen (e.g. cells known to be infected with virus on

Fig. 6.8 Antibody (Ab) and antigen (Ag) detection by enzyme-linked immunosorbent assay (ELISA). This can be configured in various ways.

A Patient Ab binds to immobilised specific Ag, and is detected by addition of anti-immunoglobulin–enzyme conjugate and chromogenic substrate. **B** Patient Ab binds to immobilised Ig subclass-specific Ag, and is detected by addition of specific Ag followed by antibody–enzyme conjugate and chromogenic substrate. **C** Patient Ab and antibody–enzyme conjugate bind to immobilised specific Ag. Magnitude of colour change reaction is inversely proportional to concentration of patient Ab. **D** Patient Ag binds to immobilised Ab, and is detected by addition of antibody–enzyme conjugate and chromogenic substrate. In A the conjugate Ab is specific for human immunoglobulin. In B–D it is specific for Ag from the disease-causing organism.

a glass slide) and antibody binding is detected using a fluorescent-labelled anti-human immunoglobulin (the 'secondary' antibody). This method can also detect organisms in clinical samples (usually tissue or centrifuged cells) using a specific antibody in place of patient serum. In direct immunofluorescence clinical samples are incubated directly with fluorescent-labelled specific antibodies to detect antigen, eliminating the need for secondary antibody.

Complement fixation test (CFT)

In a CFT, patient serum is heat-treated to inactivate complement, and added to specific antigen. Any specific antibody present in the serum will complex with the antigen. Complement is then added to the reaction. If antigen-antibody complexes are present, the complement will be 'fixed' (consumed). Sheep erythrocytes, coated with an anti-erythrocyte antibody, are added. The degree of erythrocyte lysis reflects the remaining complement and is inversely proportional to the level of the specific antigen-antibody complexes.

Agglutination tests

When antigens are present on the surface of particles (e.g. cells, latex particles or microorganisms) and cross-linked with antibodies, visible clumping (or 'agglutination') occurs.

- In *direct agglutination*, patient serum is added to a suspension of organisms that express the test antigen. For example, in the Weil-Felix test, host antibodies to various rickettsial species cause agglutination of *Proteus* bacteria because they cross-react with bacterial cell surface antigens.
- In *indirect (passive) agglutination*, specific antigen is attached to the surface of carrier particles which agglutinate when incubated with patient samples that contain specific antibodies.
- In *reverse passive agglutination* (an antigen detection test), the carrier particle is coated with antibody rather than antigen.

Other tests

Immunodiffusion. This involves antibodies and antigen migrating through gels, with or without the assistance of electrophoresis, and forming insoluble complexes where they meet. The complexes are seen on staining as 'precipitin bands'. Immunodiffusion is used in the diagnosis of chronic and allergic bronchopulmonary aspergillosis.

Immunochromatography. This is used for detection of antigen. The system consists of a porous test strip (e.g. a nitrocellulose membrane), at one end of which there is target-specific antibody, complexed with coloured microparticles. Further specific antibody is immobilised in a transverse narrow line some distance along the strip. Test material (e.g. blood or urine) is added to the antibody-particle complexes, which then migrate along the strip by capillary action. If these are complexed with antigen, they will be immobilised by the specific antibody and visualised as a transverse line across the strip. If the test is negative, the antibody-particle complexes will bind to a line of immobilised anti-immunoglobulin antibody placed further along the strip, which acts as a negative control. Immunochromatographic tests are rapid and relatively cheap to perform, and are appropriate for point-of-care testing, e.g. in HIV 1.

Antibody-independent immunological tests

It is also possible to measure components of the host immune response other than antibody responses. Many investigations in patients with infectious disease reflect the non-specific innate immune response and acute phase response (p. 81), including peripheral blood neutrophil counts and CRP levels. These are used in combination with microbiological tests to assess the likelihood of infectious disease and its severity.

A few tests assess specific cellular immunity. For example, IFN- γ release assays are used to diagnose tuberculosis, since blood lymphocytes from infected individuals produce IFN- γ in response to specific mycobacterial antigens.

Antimicrobial susceptibility testing

If growth of microorganisms in culture is inhibited by the addition of an antimicrobial agent, the organism is considered to be susceptible. This information is often used to select antimicrobial therapy (p. 148). Bacteriostatic agents cause reversible inhibition of growth and bactericidal agents cause cell death. The lowest concentration of antimicrobial agent at which growth is inhibited is the minimum inhibitory concentration (MIC), and the lowest concentration that causes cell death is the minimum bactericidal concentration (MBC) (the terms fungistatic/fungicidal are used for antifungal agents, and virustatic/virucidal for antiviral agents). If the MIC is less than a predetermined threshold, the organism is considered to be susceptible, and if the MIC is greater than or equal to the threshold, the organism is resistant.

Threshold MICs are determined for each antimicrobial agent from a combination of pharmacokinetic and clinical data. In reality, the relationship between antimicrobial susceptibility in culture and clinical response is more complex, as it depends on comorbidities, immune status, pharmacokinetic variability (p. 26) and antibiotic dosing, as well as MIC/MBC. Thus, susceptibility testing does not guarantee therapeutic success, but does indicate its probability.

Susceptibility testing is most often carried out by disc diffusion (Fig. 6.9). Antibiotic-impregnated filter

Fig. 6.9 Antimicrobial susceptibility testing by disc diffusion.

The test organism is grown as a 'lawn' on an agar plate in the presence of antimicrobial-impregnated discs. The organism is considered susceptible if the diameter of the zone of inhibition exceeds a predetermined threshold.

paper discs are placed on an agar plate containing bacteria. The antibiotic diffuses through the agar, resulting in a concentration gradient centred on the disc. Bacteria are unable to grow where the antibiotic concentration exceeds the MIC, and the size of the resulting zone of inhibition is inversely proportional to the MIC. Susceptibility testing methods using serial dilutions of antimicrobial in liquid media are generally more accurate and reproducible, and are used for generating epidemiological data.

EPIDEMIOLOGY OF INFECTION

The potential of infectious diseases for transmission means that, once a clinician has diagnosed an infectious disease, potential exposure of other patients must be considered. The patient may require treatment in isolation, or an outbreak of disease may need to be investigated in the community (Ch. 5). The approach will be specific to the microorganism involved (Chs 13–15) but the principles are outlined below.

Geographic and temporal patterns of infection

Endemic disease

Endemic disease has a constant presence within a given geographic area or population. The infectious agent may have a reservoir, vector or intermediate host that is geographically restricted, or may itself have restrictive environmental requirements (e.g. temperature range, humidity). The population affected may be geographically isolated, or the disease may be limited to unvaccinated populations. Factors that alter geographical restriction include:

- expansion of an animal reservoir (e.g. Lyme disease from reforestation)
- vector escape (e.g. airport malaria)
- extension of host range (e.g. schistosomiasis from dam construction)
- human migration (e.g. HIV)
- public health service breakdown (e.g. diphtheria in unvaccinated areas)
- climate change.

Emerging and re-emerging disease

An emerging infectious disease is one that has newly appeared in a population, or that has been known for some time but is rapidly increasing in incidence or geographic range. If the disease was previously known and thought to have been controlled or eradicated, it is considered to be re-emerging. Emergence may result from an organism adapting to cause a truly 'new' disease or escaping from a pre-existing restriction. Many emerging diseases are caused by organisms which infect animals and have undergone adaptations that enable them to infect humans. This is exemplified by HIV, which is believed to have originated in higher primates in Africa. The geographical pattern of some recent emerging and re-emerging infections is shown in Figure 6.10.

Reservoirs of infection

The US Centers for Disease Control (CDC) define a reservoir of infection as 'one or more epidemiologically connected populations or environments in which a pathogen can be permanently maintained, and from which infection is transmitted to a defined target population'. Reservoirs of infection may be human, animal or environmental.

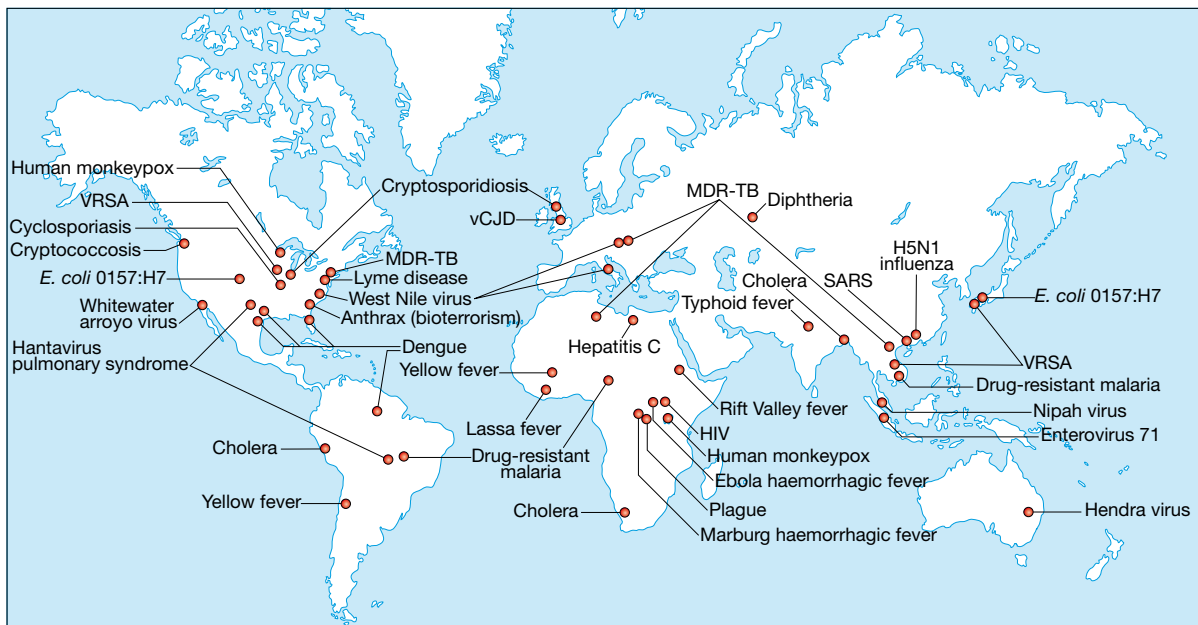

Fig. 6.10 Recent locations of some emerging and re-emerging diseases. (MDR-TB = multidrug-resistant tuberculosis; SARS = severe acute respiratory syndrome; vCJD = variant Creutzfeldt–Jakob disease; VRSA = vancomycin-resistant *Staph. aureus*)

Human reservoirs

Colonised individuals or those with clinical infectious disease may act as reservoirs, e.g. for *Staph. aureus* (including MRSA), which is carried in the nares of 30–40% of humans, and *C. difficile*. For infected humans to act as reservoirs, the infections caused must be long-lasting and/or non-fatal, at least in a proportion of those affected, to enable onward transmission (e.g. tuberculosis, typhoid and sexually transmitted infections). Humans are the only reservoir for some organisms (e.g. smallpox and measles).

Animal reservoirs

The World Health Organisation (WHO) defines a zoonosis as 'a disease or infection that is naturally transmissible from vertebrate animals to humans'. The infection may be asymptomatic in the animal. Zoonotic agents may be transmitted via any of the routes described below. Primary infection with zoonoses may on rare occasions be transmitted onward between humans by sexual contact (e.g. Q fever, brucellosis, Marburg, Ebola), causing secondary disease.

Environmental reservoirs

Many infective pathogens are acquired from an environmental source. However, some of these are maintained in human or animal reservoirs, with the environment acting simply as a conduit for infection.

Transmission of infection

Infectious agents may be transmitted by multiple routes.

- *The respiratory route* refers to acquisition of infection by inhalation.
- *The faecal–oral route* describes acquisition by ingestion of infectious material originating from faecal matter.
- *Sexually transmitted infections* are acquired by direct contact between mucous membranes.
- *Blood-borne infections* are transmitted by direct inoculation of infected blood or body fluids.
- *Direct contact*. Very few organisms are capable of causing infection by direct contact with intact skin.

Most infection by this route requires inoculation or contact with damaged skin.

In many infections there is an intermediary, which bridges the gap between the infected host (or the reservoir) and the uninfected host.

- If the intermediary is animate it is known as a *vector* (e.g. mosquitoes in malaria and dengue, fleas in plague, humans in MRSA).
- Inanimate intermediaries are known as *fomites*, and are particularly associated with health care-associated infection, where fomites include door handles, water taps, ultrasound probes etc.

The likelihood of infection following transmission of an infectious agent depends on both organism factors and host susceptibility. The numbers of organisms required to cause infection or death in 50% of the exposed population

i

6.7 Incubation periods of important infections¹

Infection	Incubation period
Short incubation periods	
Anthrax, cutaneous ³	9 hrs–2 weeks
Anthrax, inhalational ³	2 days ²
Bacillary dysentery ⁵	1–6 days
Cholera ³	2 hrs–5 days
Dengue haemorrhagic fever ⁶	3–14 days
Diphtheria ⁶	1–10 days
Gonorrhoea ⁴	2–10 days
Influenza ⁵	1–3 days
Meningococcaemia ³	2–10 days
SARS coronavirus ³	2–7 days ²
Scarlet fever ⁵	2–4 days
Intermediate incubation periods	
Amoebiasis ⁶	1–4 weeks
Brucellosis ⁴	5–30 days
Chickenpox ⁵	11–20 days
Lassa fever ³	3–21 days
Malaria ³	10–15 days
Measles ⁵	6–19 days
Mumps ⁵	15–24 days
Poliomyelitis ⁶	3–35 days
Psittacosis ⁴	1–4 weeks
Rubella ⁵	15–20 days
Typhoid ⁵	5–31 days
Whooping cough ⁵	5–21 days
Long incubation periods	
Hepatitis A ⁵	3–7 weeks
Hepatitis B ⁴	6 weeks–6 months
Leishmaniasis, cutaneous ⁶	Weeks–months
Leishmaniasis, visceral ⁶	Months–years
Leprosy ³	5–20 years
Rabies ⁴	2–8 weeks ²
<i>Trypanosoma brucei gambiense</i> infection ⁶	Months–years
Tuberculosis ⁵	1–12 months

¹Incubation periods are approximate and may differ from local or national guidance.

²Longer incubation periods have been reported.

6.6 Periods of infectivity in childhood infectious diseases¹

Disease	Infectious period
Chickenpox	From 4 days before ² until 5 days after appearance of the rash ³
Measles	From 1–2 days before onset of rash; duration unknown ³
Mumps	Unknown ⁴
Rubella	Unknown, but most infectious during prodromal illness ³
Scarlet fever	Unknown ⁵
Whooping cough	Unknown ^{5,6}

¹From Richardson M, Elliman D, Maguire H, et al. *Pediatr Infect Dis J* 2001; 20:380–388. These recommendations may differ from local or national guidance.

²Transmission before 48 hours prior to the onset of rash is rare.

^{3,4,5}Exclude from contact with non-immune and immunocompromised people for 5 days from ³onset of rash, ⁴onset of parotitis or ⁵start of antibiotic treatment.

⁶Exclude for 3 weeks if untreated.

are referred to as the ID₅₀ (infectious dose) and LD₅₀ (lethal dose), respectively. The incubation period is the time between exposure and development of disease, and the period of infectivity is the period after exposure during which the patient is infectious to others. Knowledge of incubation periods and periods of infectivity is important in controlling the spread of disease (Boxes 6.6 and 6.7).

Bioterrorism and deliberate release

Infectious agents may be released or transmitted deliberately with the intention of causing disease. The large-scale use of microorganisms for this purpose is known as biological warfare or bioterrorism, depending on the context. Deliberate-release incidents have included a 750-person outbreak of *Salmonella typhimurium* by deliberate contamination of salads in 1984 (Oregon, USA) and 22 cases of anthrax (five fatal) from the mailing of finely powdered (weaponised) anthrax spores in

2001 (New Jersey, USA). Diseases with high potential for use in bioterrorism include anthrax, plague, tularemia, smallpox and botulism (through toxin release).

CONTROL AND PREVENTION OF INFECTION

Infection prevention and control (IPC) describes the measures applied to populations with the aim of breaking the chain of infection (see Fig. 6.1, p. 132).

Health care-acquired infection

Admission to a health-care facility in the developed world carries a considerable risk of acquiring infection, estimated by the UK Department of Health as 6–10%. The factors that contribute to health care-acquired (nosocomial) infection in an individual patient are shown in Box 6.8. Many nosocomial bacterial infections are caused by organisms that are resistant to numerous antibiotics (multi-resistant bacteria), including meticillin-resistant

6.8 Risk factors for nosocomial infection

Predisposing factor	Likely infection
Environmental	
Inadequate cleaning of potential fomites (furniture, shared facilities, medical equipment etc.)	Diverse organisms
Building work and dust	<i>Aspergillus</i> spp.
Contaminated water supply	<i>Cryptosporidium</i> spp., <i>Legionella pneumophila</i> , enteric organisms
Contact with health-care staff	<i>Staph. aureus</i> including MRSA, Enterobacteriaceae including ESBL, GRE, <i>C. difficile</i> , <i>Candida</i> spp.
Contact with other patients	Norovirus, respiratory viruses (RSV, influenza, parainfluenza), VZV, <i>Staph. aureus</i> including MRSA, <i>Strep. pyogenes</i> , <i>C. difficile</i>
Personal	
Prolonged admission	Diverse organisms
Immunocompromise due to disease (haematological malignancy, HIV, diabetes mellitus, organ failure etc.) or therapy (e.g. cytotoxic agents, corticosteroids)	Diverse organisms
Antibiotic use, especially broad-spectrum (e.g. cephalosporins)	Multi-resistant organisms (MRSA, ESBL-containing Enterobacteriaceae, multi-resistant <i>Acinetobacter</i> spp., <i>Stenotrophomonas maltophilia</i> , GRE, <i>C. difficile</i>)
Receipt of blood products	Blood-borne infections (p. 1010)
Insertion of prosthesis (joint or cardiac valve) or other device (cannulae, catheters, shunts etc.)	Biofilm-related organisms (coagulase-negative staphylococci, <i>Staph. aureus</i> including MRSA, <i>Candida</i> spp.)
Surgical procedures	Diverse organisms

(ESBL = extended-spectrum β -lactamase; GRE = glycopeptide-resistant enterococci; RSV = respiratory syncytial virus; VZV = varicella zoster virus)

6.9 Methods used in the prevention and control of infection in hospitals

Institutional	
<ul style="list-style-type: none"> • Handling, storage and disposal of clinical waste • Containment and safe removal of spilled blood and body fluids • Cleanliness of environment and medical equipment • Specialised ventilation (e.g. laminar flow, air filtration, controlled pressure gradients) • Sterilisation and disinfection of instruments and equipment • Food hygiene • Laundry management 	
Health-care staff	
<ul style="list-style-type: none"> • Education • Hand hygiene, including hand-washing (see Fig. 6.11) • Sharps management and disposal • Use of personal protective equipment (masks, sterile and non-sterile gloves, gowns and aprons) • Screening health workers for disease (e.g. tuberculosis, hepatitis B virus, MRSA) • Immunisation and post-exposure prophylaxis 	
Clinical practice	
<ul style="list-style-type: none"> • Antibiotic stewardship (use only when necessary; avoid drugs known to select multi-resistant organisms or predispose to other infections) • Aseptic technique (see Box 6.10) • Perioperative antimicrobial prophylaxis • Screening patients for colonisation or infection (e.g. MRSA, GRE) 	
Response to infections	
<ul style="list-style-type: none"> • Surveillance to detect alert organism (see text) outbreaks and antimicrobial resistance • Antibiotic chemoprophylaxis to infectious disease contacts, if indicated (see Box 6.20, p. 151) • Isolation (see Box 6.11) • Reservoir control • Vector control 	

(MRSA = meticillin-resistant *Staphylococcus aureus*; GRE = glycopeptide-resistant enterococci)

Staph. aureus (MRSA) (p. 326), extended-spectrum β -lactamase (ESBL)-producing Enterobacteriaceae and glycopeptide-resistant enterococci (GRE). Other infections of particular concern in hospitals include *C. difficile* (p. 338) and norovirus (p. 323).

IPC measures are described in Box 6.9. The most important infection control practice is maintenance of good hand hygiene (Fig. 6.11). Hand decontamination or washing is *mandatory* before and after every patient contact. In most cases, decontamination with alcohol gel is adequate. However, hand-washing (with hot water, liquid soap and complete drying) is required after undertaking any procedure that involves more than casual physical contact, or if hands are visibly soiled. In situations where the prevalence of *C. difficile* is high (e.g. a local outbreak), alcohol gel decontamination between patient contacts is inadequate, as it does not kill *C. dif-*

EBM 6.10 Skin antisepsis prior to insertion of central venous catheters

'Skin preparation with chlorhexidine in 70% isopropyl alcohol is more effective than povidone-iodine or aqueous antiseptic solutions in preventing catheter infections.'

• Pratt RJ, et al. J Hosp Infect 2007; 65S: S1–S64.

ficile spores, and hands must be washed with soap and water.

To avoid infection, all invasive procedures must be performed with strict aseptic technique (Box 6.10). Some infections necessitate additional measures to prevent cross-infection (Box 6.11).

Outbreaks of infection

Descriptive terms are defined in Box 6.12. Confirmation of an infectious disease outbreak usually requires evidence from typing (p. 136) that the causal organisms have identical genotypic characteristics. If this is found not to be the case, the term pseudo-outbreak is used. When an outbreak of infection is suspected, a case definition is agreed. The number of cases that meet the case definition is then assessed by case finding, using methods ranging from administration of questionnaires to national reporting systems. Case finding usually includes microbiological testing, at least in the early stages of an outbreak. Temporal changes in cases are noted to plot an outbreak curve, and demographic details are collected to identify possible sources of infection. A case control study, in which recent activities (potential exposures) of affected 'cases' are compared to those of unaffected 'controls', may be undertaken to establish the outbreak source, and measures are taken to manage the outbreak and control its spread. Good communication between relevant personnel during and after the outbreak is important to inform practice in future outbreaks.

Surveillance ensures that disease outbreaks are either pre-empted or identified early. In hospitals, staff are alerted to the isolation of *alert organisms*, which have the propensity to cause outbreaks, and *alert conditions* (infectious diseases), which are likely to be caused by such organisms. Similar systems are used nationally; many countries publish lists of organisms and diseases which, if detected (or suspected), must be reported to public health authorities (Box 6.13).

Principles of food hygiene

'Food poisoning' (p. 302) is largely preventable by food hygiene measures. The main principles are:

- segregation of uncooked food (which may be contaminated with pathogenic microorganisms) from cooked food during storage, handling and preparation
- avoidance of conditions which allow growth of pathogenic bacteria before or after cooking
- adequate bacterial killing during cooking.

Safe storage requires knowledge of the temperatures at which food bacteria are inhibited and destroyed (Fig. 6.12).

Wash hands only when visibly soiled! Otherwise use handrub!

Duration of the entire procedure: 40–60 sec.

Fig. 6.11 Hand-washing. Good hand hygiene, whether with soap/water or alcohol handrub, includes areas that are often missed, such as fingertips, web spaces, palmar creases and the backs of hands. Adapted from WHO guidance at www.who.int.

i

 6.11 Types of isolation precaution¹

Airborne transmission	Contact transmission	Droplet transmission
Precautions Negative pressure room with air exhausted externally or filtered N95 masks or personal respirators for staff; avoid using non-immune staff	Private room preferred (otherwise inter-patient spacing ≥ 1 m) Gloves and gown for staff in contact with patient or contaminated areas	Private room preferred (otherwise inter-patient spacing ≥ 1 m) Surgical masks for staff in close contact with patient
Infections managed with these precautions Measles Tuberculosis, pulmonary or laryngeal, confirmed or suspected	Enteroviral infections in young children (diapered or incontinent) Norovirus ² <i>C. difficile</i> infection Multidrug-resistant organisms (e.g. MRSA, ESBL, GRE, VRSA, penicillin-resistant <i>Strep. pneumoniae</i>) ³ Parainfluenza in infants and young children Rotavirus RSV in infants, children and immunocompromised Viral conjunctivitis, acute	Diphtheria, pharyngeal <i>Haemophilus influenzae</i> type B infection Herpes simplex virus, disseminated or severe Influenza Meningococcal infection Mumps <i>Mycoplasma pneumoniae</i> Parvovirus (erythrovirus) B19 (erythema infectiosum, fifth disease) Pertussis Plague, pneumonic/bubonic Rubella <i>Strep. pyogenes</i> (group A), pharyngeal
Infections managed with multiple precautions 		

¹ Recommendations based on 2007 CDC guideline for isolation precautions. May differ from local or national recommendations.

² Not a CDC recommendation.

³ Subject to local risk assessment.

⁴ Or in any immunocompromised patient until possibility of disseminated infection excluded.

(VRSA = vancomycin-resistant *Staph. aureus*)

i

6.12 Terminology in outbreaks of infection

Term	Definition
Classification of related cases of infectious disease*	
Cluster	An aggregation of cases of a disease which are closely grouped in time and place, and may or may not exceed the expected number
Epidemic	The occurrence of more cases of disease than expected in a given area or among a specific group of people over a particular period of time
Outbreak	Synonymous with epidemic. Alternatively, a localised as opposed to generalised epidemic
Pandemic	An epidemic occurring over a very wide area (several countries or continents) and usually affecting a large proportion of the population
Classification of affected patients (cases)	
Index case	The first case identified in an outbreak
Primary cases	Cases acquired from a specific source of infection
Secondary cases	Cases acquired from primary cases
Types of outbreak	
Common source outbreak	Exposure to a common source of infection (e.g. water-cooling tower, medical staff member shedding MRSA). New primary cases will arise until the source is no longer present
Point source outbreak	Exposure to a single source of infection at a specific point in time (e.g. contaminated food at a party). Primary cases will develop disease synchronously
Person-to-person spread	Outbreak with both primary and secondary cases. May complicate point source or common source outbreak

*Adapted from www.cdc.gov.

Immunisation

Immunisation may be passive or active. Passive immunisation is achieved by administering antibodies targeted against a specific pathogen. Antibodies are obtained from human blood, so confer some of the risks associated with blood products (p. 1008). The protection afforded by passive immunisation is immediate but of short duration (a few weeks or months); it is used to prevent or attenuate infection before or after exposure (Box 6.14).

Vaccination

Active immunisation is achieved by vaccination with entire organisms or antigenic components such as proteins and polysaccharides. DNA vaccines are also under investigation. Desirable vaccine attributes include:

- minimal vaccine-related adverse effects
- a high level of immunity (i.e. few vaccine failures)
- long-lasting protection
- minimal cost
- ease of delivery.

Types of vaccine

Vaccine types in current use are shown in Box 6.15.

Vaccines may be either live or inactivated. Live vaccines contain organisms with attenuated (reduced)

6.14 Indications for post-exposure prophylaxis with immunoglobulins

Human normal immunoglobulin (pooled immunoglobulin)

- Hepatitis A (unvaccinated contacts*)
- Measles (if exposed child has heart or lung disease)

Human specific immunoglobulin

- Hepatitis B (sexual partners, inoculation injuries, infants born to infected mothers)
- Tetanus (high-risk wounds or when immunisation status is incomplete or unknown)
- Rabies
- Chickenpox (immunosuppressed children and adults, pregnant women)

*Active immunisation is preferred if contact is with a patient who is within 1 week of onset of jaundice.

6.15 Vaccines in current clinical use

Live attenuated vaccines

- Measles, mumps, rubella (MMR)
- Oral poliomyelitis (OPV, not used in UK)
- Tuberculosis (bacille Calmette–Guérin, BCG)
- Typhoid (oral typhoid vaccine)
- Varicella zoster virus

Inactivated (killed) whole-cell vaccines

- Cholera
- Hepatitis A
- Rabies

Toxin/toxoid/polysaccharide vaccines

- Anthrax (adsorbed antigens)
- Diphtheria (adsorbed toxoid)
- Hepatitis B (adsorbed antigen)
- *Haemophilus influenzae* type B (Hib; conjugated polysaccharide)
- Meningococcal, quadrivalent A, C, Y, W135 (polysaccharide)
- Meningococcal, serogroup C (conjugated polysaccharide)
- Pertussis (adsorbed components)
- Pneumococcal conjugate (PCV; conjugated polysaccharide, 7 or more serotypes)
- Pneumococcal polysaccharide (PPV; polysaccharide, 23 serotypes)
- Inactivated poliomyelitis (IPV; adsorbed antigens)
- Tetanus (adsorbed toxoid)
- Typhoid (Vi polysaccharide)

virulence, which result in a fully integrated T lymphocyte and humoral response (p. 75) and are therefore more immunogenic than inactivated vaccines. However, the use of live vaccines in immunocompromised individuals requires careful consideration. Inactivated vaccines consist of whole killed organisms or their antigenic components.

Vaccines consisting only of polysaccharides, such as pneumococcal polyvalent vaccine (PPV), are poor activators of T lymphocytes, and produce a short-lived antibody response without long-lasting memory. Protein antigens are more immunogenic than polysaccharides. Conjugation of a polysaccharide moiety to a protein, as in *Haemophilus influenzae* type B (Hib), *Neisseria meningitidis* serogroup C (MenC) and pneumococcal conjugate (PCV) vaccines, activates T lymphocytes, which results in a sustained response and immunological memory. Toxoids are bacterial toxins that have been modified to reduce toxicity but maintain antigenicity. Response can be improved further by co-administration with mildly pro-inflammatory adjuvants such as aluminium hydroxide.

Use of vaccines

Guidelines for individuals are shown in Box 6.16. Vaccination may be applied to entire populations (as in childhood vaccination schedules) or populations at specific risk through travel, occupation or other risk activities. In ring vaccination, the population immediately surrounding a case or outbreak of infectious disease is vaccinated, to curtail further spread.

Vaccination becomes successful once the number of susceptible hosts in a population falls below the level required to sustain continued transmission of the target organism (herd immunity). Naturally acquired smallpox was declared to have been eradicated world-wide in 1980 through mass vaccination. In 1988 the WHO resolved to eradicate poliomyelitis by vaccination; the number of cases world-wide has since fallen from approximately 350 000 p.a. to 1651 in 2008. Measles virus, however, is very infectious, and over 90% of a population needs to be vaccinated to achieve herd immunity. A recent decline in the uptake of measles vaccination in the UK has been associated with increased prevalence of disease. Recommended vaccination schedules vary between different countries.

6.16 Guidelines for vaccination against infectious disease

- The principal contraindication to inactivated vaccines is an anaphylactic reaction to a previous dose or a component of the vaccine
- Live vaccines should not be given to pregnant women, to the immunosuppressed, or in the presence of an acute infection
- If two live vaccines are required, they should be given either simultaneously in opposite arms or 4 weeks apart
- Live vaccines should not be given for 3 months after an injection of human normal immunoglobulin (HNI)
- HNI should not be given for 2 weeks after a live vaccine
- Hay fever, asthma, eczema, sickle-cell disease, topical corticosteroid therapy, antibiotic therapy, prematurity and chronic heart and lung diseases, including tuberculosis, are not contraindications to vaccination

TREATMENT OF INFECTIOUS DISEASES

The key components of treating infectious disease are:

- Address any identifiable predisposing factor, e.g. diabetes mellitus or known immune deficit (HIV, neutropenia).
- Antimicrobial therapy (see below).
- Adjuvant therapy, without which eradication of infection is unlikely, e.g. removal of an indwelling catheter (urinary or vascular), abscess drainage or débridement of an area of necrotising fasciitis.
- Treatment of the consequences of infection, e.g. the systemic inflammatory response syndrome (SIRS; p. 184), inflammation and pain.

For communicable disease, treatment must also take into account contacts of the infected patient, and may include infection prevention and control activities such as isolation, antimicrobial prophylaxis, vaccination and contact tracing.

Principles of antimicrobial therapy

When infection is diagnosed, it is often important to start antimicrobial therapy promptly. The general principles underlying the use of drugs are discussed in Chapter 2. Factors specific to antimicrobial agents are discussed below. The process of selecting antimicrobial therapy is illustrated in Figure 6.13.

Antimicrobial action and spectrum

Antimicrobial agents bring about killing by inhibiting, damaging or destroying a target that is a required component of the organism. Every antimicrobial agent is able to kill a specific range of microorganisms, and this must be considered in selecting appropriate antimicrobial therapy. The mechanisms of action of the major classes of antibacterial agent are listed in Box 6.17 and appropriate antibiotic choices for a range of common infecting organisms are shown in Box 6.18. In severe infections and/or immunocompromised patients, it is customary to use bactericidal agents in preference to bacteriostatic agents.

Empiric versus targeted therapy

Empiric antimicrobial therapy is selected to treat a clinical syndrome (e.g. meningitis) before a microbiological diagnosis has been made. Targeted therapy is aimed at the causal pathogen(s) of known antimicrobial sensitivity. Ideally, broad-spectrum agents are used in empiric therapy, and narrow-spectrum agents in targeted therapy. Optimum empiric therapy differs according to clinical presentation (e.g. pneumonia versus meningitis), patient groups (e.g. children, immunocompromised hosts) and local antimicrobial resistance patterns. Hospitals should establish local antibiotic policies to guide rational antimicrobial prescribing, maximising efficacy while minimising antimicrobial resistance and cost.

Combination therapy

Antimicrobial combination therapy is usually restricted to three settings:

- to increase efficacy (e.g. enterococcal endocarditis, where a β -lactam/aminoglycoside combination results in better outcomes than a β -lactam alone)

- when no single agent's spectrum covers all potential pathogens (e.g. in polymicrobial infection or empiric treatment of sepsis)
- to reduce antimicrobial resistance, as the organism would need to develop resistance to multiple agents simultaneously (e.g. antituberculous chemotherapy, highly active anti-retroviral therapy (HAART, p. 403)).

Antimicrobial resistance

Microorganisms have evolved in the presence of antibiotics, which are antimicrobial agents produced naturally by bacteria and fungi. They have therefore developed multiple resistance mechanisms (categorised in Fig. 6.14) to all classes of antimicrobial agent (antibiotics and their derivatives). Resistance may be an innate property of a microorganism (intrinsic resistance) or may be acquired, by either spontaneous mutation or horizontal transfer of genetic material from another organism. For some agents, e.g. penicillins, a degree of resistance occurs in vivo when the bacterial load is high and the molecular target for the antimicrobial is down-regulated (an 'inoculum effect').

The *mecA* gene encodes a low-affinity penicillin-binding protein, which confers resistance to methicillin and other penicillinase-resistant penicillins in *Staph. aureus*. It is common for plasmids to encode resistance to multiple antimicrobials, which may be transferred horizontally. Extended spectrum β -lactamases (ESBL) are

6.18 Antimicrobial options for common infecting bacteria

Organism	Antimicrobial options*
Gram-positive organisms	
<i>Enterococcus faecalis</i>	Ampicillin, tigecycline, vancomycin/teicoplanin
<i>Enterococcus faecium</i>	Tigecycline, vancomycin/teicoplanin, linezolid
Glycopeptide-resistant enterococci (GRE)	Linezolid, tigecycline, quinupristin-dalfopristin
MRSA	Clindamycin, vancomycin, rifampicin (never used as monotherapy), linezolid, daptomycin, tetracyclines, tigecycline, co-trimoxazole
<i>Staph. aureus</i>	Flucloxacillin, clindamycin
<i>Strep. pyogenes</i>	Penicillin, clindamycin, erythromycin
<i>Strep. pneumoniae</i>	Penicillin, macrolides, cephalosporins, levofloxacin, vancomycin
Gram-negative organisms	
<i>E. coli</i> , 'coliforms' (enteric Gram-negative bacilli)	Trimethoprim, cefuroxime, ciprofloxacin, co-amoxiclav, amoxicillin (resistance common)
<i>Enterobacter</i> spp., <i>Citrobacter</i> spp.	Ciprofloxacin, meropenem, aminoglycosides
ESBL-producing Enterobacteriaceae	Ciprofloxacin, meropenem, piperacillin-tazobactam, aminoglycosides, tigecycline
<i>Haemophilus influenzae</i>	Amoxicillin, co-amoxiclav, macrolides, cefuroxime, cefotaxime, ciprofloxacin
<i>Legionella pneumophila</i>	Azithromycin, levofloxacin, doxycycline
<i>Neisseria gonorrhoeae</i>	Ceftriaxone/cefixime, spectinomycin
<i>Neisseria meningitidis</i>	Penicillin, cefotaxime, chloramphenicol
<i>Pseudomonas aeruginosa</i>	Ciprofloxacin, piperacillin-tazobactam, aztreonam, meropenem, aminoglycosides, ceftazidime/cefepime
<i>Salmonella typhi</i>	Ciprofloxacin, ceftriaxone, chloramphenicol (resistance common)
Strict anaerobes	
<i>Bacteroides</i> spp.	Metronidazole, clindamycin, co-amoxiclav, piperacillin-tazobactam, meropenem
<i>Clostridium difficile</i>	Metronidazole, vancomycin (oral)
<i>Clostridium</i> spp.	Penicillin, metronidazole, clindamycin
<i>Fusobacterium</i> spp.	Penicillin, metronidazole, clindamycin
Other organisms	
<i>Chlamydia trachomatis</i>	Azithromycin, doxycycline
<i>Treponema pallidum</i>	Penicillin, doxycycline

*Antibiotic selection depends on multiple factors, including local susceptibility patterns. There are many appropriate alternatives to those listed.

Fig. 6.13 Stages in the selection and refinement of antimicrobial therapy.

encoded on plasmids, which are transferred relatively easily between bacteria including *Enterobacteriaceae*. Plasmid-mediated carbapenemases have been detected in strains of *Klebsiella pneumoniae*. Glycopeptide resistance in enterococci is also transferred on mobile genetic elements. Strains of MRSA have been described that exhibit intermediate resistance to glycopeptides, through the development of a relatively impermeable cell wall (GISA).

Factors implicated in the emergence of antimicrobial resistance include the inappropriate use of antibiotics when not indicated (e.g. in viral infections), inadequate dosage or treatment duration, excessive use of broad-spectrum agents, and use of antimicrobials as growth-promoters in agriculture. However *any* antimicrobial use exerts a selection pressure that favours the development of resistance. Combination antimicrobial therapy may reduce the emergence of resistance. This is recommended in treatment of patients infected with HIV, which is highly prone to spontaneous mutation (p. 406). Despite use of combination therapy for *M. tuberculosis*, multidrug-resistant TB (MDR-TB, resistant to isoniazid and rifampicin) and extremely drug-resistant TB (XDR-TB, resistant to isoniazid and rifampicin, any fluoroquinolone, and at least one injectable antimicrobial antituberculous agent) have been reported worldwide and are increasing in incidence (p. 693).

Duration of therapy

Treatment duration generally reflects severity of infection and the accessibility of the infected site to antimicrobial agents. For most infections there is limited clinical evidence available to support a specific duration of treatment (Box 6.19). When initial therapy is intravenous, it is often possible to switch to oral therapy after a patient has been afebrile for approximately 48 hours. In the absence of specific

guidance, antimicrobial therapy should be stopped when there is no longer any clinical evidence of infection.

Antimicrobial prophylaxis

Prophylaxis is used when there is a risk of infection from a procedure or exposure (Box 6.20). It may be combined with (or replaced by) passive immunisation (see Box 6.15). Ideally, prophylaxis should be of short duration, have minimal adverse effects and not encourage growth of resistant pathogens.

Pharmacokinetics and pharmacodynamics

Pharmacokinetics of antimicrobial agents determine whether adequate concentrations are obtained at the primary site of infection and likely areas of dissemination. Septic patients often have poor gastrointestinal absorption, so the preferred initial route of therapy is intravenous. Knowledge of anticipated antimicrobial drug concentrations at sites of infection is critical. For example, achieving a 'therapeutic' blood level of gentamicin is of little practical use in treating meningitis, as CSF penetration of the drug is severely limited. Knowledge of routes of elimination is also critical in antimicrobial therapy; for instance, a urinary tract infection is more appropriately treated with a drug that is excreted unchanged in the urine than one which is fully eliminated by hepatic metabolism.

Pharmacodynamics describes the relationship between antimicrobial concentration and microbial killing. For many agents, antimicrobial effect can be categorised as concentration-dependent or time-dependent. The concentration of antimicrobial achieved after a single dose is illustrated in Figure 6.15. The maximum concentration achieved is C_{max} and the measure of overall exposure is the area under the curve (AUC). The efficacy of antimicrobial agents whose killing is concentration-dependent (e.g. aminoglycosides) increases with the amount by which C_{max} exceeds the minimum

Fig. 6.14 Examples of mechanisms of antimicrobial resistance. (ESBL = extended spectrum β -lactamases; GISA = glycopeptide-intermediate *Staph. aureus*; GRE = glycopeptide-resistant enterococci).

inhibitory concentration (C_{\max} :MIC ratio). For this reason, it has become customary to administer aminoglycosides (e.g. gentamicin) infrequently at high doses (e.g. 7 mg/kg) rather than frequently at low doses. This has the added advantage of minimising toxicity by reducing the likelihood of drug accumulation. Conversely, the β -lactam antibiotics, macrolides and clindamycin exhibit time-dependent killing, and their efficacy depends on C_{\max} exceeding the MIC for a certain time (which is different for each class of agent). This is reflected in the dosing interval of benzylpenicillin, which is usually given every 4 hours in severe infection (e.g. meningococcal meningitis), and may be administered by continuous intravenous infusion. For other antimicrobial agents the relationships between MIC, C_{\max} and AUC are more complex and often less well understood. With some agents bacterial inhibition persists after antimicrobial exposure (post-antibiotic and post-antibiotic sub-MIC effects).

Therapeutic drug monitoring

Therapeutic drug monitoring is used to confirm non-toxic levels of antimicrobial agents with a low therapeutic index (e.g. aminoglycosides), and to confirm effective levels (if these are known) of agents with marked inter-patient pharmacokinetic variability (e.g. vancomycin, itracon-

azole). Specific recommendations for monitoring depend on individual drugs and regimens, so specialist advice should be sought. For instance, different pre- and post-dose levels of gentamicin are recommended depending on whether it is being used in traditional divided doses, once daily or for synergy in endocarditis (p. 624).

Beta-lactam antibiotics

These antibiotics have a β -lactam ring structure and exert a bactericidal action by inhibiting enzymes involved in cell wall synthesis (penicillin-binding proteins, PBP). They are classified in Box 6.23.

Pharmacokinetics

- Good drug levels are achieved in lung, kidney, bone, muscle and liver, and in pleural, synovial, pericardial and peritoneal fluids.
- CSF levels are low, except in the presence of inflammation.
- Activity is not inhibited in abscess (e.g. by low pH and PO_2 , high protein and polymorphonuclear cells).
- β -lactams are subject to an 'inoculum effect' – activity is reduced in the presence of a high

6.19 Duration of antimicrobial therapy for some common infections*	
Infection	Duration of therapy
Viral infections	
Herpes simplex encephalitis	2–3 weeks
Bacterial infections	
Gonorrhoea	Single dose
Infective endocarditis (streptococcal, native valve)	4 weeks ± gentamicin for first 2 weeks
Infective endocarditis (prosthetic valve)	≥6 weeks
Osteomyelitis	4–6 weeks
Pneumonia (community-acquired, severe)	10 days (no organism identified), 14–21 days (<i>Staph. aureus</i> or <i>Legionella</i> spp.)
Septic arthritis	2–4 weeks
Urinary tract infection (male)	2 weeks
Urinary tract infection, upper (female)	7 days
Urinary tract infection, lower (female)	3 days
Mycobacterial infections	
Tuberculosis (meningeal)	12 months
Tuberculosis (pulmonary)	6 months
Fungal infections	
Invasive pulmonary aspergillosis	Until clinical/radiological resolution and reversal of predisposition
Candidaemia (acute disseminated)	2 weeks after last positive blood culture and resolution of signs and symptoms

*All recommendations are indicative. Actual duration takes into account predisposing factors, specific organisms and antimicrobial susceptibility, adjuvant therapies and clinical response.

organism burden (PBP expression is down-regulated by high organism density).

- Generally safe in pregnancy (except imipenem/cilastatin).

Adverse reactions

Generalised allergy to penicillin occurs in 0.7–10% of cases and anaphylaxis in 0.004–0.015%. Over 90% of patients with infectious mononucleosis develop a rash if given aminopenicillins; this does not imply lasting allergy. The relationship between allergy to penicillin and allergy to cephalosporins depends on the specific cephalosporin used. Although there is significant cross-reactivity with first-generation cephalosporins, cross-reactivity to second- and third-generation cephalosporins is much less common (and may be negligible with some agents). However, it is usually recommended to avoid cephalosporins in patients who have a type 1 penicillin allergy (e.g. anaphylaxis, urticaria, angio-oedema).

Gastrointestinal upset and diarrhoea are common, and a mild reversible hepatitis is well recognised with

6.20 Recommendations for antimicrobial prophylaxis in adults*	
Infection risk	Recommended antimicrobial
Bacterial	
Diphtheria (prevention of secondary cases)	Erythromycin
Gas gangrene (after high amputation or major trauma)	Penicillin or metronidazole
Lower gastrointestinal tract surgery	Cefuroxime + metronidazole, gentamicin + metronidazole, or co-amoxiclav (single dose only)
Meningococcal disease (prevention of secondary cases)	Rifampicin or ciprofloxacin
Rheumatic fever (prevention of recurrence)	Phenoxymethylpenicillin or sulfadiazine
Tuberculosis (prevention of secondary cases)	Isoniazid ± rifampicin
Whooping cough (prevention of secondary cases)	Erythromycin
Viral	
HIV, occupational exposure (sharp injury)	Combination tenofovir/emtricitabine and lopinavir/ritonavir. Modified if index case's virus known to be resistant
Influenza A (prevention of secondary cases in adults with chronic respiratory, cardiovascular renal disease, immunosuppression or diabetes mellitus)	Oseltamivir
Fungal	
Aspergillosis (in high-risk haematology patients)	Itraconazole or posaconazole
<i>Pneumocystis pneumonia</i> (prevention in HIV and other immunosuppressed states)	Co-trimoxazole, pentamidine or dapsone
Protozoal	
Malaria (prevention of travel-associated disease)	Specific antimalarials depend on travel itinerary (p. 352)

*These are based on current UK practice. Recommendations may vary locally or nationally. There is currently no recommendation in the UK to administer antimicrobial prophylaxis for infective endocarditis during dental procedures.

many β -lactams. Leucopenia, thrombocytopenia and coagulation deficiencies can occur. Interstitial nephritis and increased renal damage in combination with aminoglycosides are also recognised (p. 504). Seizures and encephalopathy have been reported, particularly with high doses in the presence of renal insufficiency. Thrombophlebitis occurs in up to 5% of patients receiving parenteral β -lactams. Direct intrathecal injection of a β -lactam is contraindicated.

Drug interactions

Synergism occurs in combination with aminoglycosides. Simultaneous dual β -lactam administration can result in either synergy or antagonism. Ampicillin decreases the biological effect of oral contraceptives

Fig. 6.15 Antimicrobial pharmacodynamics. The curve represents drug concentrations after a single dose of an antimicrobial agent. Factors that determine microbial killing are C_{\max} :MIC ratio (concentration-dependent killing), time above MIC (time-dependent killing) and AUC:MIC ratio.

6.21 Antimicrobial agents in pregnancy¹

Contraindicated

- Chloramphenicol: neonatal 'grey baby' syndrome—collapse, hypotension and cyanosis
- Fluconazole: teratogenic in high doses
- Quinolones, nalidixic acid: arthropathy in animals
- Sulphonamides: neonatal haemolysis and methaemoglobinaemia
- Tetracyclines, glycyclines: skeletal abnormalities in animals in 1st trimester; fetal dental discoloration and maternal hepatotoxicity with large parenteral doses in 2nd or 3rd trimesters
- Trimethoprim: teratogenic in 1st trimester

Relatively contraindicated

- Aminoglycosides: potential damage to fetal auditory and vestibular nerves in 2nd and 3rd trimesters
- Metronidazole: avoidance of high dosages is recommended²

Not known to be harmful; use only when necessary

- Aciclovir
- Cephalosporins
- Clarithromycin
- Clindamycin
- Erythromycin
- Glycopeptides
- Linezolid
- Meropenem
- Penicillins

¹ Data extracted from Joint Formulary Committee. British National Formulary, 55th edn. London: BMJ and RPS; 2008.

² Theoretical risk of teratogenicity, not supported by available clinical evidence.

and the whole class is significantly affected by concurrent administration of probenecid, producing a 2–4-fold increase in the peak serum concentration.

Penicillins

Natural penicillins are primarily effective against Gram-positive organisms (except staphylococci, most of which produce a penicillinase) and anaerobic organisms. *Strep. pyogenes* has remained sensitive to natural penicillins world-wide. The prevalence of penicillin resistance in *Strep. pneumoniae* in Europe in 2006 was

6.22 Problems with antimicrobial therapy in old age

- ***Clostridium difficile* infection:** many antibiotics predispose, especially second- and third-generation cephalosporins.
- **Hypersensitivity reactions:** rise in incidence due to increased previous exposure.
- **Renal impairment:** may be significant in old age despite 'normal' creatinine levels (p. 465)
- **Nephrotoxicity** is more likely, e.g. first-generation cephalosporins, aminoglycosides.
- **Accumulation of β -lactam antibiotics:** may result in myoclonus, seizures or coma.
- **Reduced gastric acid production:** gastric pH is higher, which causes increased penicillin absorption.
- **Reduced hepatic metabolism:** results in a higher risk of isoniazid-related hepatotoxicity.
- **Quinolones:** associated with confusion and may increase the risk of seizures.

6.23 Beta-lactam antibiotics

Penicillins

- Natural penicillins: benzylpenicillin, phenoxymethylpenicillin
- Penicillinase-resistant penicillins: methicillin, flucloxacillin, nafcillin, oxacillin
- Aminopenicillins: ampicillin, amoxicillin
- Carboxy- and ureido-penicillins: ticarcillin, piperacillin

Cephalosporins

- See Box 6.24

Monobactams

- Aztreonam

Carbapenems

- Imipenem, meropenem, ertapenem

9%. This figure includes both low- and high-level resistance (non-severe infections with low-level resistant strains may be treated with high-dose penicillins).

Penicillinase-resistant penicillins are the mainstay of treatment for infections with *Staph. aureus*, other than methicillin-resistant strains (MRSA). In 2006 24% of invasive *Staph. aureus* isolates in Europe were methicillin-resistant.

Aminopenicillins have the same spectrum of activity as the natural penicillins, with additional Gram-negative cover against Enterobacteriaceae. Amoxicillin has much better oral absorption than ampicillin. Resistance to these agents is widespread (57% of *E. coli* in the UK in 2006), mainly due to β -lactamase production, but can be overcome by the addition of β -lactamase inhibitors (clavulanic acid or sulbactam).

Carboxy- and ureidopenicillins are particularly active against Gram-negative organisms, especially *Pseudomonas* spp. which are resistant to the aminopenicillins. Beta-lactamase inhibitors may be added to extend their spectrum of activity.

Cephalosporins and cephamycins

Cephalosporins are safe and reliable and have a broad spectrum of activity. The more active compounds are only available in intravenous form. They are significantly associated with *C. difficile* infection (CDI) (p. 338).

6.24 Cephalosporins	
First generation	
• Cefalexin, cefradine (oral)	• Cefazolin (i.v.)
Second generation	
• Cefuroxime (oral/i.v.)	• Cefoxitin (i.v.)
• Cefaclor (oral)	
Third generation	
• Cefixime (oral)	• Ceftriaxone (i.v.)
• Cefotaxime (i.v.)	• Ceftazidime (i.v.)
Fourth generation	
• Cefepime (i.v.)	
'Next generation'	
• Ceftobiprole (i.v.)	• Ceftaroline (i.v.)

The group has no activity against *Enterococcus* spp. and little anti-anaerobic activity (with the exception of cephamycins). Cephalosporins are arranged in 'generations' (Box 6.24).

- *First-generation compounds* have excellent activity against Gram-positive organisms and some activity against Gram-negative ones. Many of them are potentially nephrotoxic.
- *Second-generation drugs* retain Gram-positive activity but have extended Gram-negative activity. Cephamycins (e.g. cefoxitin), which are included in this group, have good activity against anaerobic Gram-negative bacilli.
- *Third-generation agents* further improve anti-Gram-negative cover. For some (e.g. ceftazidime), this is extended to include *Pseudomonas* spp. Cefotaxime and ceftriaxone have excellent Gram-negative activity and retain good activity against *Strep. pneumoniae* and β -haemolytic streptococci. Ceftriaxone is administered once daily, and is therefore a suitable agent for outpatient antimicrobial therapy.
- *Fourth-generation agents* have an extremely broad spectrum of activity, including *Pseudomonas* spp., *Staph. aureus* and streptococci.
- *'Next generation' agents* have a fourth-generation spectrum enhanced to include MRSA.

Monobactams

Aztreonam is the only agent available in this class. It has excellent Gram-negative activity but no useful activity against Gram-positive organisms or anaerobes. It is available only as a parenteral preparation. It can be used safely in penicillin-allergic patients.

Carbapenems

These have the broadest antibiotic activity of the β -lactam antibiotics and include activity against anaerobes. They are available in intravenous formulation only.

Macrolide and lincosamide antibiotics

Macrolides (erythromycin, clarithromycin and azithromycin) and lincosamides (lincomycin, clindamycin) have related properties and are bacteriostatic agents.

Both classes bind to the same element of the ribosome so they are potentially competitive and should not be administered together. Macrolides are used in Gram-positive infections in penicillin-allergic patients and in *Mycoplasma* and *Chlamydia* infections. Erythromycin is administered 6-hourly and clarithromycin 12-hourly. The long intracellular half-life of azithromycin allows single-dose/short-course therapy for genitourinary *Chlamydia*/*Mycoplasma* spp. infections. Clarithromycin and azithromycin are also used to treat legionellosis.

Pharmacokinetics

Macrolides

- Variable bioavailability.
- Short half-life (except azithromycin).
- High protein binding.
- Excellent intracellular accumulation.

Lincosamides (e.g. clindamycin)

- Good bioavailability.
- Food has no effect on absorption.
- Limited CSF penetration.

Adverse effects

- Generally very safe.
- Gastrointestinal upset, especially in young adults (erythromycin 30%).
- Cholestatic jaundice with erythromycin estolate.
- Prolongation of QT interval on ECG, potential for torsades de pointes.
- Clindamycin predisposes to *C. difficile* infection.

Ketolides

The ketolides were developed in response to the emergence of penicillin and macrolide resistance in respiratory pathogens. Cross-resistance with macrolides is uncommon. Telithromycin is administered orally and has useful activity against common bacterial causes of respiratory infection, as well as *Mycoplasma*, *Chlamydia* and *Legionella* spp.

Aminoglycosides

Aminoglycosides are very effective anti-Gram-negative antibiotics, e.g. in intra-abdominal and urinary tract sepsis. They act synergistically with β -lactam antibiotics and are particularly useful where β -lactam or quinolone resistance occurs in health care-acquired infections. They cause very little local irritation at injection sites and negligible allergic responses. Oto- and nephrotoxicity must be avoided by monitoring of renal function and drug levels and use of short treatment regimens. Aminoglycosides are not subject to an inoculum effect (p. 149) and they all exhibit a post-antibiotic effect (p. 151).

Pharmacokinetics

- Negligible oral absorption, i.v. administration.
- Hydrophilic, so excellent penetration to extracellular fluid in body cavities and serosal fluids.
- Very poor intracellular penetration (except hair cells in cochlea and renal cortical cells).

Fig. 6.16 Dosing of aminoglycosides using the Hartford nomogram.

The nomogram is used to determine the dose interval for 7 mg doses of gentamicin or tobramycin, using measurements of drug levels in plasma 6–14 hours after a single dose.

- Negligible CSF and corneal penetration.
- Peak plasma levels 30 minutes after infusion.
- Once-daily administration possible in many infections.
- Monitoring of therapeutic levels required.

Gentamicin dosing

- Except in endocarditis, pregnancy, severe burns, end-stage renal disease and paediatric patients, gentamicin may be administered at 7 mg/kg body weight. The appropriate dose interval depends on drug clearance, and is determined by reference to the Hartford nomogram (Fig. 6.16).
- In streptococcal and enterococcal endocarditis, gentamicin is used with a cell wall active agent (usually a β -lactam), to provide synergy. The usual dose is 1 mg/kg/day every 8 or 12 hours. Target pre- and post-dose levels are < 1 mg/L and 3–5 mg/L respectively.
- For other indications, gentamicin is administered 8- or 12-hourly at 3–5 mg/kg/day. Target pre- and post-dose levels are < 2 mg/L and 5–10 mg/L (7–10 mg/L with less sensitive organisms, e.g. *Pseudomonas* spp.) respectively.
- For dosing of other aminoglycosides, consult local guidance.

Adverse reactions

- Renal toxicity (usually reversible) accentuated by other nephrotoxic agents.
- Cochlear toxicity (permanent) more likely in older people and those with a predisposing mitochondrial gene mutation.
- Neuromuscular blockade after rapid i.v. infusion (potentiated by calcium channel blockers, myasthenia gravis and hypomagnesaemia).

Quinolones and fluoroquinolones

These are bactericidal agents that are usually well tolerated and effective. The quinolones have purely anti-Gram-negative activity, whereas the fluoro-

6.25 Quinolones and fluoroquinolones

Agent	Route of administration	Typical antimicrobial spectrum
Quinolones		
Nalidixic acid	Oral	Enteric Gram-negative bacilli (not <i>Pseudomonas aeruginosa</i>)
Fluoroquinolones		
Ciprofloxacin	I.v./oral	Enteric Gram-negative bacilli, <i>P. aeruginosa</i> , <i>Haemophilus</i> spp., 'atypical' respiratory pathogens*
Norfloxacin	Oral	
Ofloxacin	I.v./oral/topical	
Levofloxacin (L-isomer of ofloxacin)	I.v./oral	<i>Haemophilus</i> spp., <i>Strep. pneumoniae</i> , 'atypical' respiratory pathogens*
Moxifloxacin	Oral	<i>Strep. pneumoniae</i> , <i>Staph. aureus</i> , 'atypical' respiratory pathogens* and anaerobes

*'Atypical' pathogens include *Mycoplasma pneumoniae* and *Legionella* spp. Fluoroquinolones have variable activity against *M. tuberculosis* and other mycobacteria.

quinolones are broad-spectrum agents (Box 6.25). Ciprofloxacin has anti-pseudomonal activity but resistance emerges rapidly. In Europe in 2006 between 5 and 48% of invasive *E. coli* isolates were resistant to ciprofloxacin.

Pharmacokinetics

- Well absorbed after oral administration but delayed by food, antacids, ferrous sulphate and multivitamins. Excellent anti-Gram-negative activity.
- Wide volume of distribution; tissue concentrations twice those in serum.
- Good intracellular penetration, concentrating in phagocytes.

Adverse reactions

- Gastrointestinal side-effects in 1–5%.
- Rare skin reactions (phototoxicity).
- Achilles tendon rupture is reported, especially in older people.
- CNS effects (confusion, tremor, dizziness and occasional seizures in 5–12%), especially in older people.
- Reduces clearance of xanthines and theophyllines, potentially inducing insomnia and increased seizure potential.
- Reports of prolongation of QT interval on ECG with newer fluoroquinolones.
- Cases of hypo- or hyperglycaemia in association with gatifloxacin, so glucose monitoring is needed in patients with diabetes or those with severe hepatic dysfunction.
- Quinolone use is associated with the acquisition of MRSA and emergence of a highly virulent strain of *C. difficile* (ribotype 027).

Glycopeptides

Glycopeptides (vancomycin and teicoplanin) are only effective against Gram-positive organisms, and are used against MRSA and ampicillin-resistant enterococci. Some staphylococci and enterococci demonstrate intermediate sensitivity or resistance. Vancomycin use should be restricted, particularly in the management of *C. difficile* infections, to limit emergence of resistant strains. Teicoplanin is not available in all countries. Neither drug is absorbed after oral administration, but vancomycin is used orally in the treatment of *C. difficile* infection.

Pharmacokinetics

Vancomycin

- Administered by slow i.v. infusion, good tissue distribution and short half-life.
- Enters CSF only in the presence of inflammation.
- Therapeutic monitoring of i.v. vancomycin is recommended, to maintain pre-dose levels of > 10 mg/L (10–20 mg/L in serious staphylococcal infections).

Teicoplanin

- Long half-life allows once-daily dosing.

Adverse effects

- Histamine release due to rapid vancomycin infusion produces a 'red man' reaction (rare with modern preparations).
- Nephrotoxicity is rare, but may occur with concomitant aminoglycoside use.
- Teicoplanin can cause rash, bronchospasm, eosinophilia and anaphylaxis.

Folate antagonists

These bacteriostatic antibiotics interfere with the prokaryotic cell metabolism of para-aminobenzoic acid to folic acid. A combination of a sulphonamide and either trimethoprim or pyrimethamine is most commonly used and interferes with two consecutive steps in the metabolic pathway. Combinations in use include trimethoprim/sulfamethoxazole (co-trimoxazole) and pyrimethamine with either sulfadoxine (used to treat malaria) or sulfadiazine (used in toxoplasmosis). Co-trimoxazole in high dosage (120 mg/kg daily in 2–4 divided doses) is the first-line drug for *Pneumocystis jirovecii* (*carinii*) infection in HIV disease. The clinical use of these agents is limited by adverse effects. Folate supplements should be given if these agents are used in pregnancy.

Pharmacokinetics

- Well absorbed orally.
- Sulphonamides are hydrophilic, distributing well to the extracellular fluid.
- Trimethoprim is lipophilic with high tissue concentrations.

Adverse reactions

- Trimethoprim is generally well tolerated with few adverse effects.
- Sulphonamides and dapsone may cause haemolysis in glucose-6-phosphate dehydrogenase deficiency (p. 1024).

- Sulphonamides and dapsone cause skin and mucocutaneous reactions including Stevens-Johnson syndrome and 'dapsone syndrome' (rash, fever and lymphadenopathy).
- Dapsone causes methaemoglobinaemia and peripheral neuropathy.
- Adverse effects of co-trimoxazole relate mainly to the sulphonamide component, and increase with dose and duration.

Tetracyclines and glycyclines

Tetracyclines

Of this mainly bacteriostatic class, the newer drugs doxycycline and minocycline show better absorption and distribution than older ones. Most streptococci and Gram-negative bacteria are now resistant, in part due to use in animals (which is banned in Europe). Tetracyclines are indicated for *Mycoplasma* spp., *Chlamydia* spp., *Rickettsia* spp., *Coxiella* spp., *Bartonella* spp., *Borrelia* spp., *Helicobacter pylori*, *Treponema pallidum* and atypical mycobacterial infections. Minocycline is occasionally used in chronic staphylococcal infections.

Pharmacokinetics

- Best oral absorption is in the fasting state (doxycycline is 100% absorbed unless gastric pH rises).

Adverse reactions

- All tetracyclines except doxycycline are contraindicated in renal failure.
- Dizziness with minocycline.
- Binding to metallic ions in bones and teeth causes discoloration (avoid in children and pregnancy) and enamel hypoplasia.
- Phototoxic skin reactions.

Glycyclines (tigecycline)

Chemical modification of tetracycline has produced tigecycline, a broad-spectrum parenteral-only antibiotic with activity against resistant Gram-positive and Gram-negative pathogens such as MRSA and ESBL (but excluding *Pseudomonas* spp.). Tigecycline has prominent gastrointestinal side-effects.

Nitroimidazoles (metronidazole, tinidazole)

Nitroimidazoles are highly active against strictly anaerobic bacteria, especially *B. fragilis*, *C. difficile* and other *Clostridium* spp. They also have significant anti-protozoal activity against amoebae and *Giardia lamblia*.

Pharmacokinetics

- Almost completely absorbed after oral administration (60% after rectal administration).
- Well distributed, especially to brain and CSF.
- Safe in pregnancy.

Adverse effects

- Metallic taste (dose-dependent).
- Severe vomiting if taken with alcohol – 'Antabuse effect'.
- Peripheral neuropathy with prolonged use.

Other antibacterial agents

Chloramphenicol

This is a potent and cheap antibiotic, still widely prescribed throughout the world despite its potential toxicity. Its use, however, is increasingly reserved for severe and life-threatening infections where other antibiotics are either unavailable or impractical. It is bacteriostatic to most organisms but apparently bactericidal to *H. influenzae*, *Strep. pneumoniae* and *N. meningitidis*. It has a very broad spectrum of activity against aerobic and anaerobic organisms, spirochaetes, *Rickettsia*, *Chlamydia* and *Mycoplasma* spp. It also has quite useful activity against anaerobes such as *Bacteroides fragilis*. It competes with macrolides and lincosamides for ribosomal binding sites, so should not be used in combination with these agents.

Pharmacokinetics

- Well absorbed after i.v. or oral dose (not i.m.). Good tissue distribution and levels.
- Good CSF levels.
- Crosses placenta and reaches breast milk.

Adverse reactions

- Dose-dependent 'grey baby' syndrome in infants (cyanosis and circulatory collapse due to inability to conjugate drug and excrete active form in urine).
- Reversible dose-dependent bone marrow depression in adults if > 4 g per day administered or cumulative dose > 25 g.
- Severe idiopathic aplastic anaemia in 1:25 000–40 000 exposures (unrelated to dose, duration of therapy or route of administration).

Daptomycin

Daptomycin is a cyclic lipopeptide which has bactericidal activity against Gram-positive organisms (including MRSA and GRE) but no activity against Gram-negatives. It is not absorbed orally, and is used intravenously to treat resistant Gram-positive infections, e.g. soft tissue infections and infective endocarditis, where other options are not available.

Fusidic acid

This antibiotic, active against Gram-positive bacteria, is available in intravenous, oral or topical formulations. It is lipid-soluble and distributes well to tissues. However, its antibacterial activity is unpredictable. Fusidic acid is used in combination, typically with anti-staphylococcal penicillins, or for MRSA with clindamycin or rifampicin. It interacts with coumarin derivatives and oral contraceptives.

Nitrofurantoin

This drug has very rapid renal elimination and is active against aerobic Gram-negative and Gram-positive bacteria, including enterococci. It is used only for treatment of urinary tract infection, being generally safe in pregnancy and childhood. However, it can produce eosinophilic lung infiltrates, fever, pulmonary fibrosis, peripheral neuropathy, hepatitis and haemolytic anaemia.

Linezolid

Linezolid is the only currently licensed member of the oxazolidinone class, which shows excellent oral absorption with good activity against Gram-positive organisms, including MRSA and GRE. It is competitively inhibited by co-administration of chloramphenicol, vancomycin or clindamycin. It appears to be very safe, although mild gastrointestinal side-effects and tongue discoloration are common. Myelodysplasia and peripheral neuropathy can occur with prolonged use. Co-administration with monoamine oxidase inhibitors or serotonin re-uptake inhibitor antidepressants should be avoided, as it may precipitate a serotonin syndrome (neuromuscular effects, autonomic hyperactivity and altered mental status).

Spectinomycin

Chemically similar to the aminoglycosides and given intramuscularly, spectinomycin was developed to treat strains of *N. gonorrhoeae* resistant to β -lactam antibiotics. Unfortunately, resistance to spectinomycin is very common and its only indication is the treatment of gonococcal urethritis in pregnancy or in patients allergic to β -lactam antibiotics.

Streptogramins

Quinupristin/dalfopristin (supplied as a 30:70% combination) is active against MRSA and GRE (*Enterococcus faecium* but not *E. faecalis*), and its use should be reserved for these organisms. It is available in intravenous formulation only and shows good tissue penetration, but does not cross the blood-brain barrier or the placenta. Significant phlebitis occurs at injection sites and a raised serum creatinine and eosinophilia may occur.

Antifungal agents

See Box 6.26.

Azole antifungals

The azoles (imidazoles and triazoles) inhibit synthesis of ergosterol, a key constituent of the fungal cell membrane. Side-effects vary but include gastrointestinal upset, hepatitis and rash. Azoles are amongst the drugs metabolised by cytochrome p450 enzymes, so must be used cautiously if combined with other such drugs with which they may interact (p. 34).

Imidazoles

Miconazole, econazole, clotrimazole and ketoconazole are relatively toxic and therefore mainly administered topically. Clotrimazole is used extensively to treat superficial fungal infections. Ketoconazole may be given orally, but causes severe hepatitis in ~1:15 000 cases and inhibits enzymes involved in steroid biosynthesis in the adrenals and gonads. Triazoles are preferred for systemic administration because of their reduced toxicity.

Triazoles

Fluconazole is effective against yeasts only (*Candida* and *Cryptococcus* spp.). It is well absorbed after oral administration, and has a long half-life (approximately 30 hours) and an excellent safety profile. The drug is highly water-soluble

6.26 Antifungal agents

Agent (usual route(s) of administration)	Clinically relevant antifungal spectrum	
Imidazoles		
Miconazole (topical) Econazole (topical) Clotrimazole (topical)	} <i>Candida</i> spp., dermatophytes	
Ketoconazole (topical, oral)		<i>Malassezia</i> spp., dermatophytes, agents of eumycetoma
Triazoles		
Fluconazole (oral, i.v.)	Yeasts (<i>Candida</i> and <i>Cryptococcus</i> spp.)	
Itraconazole (oral, i.v.)	Yeasts, dermatophytes, dimorphic fungi (p. 376), <i>Aspergillus</i> spp.	
Voriconazole (oral, i.v.)	Yeasts and most filamentous fungi (excluding <i>Mucorales</i>)	
Posaconazole (oral)	Yeasts and most filamentous fungi (including most <i>Mucorales</i>)	
Echinocandins		
Anidulafungin (i.v. only) Caspofungin (i.v. only) Micafungin (i.v. only)	} <i>Candida</i> spp., <i>Aspergillus</i> spp. (no activity against <i>Cryptococcus</i> spp. or <i>Mucorales</i>)	
Polyenes		
Amphotericin B (i.v.) Nystatin (topical)		} Yeasts and most dimorphic and filamentous fungi (including <i>Mucorales</i>)
Others		
5-fluorocytosine (oral, i.v.)	Yeasts	
Griseofulvin (oral)	Dermatophytes	
Terbinafine (topical, oral)	Dermatophytes	

and distributes widely to all body sites and tissues, including CSF.

Itraconazole is lipophilic and distributes extensively, including to toenails and fingernails. CSF penetration is poor. Oral absorption is erratic and formulation-dependent, which necessitates monitoring of blood levels.

Voriconazole is extremely well absorbed (96% oral bioavailability) and is used mainly in the treatment of aspergillosis.

Posaconazole is the broadest-spectrum antifungal azole, and the only one with consistent activity against the *Mucorales*. It is currently available as an oral agent only.

Echinocandins

Anidulafungin, caspofungin and micafungin inhibit β -1,3-glucan synthesis in the fungal cell wall. They do not demonstrate cross-resistance with azoles or polyenes and have very few significant adverse effects. Caspofungin, anidulafungin and micafungin are used to treat candidaemia, and caspofungin is also used in aspergillosis.

Polyenes

Amphotericin B deoxycholate causes cell death by binding to ergosterol and damaging the fungal cytoplasmic membrane. Its use in resource-rich countries is being supplanted by less toxic antifungal agents. It is

lipophilic, insoluble in water and not absorbed orally. Its long half-life enables once-daily administration. CSF penetration is poor.

Adverse reactions include immediate anaphylaxis (a test dose should always be given before infusion), other infusion-related reactions, and nephrotoxicity. Nephrotoxicity may be sufficient to require dialysis, and occurs in most patients who are adequately dosed. It may be ameliorated by concomitant infusion of normal saline. Irreversible nephrotoxicity occurs with large cumulative doses of amphotericin B.

Nystatin has a similar spectrum of antifungal activity to amphotericin B. Its toxicity limits it to topical use, e.g. in oral and vaginal candidiasis.

Lipid formulations of amphotericin B

Lipid formulations of amphotericin B (AmB) have been developed to reduce the toxicity of the parent compound. These consist of AmB encapsulated in liposomes (liposomal AmB, L-AmB) or complexed with phospholipids (AmB lipid complex, ABLC) or cholesteryl sulphate (AmB colloidal dispersion, ABCD). The drug becomes active dissociating from its lipid component after administration. Adverse reactions are similar to, but considerably less frequent than, those with AmB deoxycholate, and efficacy is similar. Lipid formulations of AmB are used as empirical therapy in patients with neutropenic fever (p. 1000), and also in visceral leishmaniasis.

Other antifungal agents

5-fluorocytosine

This drug has particular activity against yeasts. When used as monotherapy, resistance develops rapidly, so it should be administered in combination with another antifungal agent. Oral dosing is effective. Adverse reactions include myelosuppression, gastrointestinal upset and hepatitis.

Griseofulvin

Griseofulvin has been largely superseded by terbinafine and itraconazole for treatment of dermatophyte infections, except in children, for whom these agents remain unlicensed. It demonstrates excellent oral bioavailability and is deposited in keratin precursor cells, which become resistant to fungal invasion. The duration of treatment is 2–4 weeks for tinea corporis/capitis, 4–8 weeks for tinea pedis, and 4–6 months for onychomycosis (fungal nail infections).

Terbinafine

Terbinafine is well absorbed orally, can be given once daily and distributes with high concentration to sebum and skin with a half-life of greater than 1 week. It is used topically for skin infections and orally for onychomycosis (nail infections). The major adverse reaction is hepatic toxicity (approximately 1:50 000 cases). Terbinafine is not recommended for breastfeeding mothers and should not be applied vaginally.

Antiviral agents

Most viral infections in immunocompetent individuals resolve without intervention. Antiviral therapy is available only for a limited number of infections (Boxes 6.27 and 14.23, p. 404).

6.27 Antiviral agents

Drug	Route(s) of administration	Indications	Significant side-effects
Highly active antiretroviral therapy (HAART, p. 403)			
	Oral	HIV infection (including AIDS)	CNS symptoms, anaemia, lipodystrophy
Anti-herpes virus agents			
Aciclovir	Topical Oral I.v. }	Herpes zoster Chickenpox (esp. in immunosuppressed) Herpes simplex infections: encephalitis (i.v. only), genital tract, oral, ophthalmic	Significant side-effects rare. Hepatitis, renal impairment and neurotoxicity reported rarely
Valaciclovir	Oral	Herpes zoster, herpes simplex	As for aciclovir
Famciclovir	Oral	Herpes zoster, herpes simplex (genital)	As for aciclovir
Penciclovir	Topical	Labial herpes simplex	Local irritation
Ganciclovir	I.v.	Treatment and prevention of CMV infection in immunosuppressed	Gastrointestinal symptoms, liver dysfunction, neurotoxicity, myelosuppression, renal impairment, fever, rash, phlebitis at infusion sites. Potential teratogenicity
Valganciclovir	Oral	Treatment and prevention of CMV infection in immunosuppressed	As for ganciclovir but neutropenia is predominant
Cidofovir	I.v. Topical	HIV-associated CMV infections and occasionally other viruses (see text)	Renal impairment, neutropenia
Foscarnet	I.v.	CMV and aciclovir-resistant HSV and VZV infections in immunosuppressed	Gastrointestinal symptoms, renal impairment, electrolyte disturbances, genital ulceration, neurotoxicity
Anti-influenza agents			
Zanamivir	Inhalation	Influenza A and B	Allergic reactions (very rare)
Oseltamivir	Oral	Influenza A and B	Gastrointestinal side-effects, rash, hepatitis (very rare)
Amantadine, rimantadine	Oral	Influenza A (but see text)	CNS symptoms, nausea
Other antiviral agents			
Ribavirin	Oral/i.v./inhalation	Hepatitis C infection (with interferons) (oral) Lassa fever (i.v.) RSV infection in infants (inhalation)	Haemolytic anaemia, cough, dyspnoea, bronchospasm and ocular irritation (when given by inhalation)
Interferon- α	S.c.	Chronic hepatitis B and (with ribavirin)	Influenza-like syndrome following dose,
Pegylated interferon- α	S.c.	hepatitis C	gastrointestinal symptoms, hepatitis, myelosuppression
Adefovir dipivoxil, entecavir, lamivudine, telbivudine	Oral	Chronic hepatitis B infection	Generally well tolerated with minimal side-effects Creatine kinase elevation (telbivudine only)
Tenofovir	Oral	Hepatitis B in co-infection with HIV (with other antiretroviral agents)	Minimal side-effects Rarely nephrotoxicity

Antiretroviral agents

These agents, used predominantly against HIV, are discussed in Chapter 14.

Anti-herpes virus agents

Aciclovir, valaciclovir, penciclovir and famciclovir

Aciclovir, valaciclovir, penciclovir and famciclovir are acyclic analogues of guanosine, which inhibit viral DNA polymerase after being phosphorylated by virus-derived thymidine kinase (TK). Aciclovir is slowly and incompletely absorbed after oral dosing; much better levels

are achieved intravenously or by use of the pro-drug valaciclovir. Famciclovir is the pro-drug of penciclovir. Resistance is mediated by mutations in the viral kinase or polymerase.

Ganciclovir

Chemical modification of the aciclovir molecule allows preferential phosphorylation by protein kinases of CMV and other β -herpesviruses (e.g. HHV6/7) and hence greater inhibition of the DNA polymerase, but at the expense of increased toxicity. Ganciclovir is administered intravenously or as a pro-drug (valganciclovir) orally.

Cidofovir

Cidofovir inhibits viral DNA polymerases with potent activity against CMV, including most ganciclovir-resistant CMV. It also has activity against aciclovir-resistant HSV and VZV, human herpes virus 6 and occasionally adenovirus, pox virus, papillomavirus or polyoma virus, and may be used to treat these infections in immunocompromised hosts.

Foscarnet

This analogue of inorganic pyrophosphate acts as a non-competitive inhibitor of HSV, VZV, HHV6/7 or CMV DNA polymerase. It does not require significant intracellular phosphorylation and so may be effective when HSV or CMV resistance is due to altered phosphorylation of the antiviral substrate. It has variable CSF penetration.

Anti-influenza agents**Zanamivir and oseltamivir**

These agents inhibit the neuraminidase enzyme in influenza A and B, which is required for release of virus from infected cells (see Fig. 6.2, p. 133). They are used in treatment and prophylaxis of influenza. Administration within 48 hours of disease onset reduces the duration of symptoms by approximately 1–1½ days. In the UK their use is limited mainly to adults with chronic respiratory or renal disease, significant cardiovascular disease, immunosuppression or diabetes mellitus, during known outbreaks.

Amantadine and rimantadine

These drugs reduce replication of influenza A by inhibition of viral M2 protein ion channel function, which is required for uncoating (see Fig. 6.2, p. 133). Resistance develops rapidly and is widespread, and they should be used only if local prevalence of resistant strains is known to be low. They are no longer recommended for either treatment or prophylaxis in the UK or USA, having been superseded by zanamivir and oseltamivir. However, they may still be indicated to treat oseltamivir-resistant influenza A strains in patients unable to take zanamivir (e.g. ventilated patients).

Other antiviral agents**Ribavirin**

Ribavirin is a guanosine analogue that inhibits nucleic acid synthesis in a variety of viruses.

Lamivudine, adefovir dipivoxil, tenofovir, entecavir and telbivudine

These agents have excellent activity against hepatitis B virus DNA polymerase-reverse transcriptase. They are well tolerated after oral administration but resistance develops with monotherapy. Resistance seems to emerge most rapidly for lamivudine (via the tyrosine-methionine-aspartate-aspartate, or YMDD, mutation) and slowly for entecavir (multiple mutations required). Organisms resistant to lamivudine are usually also resistant to telbivudine, but not to adefovir/tenofovir. The role of monotherapy for HBV is currently a matter for debate, and combination therapy, as used in HIV treatment, is likely to be used increasingly. Lamivudine and tenofovir are also used against HIV (p. 403).

Interferon-α

The interferons are naturally occurring cytokines that are produced as an early response to viral infection (p. 72). The addition of a polyethylene glycol (PEG) moiety to the molecule significantly enhances pharmacokinetics and efficacy.

Antiparasitic agents**Drugs used against helminths****Benzimidazoles (albendazole, mebendazole)**

These agents act by inhibiting both helminth glucose uptake, causing depletion of glycogen stores, and fumarate reductase. Albendazole is used in hookworm, ascariasis, threadworm, *Strongyloides* infection, trichinellosis, *Taenia solium* (cysticercosis) and hydatid disease. Mebendazole is used for hookworm, ascariasis, threadworm and whipworm. The drugs are administered orally. Absorption is relatively poor, but increased by a fatty meal. Significant adverse reactions are uncommon.

Bithionol

Bithionol is used to treat fluke infections with *Fasciola hepatica*. It is well absorbed orally. Adverse reactions are mild (e.g. nausea, vomiting, diarrhoea, rashes) but relatively common (approximately 30%).

Diethylcarbamazine (DEC)

DEC is an oral agent used to treat filariasis and loiasis. Treatment of filariasis is often followed by fever, headache, nausea, vomiting, arthralgia and prostration. This is caused by the host response to dying microfilariae, rather than the drug, and may be reduced by pre-treatment with corticosteroids.

Ivermectin

Ivermectin binds to helminth nerve and muscle cell ion channels, causing increased membrane permeability. It is an oral agent, used in *Strongyloides* infection, filariasis and onchocerciasis. Significant side-effects are uncommon.

Niclosamide

Niclosamide inhibits oxidative phosphorylation, causing paralysis of helminths. It is an oral agent, used in *Taenia saginata* and intestinal *T. solium* infection. Systemic absorption is minimal, and it has few significant side-effects.

Piperazine

Piperazine inhibits neurotransmitter function, causing helminth muscle paralysis. It is an oral agent, used in ascariasis and threadworm (*Enterobius vermicularis*) infection. Significant adverse effects are uncommon, but include neuropsychological reactions such as vertigo, confusion and convulsions.

Praziquantel

Praziquantel increases membrane permeability to Ca⁺⁺, causing violent contraction of worm muscle. It is the drug of choice for schistosomiasis, and is also used in *T. saginata*, *T. solium* (cysticercosis), fluke infections (*Clonorchis*, *Paragonimus*) and echinococcosis. It is administered orally and well absorbed. Adverse

reactions are usually mild and transient, and include nausea and abdominal pain.

Pyrantel pamoate

This agent causes spastic paralysis of helminth muscle through a suxamethonium-like action. It is used orally in ascariasis and threadworm infection. Systemic absorption is poor, and adverse effects are uncommon.

Thiabendazole

Thiabendazole inhibits fumarate reductase, which is required for energy production in helminths. It is used orally in *Strongyloides* infection and topically to treat cutaneous larva migrans. Significant adverse effects are uncommon.

Antimalarial agents

Artemisinin (qinghaosu) derivatives

Artemisinin originates from a herb (sweet wormwood, *Artemisia annua*), which was used in Chinese medicine to treat fever. Its derivatives, artemether and artesunate, were developed for use in malaria in the 1970s. Their mechanism of action is unknown. They are used in the treatment, but not prophylaxis, of malaria, usually in combination with other antimalarials, and are effective against strains of *Plasmodium* spp. that are resistant to other antimalarials. Artemether is lipid-soluble, and may be administered via intramuscular and oral routes. Artesunate is water-soluble and is administered intravenously or orally. Serious adverse effects are uncommon. Current advice for malaria in pregnancy is that the artemisinin derivatives should be used to treat uncomplicated falciparum malaria in the second and third trimesters, but should not be used in the first trimester until more information becomes available.

Atovaquone

Atovaquone inhibits mitochondrial function. It is an oral agent, used for treatment and prophylaxis of malaria, in combination with proguanil (see below), without which it is ineffective. It is also used in the treatment of *Pneumocystis jirovecii* (carinii) pneumonia where there is intolerance to co-trimoxazole. Significant adverse effects are uncommon.

Folate synthesis inhibitors (proguanil, pyrimethamine-sulfadoxine)

Proguanil inhibits dihydrofolate reductase, and is used for malaria prophylaxis. Pyrimethamine-sulfadoxine is used in the treatment of malaria (p. 352).

Quinoline-containing compounds

Chloroquine and quinine are believed to act by intraparasitic inhibition of haem polymerisation, resulting in toxic build-up of intracellular haem. The mechanisms of action of other agents in this group (quinidine, amodiaquine, mefloquine, primaquine, etc.) may differ. They are used in the treatment and prophylaxis of malaria. Primaquine is used for radical cure of malaria due to *Plasmodium vivax* and *P. ovale* (destruction of liver hypnozoites). Chloroquine is also used in extra-intestinal amoebiasis.

Chloroquine can cause a pruritus sufficient to compromise compliance with therapy. If used in long-term, high-dose regimens, it causes an irreversible retinopathy. Overdosage causes life-threatening

cardiotoxicity. The side-effect profile of mefloquine includes neuropsychiatric effects ranging from mood change, nightmares and agitation to hallucinations and psychosis. Quinine may cause hypoglycaemia and cardiotoxicity, especially when administered parenterally. Primaquine causes haemolysis in people with glucose-6-phosphate dehydrogenase deficiency (p. 1024), which should be excluded before therapy. Chloroquine is considered safe in pregnancy, but mefloquine should be avoided in the first trimester.

Lumefantrine

Lumefantrine is used in combination with artemether to treat uncomplicated falciparum malaria, including chloroquine-resistant strains. Its mechanism of action is unknown. Significant adverse effects are uncommon.

Drugs used in trypanosomiasis

Benznidazole

Benznidazole is an oral agent used to treat South American trypanosomiasis (Chagas' disease, p. 354). Significant and common adverse effects include dose-related peripheral neuropathy, purpuric rash and granulocytopenia.

Eflornithine

Eflornithine inhibits biosynthesis of polyamines by ornithine decarboxylase inhibition, and is used in West African trypanosomiasis (*T. brucei gambiense* infection) of the CNS. It is administered as a 6-hourly intravenous infusion, which may be logistically difficult in the geographic areas affected by this disease. Significant adverse effects are common, and include convulsions, gastrointestinal upset and bone marrow depression. Eflornithine is also used (topically) to treat hirsutism (p. 759).

Melarsoprol

This is an arsenical agent, which is used to treat CNS infections in both E. and W. African trypanosomiasis (*T. brucei rhodesiense* and *gambiense*). It is administered intravenously. Melarsoprol treatment is associated with peripheral neuropathy and reactive arsenical encephalopathy (RAE), which carries a significant mortality.

Nifurtimox

Nifurtimox is administered orally to treat South American trypanosomiasis (Chagas' disease). Gastrointestinal and neurological adverse effects are common.

Pentamidine isetionate

Pentamidine is an inhibitor of DNA replication used in West African trypanosomiasis (*T. brucei gambiense*) and, to a lesser extent, in visceral and cutaneous leishmaniasis. It is also used in *Pneumocystis jirovecii* (carinii) pneumonia. It is administered via intravenous or intramuscular routes. It is a relatively toxic drug, commonly causing rash, renal impairment, profound hypotension (especially on rapid infusion), electrolyte disturbances, blood dyscrasias and hypoglycaemia.

Suramin

Suramin is a naphthalene dye derivative, used to treat East African trypanosomiasis (*T. brucei rhodesiense*). It is

administered intravenously. Adverse effects are common, and include rash, gastrointestinal disturbance, blood dyscrasias, peripheral neuropathies and renal impairment.

Other antiprotozoal agents

Pentavalent antimonials

Sodium stibogluconate and meglumine antimoniate inhibit protozoal glycolysis by phosphofructokinase inhibition. They are used parenterally (intravenous or intramuscular) to treat leishmaniasis. Adverse effects include arthralgia, myalgias, raised hepatic transaminases, pancreatitis and ECG changes. Severe cardiotoxicity leading to death is not uncommon.

Diloxanide furoate

This oral agent is used to eliminate luminal cysts following treatment of intestinal amoebiasis, or in asymptomatic cyst excretors. The drug is absorbed slowly (enabling luminal persistence) and has no effect in hepatic amoebiasis. It is a relatively non-toxic drug, the most significant adverse effect being flatulence.

Iodoquinol (di-iodohydroxyquinoline)

Iodoquinol is a quinoline derivative (p. 161) with activity against *Entamoeba histolytica* cysts and trophozoites. It is used orally to treat asymptomatic cyst excretors or, in association with another amoebicide (e.g. metronidazole), to treat extra-intestinal amoebiasis. Long-term use of this drug is not recommended, as neurological adverse effects include optic neuritis and peripheral neuropathy.

Nitazoxanide

Nitazoxanide is an inhibitor of pyruvate-ferredoxin oxidoreductase-dependent anaerobic energy metabolism in protozoa. It is a broad-spectrum agent, active

against various nematodes, tapeworms and flukes, as well as intestinal protozoa and some anaerobic bacteria and viruses. It is administered orally in giardiasis and cryptosporidiosis. Adverse effects are usually mild, and involve the gastrointestinal tract (e.g. nausea, diarrhoea and abdominal pain).

Paromomycin

Paromomycin is an aminoglycoside (p. 154), which is used to treat visceral leishmaniasis and intestinal amoebiasis. It is not significantly absorbed when administered orally, and is therefore given orally for intestinal amoebiasis and by intramuscular injection for leishmaniasis. It showed early promise in the treatment of HIV-associated cryptosporidiosis, but subsequent trials have demonstrated that this effect is marginal at best.

History

- **Slow down** the pace.
- **Ensure the patient can hear.**
- Establish the **speed of onset of the illness.**
- If the presentation is vague, carry out a **systematic enquiry.**
- Obtain full details of:
 - **all drugs**, especially any recent prescription changes
 - **past medical history**, even from many years previously
 - **usual function**
 - (a) Can the patient walk normally?
 - (b) Has the patient noticed memory problems?
 - (c) Can the patient perform all household tasks?
- **Obtain a collateral history:** confirm information with a relative or carer and the general practitioner, particularly if the patient is confused or communication is limited by deafness or speech disturbance.

Examination

- **Thorough** to identify all comorbidities.
- **Tailored to the patient's stamina** and ability to cooperate.

- Includes **functional status:**
 - cognitive function
 - gait and balance
 - nutrition
 - hearing and vision.

7 Abbreviated Mental Test

Each correct answer scores 1 mark.

1. What time is it? (*to the nearest hour*)
2. What year is it?
3. What is the name of this place/hospital?
4. How old are you? (*exact year*)
5. What is your date of birth?

Please memorise the following address: 42 West Street.

6. When did the First World War begin?
7. Who is the present monarch?
8. Please count backwards from 20 down to 1.
9. Can you recognise two people?
(*e.g. relative or photograph*)
10. Can you tell me the address I asked you to memorise a few minutes ago?

Mini-Mental State Examination is used for more detailed assessment (p. 232).

Social assessment

Home circumstances

- Living alone, with another or in a care home.

Activities of daily living (ADL)

- Tasks for which help is needed:
 - domestic ADL: shopping, cooking, housework
 - personal ADL: bathing, dressing, walking.
- Informal help: relatives, friends, neighbours.
- Formal social services: home help, meals on wheels.
- Carer stress.

Multidisciplinary team (MDT) and functional assessment

Team member	Activity assessed and promoted
Physiotherapist	Mobility, balance and upper limb function
Occupational therapist	Activities of daily living (ADL), e.g. dressing, cooking (Assessment of home environment)
Dietitian	Nutrition
Speech and language therapist	Communication and swallowing
Social worker	Care needs
Nurse	Motivation and initiation of activities Feeding Continence Skin care

12 Get up and go test

To assess balance, ask the patient to stand up from a sitting position, walk 10 m, turn and go back to the chair.

Sweeping demographic change has meant that older people now represent the core practice of medicine in many countries. A good knowledge of the effects of ageing and the clinical problems associated with old age is thus essential in most medical specialties. The older population is extremely diverse; a substantial proportion of 90-year-olds enjoy an active healthy life, while some 70-year-olds are severely disabled by chronic disease. The terms 'chronological' and 'biological' ageing have been coined to describe this phenomenon. Biological rather than chronological age is taken into consideration when making clinical decisions about, for example, the extent of investigation and intervention that is appropriate.

Geriatric medicine is concerned particularly with frail older people, in whom physiological capacity is so reduced that they are incapacitated by even minor illness. They frequently have multiple comorbidities, and acute illness may present in non-specific ways, such as confusion, falls, or loss of mobility and day-to-day functioning. These patients are prone to adverse drug reactions, partly because of polypharmacy and partly because of age-related changes in responses to drugs and their elimination (p. 28). Disability is common, but patients' function can often be improved by the interventions of the multidisciplinary team (p. 165).

Older people have been neglected in research terms and, until recently, were rarely included in randomised controlled clinical trials. There is thus little evidence on which to base practice.

DEMOGRAPHY

The demography of developed countries has changed rapidly in recent decades. In the UK, the total population grew by 8% over the last 35 years, but the number of people aged over 65 years rose by 31%, with the steepest rise in those aged over 85; the population aged under 16 fell by 19%. The proportion of the UK population aged over 65 is projected to increase further from 16% currently to 24% in 2061. This will have a significant impact on the old-age dependency ratio, i.e. the number of people of working age for each person aged over 65. Young people support older members of the population directly (e.g. through living arrangements) and financially (e.g. through taxation and pension contributions), so the consequences of a reduced ratio are far-reaching. However, many older people support the younger population, through care of children and other older people.

Life expectancy in the developed world is now prolonged, even in old age (Box 7.1); women aged 80 years can expect to live for a further 9 years. However, rates of disability and chronic illness rise sharply with ageing and have a major impact on health and social services. In the UK, the reported prevalence of a chronic illness or disability sufficient to restrict daily activities is around 25% in those aged 50–64, but 66% in men and 75% in women aged over 85.

Although the proportion of the population aged over 65 years is greater in developed countries, two-thirds of the world population of people aged over 65 live in developing countries at present, and this is projected to rise to 75% in 2025. The rate of population ageing is much faster in developing countries (Fig. 7.1) so they have less time to adjust to its impact.

7.1 Mean life expectancy in years, UK and India

	Males		Females	
	UK	India	UK	India
At birth	77	62	81	64
At 60 years	20.5	15	24	17
At 70 years	13	10	16	11
At 80 years	7.5	7	9	7

Fig. 7.1 Number of people aged 65 and over projected in the world population.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Biology of ageing

Ageing can be defined as a progressive accumulation through life of random molecular defects that build up within tissues and cells. Eventually, despite multiple repair and maintenance mechanisms, these result in age-related functional impairment of tissues and organs.

Many genes probably contribute to ageing, with those that determine durability and maintenance of somatic cell lines particularly important. However, genetic factors only account for around 25% of variance in human lifespan; nutritional and environmental factors determine the rest.

A major contribution to random molecular damage is made by reactive oxygen species produced during the metabolism of oxygen to produce cellular energy. They cause oxidative damage at a number of sites:

- *Nuclear chromosomal DNA*, causing mutations and deletions which ultimately lead to reduced gene function.
- *Telomeres*, which are the protective end regions of chromosomes which shorten with each cell division because telomerase (which copies the end of the 3' strand of linear DNA in germ cells) is absent

in somatic cells. When telomeres are sufficiently eroded, cells stop dividing. It has been suggested that telomeres represent a 'biological clock' which prevents uncontrolled cell division and cancer. Telomeres are particularly shortened in patients with premature ageing due to Werner's syndrome, in which DNA is damaged due to lack of a helicase required for DNA repair and messenger RNA formation.

- **Mitochondrial DNA** resulting in reduced cellular energy production and ultimately cell death.
- **Proteins:** for example, those increasing formation of advanced glycosylation end-products from spontaneous reactions between protein and local sugar molecules. These damage the structure and function of the affected protein, which becomes resistant to breakdown. This is the cause of yellowing of ageing nails and cornea.

The rate at which damage occurs is malleable and this is where the interplay with environment, particularly nutrition, takes place. There is evidence in some organisms that this interplay is mediated by insulin signalling pathways.

Physiological changes of ageing

The physiological features of normal ageing have been identified by examining disease-free populations of older people, to separate the effects of pathology from those due to time alone. However, the fraction of older people who age without disease ultimately declines to very low levels so that use of the term 'normal' becomes debatable. There is a marked increase in inter-individual variation in function with ageing; many physiological processes in older people deteriorate substantially when measured across populations, but some individuals show little or no change. Although there is some genetic influence over this, environmental factors such as poverty, nutrition, exercise, cigarette smoking and alcohol misuse play a large part, and a healthy lifestyle should be encouraged even when old age has been reached.

The effects of ageing are usually not enough to interfere with organ function under normal conditions, but reserve capacity is significantly reduced. Some changes of ageing, such as depigmentation of the hair, are of no clinical significance. Figure 7.2 shows many that are clinically important.

Fig. 7.2 Features and consequences of normal ageing.

Frailty

Frailty is defined as the loss of an individual's ability to withstand minor stresses because the reserves in function of several organ systems are so severely reduced that even a trivial illness or adverse drug reaction may result in organ failure and death. The same stresses would cause little upset in a fit person of the same age.

It is important to understand the difference between 'disability' and 'frailty'. Disability indicates established loss of function (e.g. mobility; see Box 7.15, p. 175), while frailty indicates increased vulnerability to loss of function. Disability may arise from a single pathological event (such as a stroke) in an otherwise healthy individual. After recovery, function is largely stable, and the patient may otherwise be in good health. When frailty and disability coexist, function deteriorates markedly even with minor illness, to the extent that the patient can no longer manage independently.

Unfortunately, the term 'frail' is often used rather vaguely, sometimes to justify a lack of adequate investigation and intervention in older people. However, it can be specifically identified by assessing function in a number of domains (Box 7.2). These are all commonly impaired by disease, illness and indeed age, but can often be improved by specific intervention. In clinical practice, 'frailty' per se is rarely measured formally, but a comprehensive assessment (see below) includes an evaluation of each domain.

Frail older people particularly benefit from a clinical approach that addresses both the precipitating acute illness and their underlying loss of reserves. It may be possible to prevent further loss of function through early intervention; for example, a frail woman with cardiac failure will benefit from specific cardiac investigation and drug treatment, but will benefit even further from an exercise programme to improve musculoskeletal function, balance and aerobic capacity, with nutritional support to restore lost weight. Establishing a patient's level of frailty also helps inform decisions regarding further investigation and management, and the need for rehabilitation.

i

7.2 Domains impaired in frailty

- Musculoskeletal function
- Aerobic capacity, i.e. cardiorespiratory function
- Cognitive function
- Integrative neurological function (e.g. balance and gait)
- Nutritional status

INVESTIGATIONS

Comprehensive geriatric assessment

Although not strictly an investigation, one of the most powerful tools in the management of older people is the Comprehensive Geriatric Assessment, which identifies all the relevant factors contributing to their presentation

EBM 7.3 Comprehensive geriatric assessment

'Inpatient comprehensive geriatric assessment reduces short-term mortality and increases the chance of patients living at home in the long term.'

• Ellis G, Langhorne P. *Br Med Bull* 2005; 71: 45–59.

(p. 164). In frail patients with multiple pathology, it may be necessary to perform the assessment in stages to allow for their reduced stamina. The outcome should be a management plan that not only addresses the acute presenting problems, but also improves the patient's overall health and function (Box 7.3).

Decisions about investigation

Accurate diagnosis is important at all ages but frail older people may not be able to tolerate lengthy or invasive procedures, and diagnoses may be revealed for which patients could not withstand intensive or aggressive treatment. On the other hand, disability should never be dismissed as due to age alone. For example, it would be a mistake to supply a patient no longer able to climb stairs with a stair lift, when simple tests would have revealed osteoarthritis of a hip and vitamin D deficiency, for which appropriate treatment would have restored his or her strength. So how do doctors decide when and how far to investigate?

The patient's general health

Does this patient have the physical and mental capacity to tolerate the proposed investigation? Does he have the aerobic capacity to undergo bronchoscopy? Will her confusion prevent her from remaining still in the MRI scanner? The more comorbidities a patient has, the less likely he or she will be able to withstand an invasive or complex intervention. Information on the outcomes in critically ill older patients is given on page 202.

Will the investigation alter management?

Would the patient be fit for, or benefit from, the treatment that would be indicated if investigation proved positive? The presence of comorbidity is more important than age itself in determining this. When a patient with severe heart failure and a previous disabling stroke presents with a suspicious mass lesion on chest X-ray, detailed investigation and staging may not be appropriate if he is not fit for surgery, radical radiotherapy or chemotherapy. On the other hand, if the same patient presented with dysphagia, investigation of the cause would be important, as he would be able to tolerate endoscopic treatment: for example, to palliate an obstructing oesophageal carcinoma.

The views of the patient and family

Older people may have strong views about the extent of investigation and treatment they wish to receive, and these should be sought from the outset. If the patient wishes, the views of relatives can be taken into account. If the patient is not able to express a view or lacks the capacity to make decisions, because of cognitive impairment or communication difficulties, then relatives' input becomes particularly helpful. They may be able to give

information on views previously expressed by the patient or on what the patient would have wanted under the current circumstances. However, families should never be made to feel responsible for difficult decisions.

Advance directives

Advance directives or 'living wills' are statements made by adults at a time when they have the capacity to decide for themselves about the treatments they would refuse or accept in the future, should they no longer be able to make decisions or communicate them. An advance directive cannot authorise a doctor to do anything that is illegal and doctors are not bound to provide a specific treatment requested, if in their professional opinion it is not clinically appropriate. However, any advance refusal of treatment, made when the patient was able to make decisions based on adequate information about their implications, is legally binding in the UK. It must be respected when it clearly applies to the patient's present circumstances and when there is no reason to believe that the patient has changed his or her mind.

PRESENTING PROBLEMS IN GERIATRIC MEDICINE

Characteristics of presenting problems in old age

Problem-based practice is integral to geriatric medicine. Most problems are multifactorial and there is rarely a unifying diagnosis. All contributing factors have to be taken into account and attention to detail is paramount. Two patients who share the same presenting problem may have completely disparate diagnoses. A wide knowledge of adult medicine is required, as disease in any and often many of the organ systems has to be managed at the same time. There are a number of features that are particular to older patients.

Late presentation

Many people (of all ages) accept ill health as a consequence of ageing and may tolerate symptoms for lengthy periods before seeking medical advice. Comorbidities may also contribute to late presentation; in a patient whose mobility is limited by stroke, angina may only present when coronary artery disease is advanced, as the patient was unable to exercise sufficiently to cause symptoms at an earlier stage.

Atypical presentation

Infection may present with acute confusion and without clinical pointers to the organ system affected. Stroke may present with falls rather than symptoms of focal weakness. Myocardial infarction may present as weakness and fatigue, without the classical symptoms of chest pain or dyspnoea. The reasons for these atypical presentations are not always easy to establish. Perception of pain is altered in old age, which may explain why myocardial infarction presents in other ways. The pyretic response is blunted in old age so that infection may not be obvious at first. Cognitive impairment may limit the patient's ability to give a history of classical symptoms.

Acute illness and changes in function

Atypical presentations in frail elderly patients include 'failure to cope', 'found on floor', 'confusion' and 'off feet', but these are *not* diagnoses. The possibility that an acute illness has been the precipitant must always be considered. It helps to establish whether the patient's current status is a change from his or her usual level of function by asking a relative or carer (by phone if necessary). Investigations aimed at uncovering an acute illness will not be fruitful in a patient whose function has been deteriorating over several months, but if function has suddenly changed, acute illness must be excluded.

Multiple pathology

Presentations in older patients have a more diverse differential diagnosis because multiple pathology is so common. There are frequently a number of causes for any single problem, and adverse effects from medication often contribute. A patient may fall because of osteoarthritis of the knees, postural hypotension due to diuretic therapy for hypertension, and poor vision due to cataracts. All these factors have to be addressed to prevent further falls, and this principle holds true for most of the common presenting problems in old age.

Approach to presenting problems in old age

For the sake of clarity, the common presenting problems are described individually, but in real life, older patients often present with several at the same time, particularly confusion, incontinence and falls. These share some underlying causes and may precipitate each other.

The approach to most presenting problems in old age can be summarised as follows:

- *Obtain a collateral history.* Find out the patient's usual status (e.g. mobility, cognitive state) from a relative or carer. Call these people by phone if they are not present.
- *Check all medication.* Have there been any recent changes?
- *Search for and treat any acute illness.* See Box 7.4.
- *Identify and reverse predisposing risk factors.* These depend on the presenting problem.

7.4 Screening investigations for acute illness

- Full blood count
- Urea and electrolytes, liver function tests, calcium and glucose
- Chest X-ray
- Electrocardiogram
- Urinalysis for leucocytes and nitrites; if positive, urine culture
- C-reactive protein: useful marker for occult infection
- Blood cultures if pyrexial

Falls

Around 30% of those aged over 65 years fall each year, this figure rising to over 40% in those aged over 80. Although only 10–15% of falls result in serious injury, they are the cause of over 90% of hip fractures in this age group, compounded by the rising prevalence of osteoporosis. Falls also lead to loss of confidence and fear, and are frequently the 'final straw' that makes an older person decide to move to institutional care. Management will vary according to the underlying cause.

Acute illness

Falls are one of the classical atypical presentations of acute illness in frail people. The reduced reserves in older people's neurological function mean that they are less able to maintain their balance when challenged by an acute illness. Suspicion should be high when falls have suddenly occurred over a period of a few days. Common underlying illnesses include infection, stroke, metabolic disturbance and heart failure. Thorough examination and investigation are required (see Box 7.4). It is also important to establish whether any drug which precipitates falls, such as a psychotropic or hypotensive agent, has been started recently. Once the underlying acute illness has been treated, falls may no longer be a problem.

Blackouts

A proportion of older people who 'fall' have in fact had a syncopal episode. It is important to ask about loss of consciousness, and if this is a possibility, to perform appropriate investigations (pp. 551 and 1149).

Mechanical and recurrent falls

Amongst patients who have tripped or are uncertain how they fell, those who have fallen more than once in the past year and those who are unsteady during a 'Get up and go' test (p. 165) require further assessment. Patients with recurrent falls are commonly frail, with multiple medical problems and chronic disabilities. Obviously, such patients may present with a fall resulting from an acute illness or syncope, but they will remain at risk of further falls even when the acute illness has resolved. The well-established risk factors for falls (Box 7.5) should be considered. If problems are identified with muscle strength, balance, vision or cognitive function, the causes of these must be identified by specific investigation, and treatment should be commenced if appropriate. Common pathologies identified include cerebrovascular disease (p. 1180), Parkinson's disease (p. 1199) and osteoarthritis of weight-bearing joints (p. 1083). Osteoporosis risk factors should also be sought and DEXA (dual energy X-ray absorptiometry) bone density scanning considered in all

7.5 Risk factors for falls

- Muscle weakness
- History of falls
- Gait or balance abnormality
- Use of a walking aid
- Visual impairment
- Arthritis
- Impaired ADL
- Depression
- Cognitive impairment
- Age over 80 years
- Psychotropic medication

EBM 7.6 Prevention of falls in older people

'Effective interventions to prevent falls in elderly people living in the community include exercise interventions, assessment and multifactorial intervention, withdrawal of psychotropic medication, a prescribing modification programme in primary care, first eye cataract surgery, pacemaker insertion in those with carotid sinus syndrome, and home safety interventions in those with severe visual impairment and in those at high risk of falling.'

• Gillespie LD, et al. Cochrane Database of Systematic Reviews 2009, issue 2. Art. no. CD0071460.

For further information:  www.nice.org.uk

7.7 Multifactorial intervention to prevent falls

- Individualised or group exercise training
- Rationalisation of medication, especially psychotropic drugs
- Correction of visual impairment, particularly cataract extraction
- Home environmental hazard assessment and safety education
- Treatment of cardiovascular disorders, including carotid sinus syndrome and postural hypotension

older patients who have recurrent falls, particularly if they have already sustained a fracture (p. 1118).

Prevention of falls and fractures

Falls can be prevented by multiple risk factor intervention (Box 7.6), individualised according to those found in a specific patient (Box 7.7). The most effective intervention is balance and strength training by physiotherapists. An assessment of the patient's home environment for hazards must be delivered by an occupational therapist, who may also provide personal alarms so that patients can summon help should they fall again. Rationalising psychotropic medication may help to reduce sedation, although many older patients are reluctant to stop hypnotics. If postural hypotension is present (defined as a drop in blood pressure of > 20 mmHg systolic or > 10 mmHg diastolic pressure on standing from supine), reducing or stopping hypotensive drugs is helpful. Other measures to address postural hypotension are shown in Box 7.8. Simple interventions, such as new glasses to correct visual acuity, and podiatry, can also have a significant impact on function.

7.8 Management of postural hypotension

- Correction of dehydration
- Head-up tilt of the bed
- Support stockings (older patients may struggle to get these on)
- Non-steroidal anti-inflammatory drugs (NSAIDs; increase circulating volume via salt and water retention; gastric and renal side-effects limit use)
- Fludrocortisone (causes salt and water retention; often poorly tolerated due to fluid overload)
- Midodrine (α -adrenergic agent; not licensed in the UK)

If osteoporosis is diagnosed, specific drug therapy should be commenced (p. 1119). In female patients in institutional care, calcium and vitamin D₃ have been shown to reduce fracture rates, and may also reduce falls by reversing the changes in neuromuscular function associated with vitamin D deficiency. They are not effective in those with osteoporosis living in the community, in whom bisphosphonates are first-line therapy.

In the UK, government policy and National Institute for Health and Clinical Excellence guidelines (www.nice.org.uk) for falls prevention have led to the development of specific Falls and Fracture Prevention Services in many parts of the country.

Delirium (acute confusion)

Delirium is very common, affecting up to 30% of older hospital inpatients either at admission or during their hospital stay. It is associated with high rates of mortality, complication and institutionalisation, and with longer lengths of stay. Characteristic features must be present to make a diagnosis of delirium (Box 7.9), but it may be missed unless routine cognitive testing with an Abbreviated Mental Test (AMT; see p. 165) is performed. Delirium often occurs in patients with

7.9 Diagnostic criteria for delirium (DSM IV*)

A patient must show each of features 1–4.

1. Disturbed consciousness with reduced ability to focus, sustain or shift attention
2. A change in cognition (e.g. memory, language, orientation) or the development of a perceptual disturbance (hallucinations) that is not accounted for by a pre-existing or developing dementia
3. Development of the disturbance over a short period (hours or days) and a tendency to fluctuate over the course of the day
4. Evidence from the history, physical examination or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition, or by substance intoxication or withdrawal

*American Psychiatric Association's Diagnostic Statistical Manual Vol. 4 (see also p. 230).

dementia, and a history from a relative or carer about the onset and course of confusion is needed to distinguish acute from chronic features. Other risk factors are shown in Box 7.10. More than one of the precipitating causes of delirium (Fig. 7.3) is often present.

Fig. 7.3 Common causes and investigation of delirium. All investigations are performed routinely, except those in *italics*. * Tend to present over weeks to months rather than hours to days. (COPD = chronic obstructive pulmonary disease; CRP = C-reactive protein; MI = myocardial infarction; SSRI = selective serotonin re-uptake inhibitor; UTI = urinary tract infection)

7.10 Risk factors for delirium

- Old age
- Dementia
- Admission with infection or dehydration
- Surgery, e.g. hip fracture repair
- Alcohol misuse
- Severe physical illness
- Frailty
- Visual impairment
- Polypharmacy
- Renal impairment

Its pathophysiology is unclear; it may be an abnormal reaction of cognitive function to the physiological increase in cortisol release in acute illness, or it may reflect a sensitivity of cholinergic neurotransmission to toxic insults.

Clinical assessment

Confused patients will be unable to give an accurate history and this must be obtained from a relative or carer. Important details are speed of onset, previous mental state and ability to manage day-to-day tasks. Symptoms suggestive of a physical illness, such as an infection or stroke, should be elicited. An accurate drug and alcohol history is required, especially to ascertain whether any drugs have been recently stopped or started.

A full physical examination should be performed, noting in particular:

- conscious level
- pyrexia and any signs of infection in the chest, skin, urine or abdomen
- oxygen saturation
- signs of alcohol withdrawal, such as tremor or sweating
- any neurological signs.

A range of investigations are needed to identify the common causes (see Fig. 7.3).

Management

Specific treatment of the underlying cause(s) must be commenced as quickly as possible. However, the symptoms of delirium also require specific management. To minimise ongoing confusion and disorientation, the environment should be kept well lit and not unduly noisy, with the patient's spectacles and hearing aids in place. Good nursing is needed to preserve orientation, prevent pressure sores and falls, and maintain hydration, nutrition and continence.

The use of sedatives should be kept to a minimum, as they can precipitate delirium; in any case, many confused patients are lethargic and apathetic rather than agitated. However, sedation is appropriate if patients' behaviour is endangering themselves or others, to relieve distress in those who are extremely agitated or hallucinating, and to allow investigation or treatment. Small doses of haloperidol (0.5mg) or lorazepam (0.5mg) are tried orally first, and increased doses given if the patient fails to respond. Sedation can be given intramuscularly but only if absolutely necessary. In those with alcohol withdrawal, a reducing course of a benzodiazepine should be prescribed (p. 247).

The resolution of delirium in old age may be slow and incomplete. Delirium may be the first presentation of an

underlying dementia, and is also a risk factor for subsequent dementia.

Urinary incontinence

Urinary incontinence is defined as the involuntary loss of urine, and comes to medical attention when sufficiently severe to cause a social or hygiene problem. It occurs in all age groups but becomes more prevalent in old age, affecting about 15% of women and 10% of men aged over 65 years. It may lead to skin damage if severe and can be socially restricting. While age-dependent changes in the lower urinary tract predispose older people to incontinence, it is not an inevitable consequence of ageing and requires investigation and appropriate treatment. Urinary incontinence is frequently precipitated by acute illness in old age and is commonly multifactorial (Fig. 7.4).

Initial management is to identify and address contributory factors. If incontinence fails to resolve, further diagnosis and management should be pursued, as described on pages 476–477.

- *Urge incontinence* is usually due to detrusor over-activity and results in urgency and frequency.

Fig. 7.4 Assessment and management of urinary incontinence in old age. See also Chapter 17 (pp. 476–7) and NICE guideline on the Management of Incontinence in Women: www.nice.org.uk.

- *Stress incontinence* is almost exclusive to women and is due to weakness of the pelvic floor muscles, which allows leakage of urine when intra-abdominal pressure rises, e.g. on coughing. Both may be compounded by atrophic vaginitis, associated with oestrogen deficiency in old age, which can be treated with oestrogen pessaries.
- *Overflow incontinence* is most commonly seen in men with prostatic enlargement, which obstructs bladder outflow and is more common in the elderly.

In patients with severe stroke disease or dementia, treatment may be ineffective, as frontal cortical inhibitory signals to bladder emptying are lost. A timed/prompted toileting programme may help. Other than in overflow incontinence, urinary catheterisation should never be viewed as first-line management but may be required as a final resort if the perineal skin is at risk of breakdown or quality of life is affected by intractable incontinence.

Adverse drug reactions

Adverse drug reactions (ADRs) and the effects of drug interactions are discussed on pages 31–35. They may result in symptoms, abnormal physical signs and altered laboratory test results (Box 7.11). ADRs are the cause of around 5% of all hospital admissions but account for up

to 20% of admissions in those aged over 65 years. This is partly because older people receive many more prescribed drugs than younger people. Polypharmacy is defined as the use of four or more drugs but may not always be inappropriate, as many conditions such as hypertension and heart failure dictate the use of several drugs, and older people may have several coexisting medical problems. However, the more drugs that are taken, the greater the risk of an ADR. This risk is compounded by age-related changes in pharmacodynamic and pharmacokinetic factors (pp. 28–29), and by impaired homeostatic mechanisms, such as baroreceptor responses, plasma volume and electrolyte control. Older people are thus especially sensitive to drugs that can cause postural hypotension or volume depletion (see Box 7.11). Non-adherence to drug therapy also rises with the number of drugs prescribed.

The clinical presentations of ADRs are diverse, so for *any* presenting problem in old age the possibility that the patient's medication is a contributory factor should *always* be considered. Failure to recognise this may lead to the use of a further drug to treat the problem, making matters worse, where the better course would be to stop or reduce the dose of the offending drug or to find an alternative.

Several factors contribute to polypharmacy (Box 7.12), and it has been shown that most ADRs are preventable. This is achieved by using as few drugs as possible, at the lowest dose possible in easy-to-take formulations, by ensuring that the patient understands the dosage regime, and by reviewing medication regularly. The patient or carer should be asked to bring all medication for review rather than the doctor relying on previous records. Those drugs that are no longer needed or that are contraindicated can then be discontinued.

7.11 Common adverse drug reactions in old age

Drug class	Adverse reaction
NSAIDs	Gastrointestinal bleeding and peptic ulceration Renal impairment
Diuretics	Renal impairment, electrolyte disturbance Gout Hypotension, PH
Warfarin	Bleeding
ACE inhibitors	Renal impairment, electrolyte disturbance Hypotension, PH
β-blockers	Bradycardia, heart block Hypotension, PH
Opiates	Constipation, vomiting Delirium Urinary retention
Antidepressants	Delirium Hyponatraemia (SSRIs) Hypotension, PH Falls
Benzodiazepines	Delirium Falls
Anticholinergics	Delirium Urinary retention Constipation

(ACE = angiotensin-converting enzyme; NSAID = non-steroidal anti-inflammatory drug; PH = postural hypotension; SSRI = selective serotonin reuptake inhibitor)

7.12 Factors leading to polypharmacy

- Multiple pathology
- Poor patient education
- Lack of routine review of all medications
- Patient expectations of prescribing
- Over-use of drug interventions by doctors
- Attendance at multiple specialist clinics
- Poor communication between specialists

Dizziness

Dizziness is very common, affecting at least 30% of those aged over 65 years in community surveys. It is a good example of the importance of a problem-based rather than an organ-based approach in older people, as it is frequently multifactorial rather than due to a single condition (pp. 551 and 1149). Acute dizziness is relatively straightforward and common causes include:

- hypotension due to arrhythmia, myocardial infarction, gastrointestinal bleed or pulmonary embolism
- onset of posterior fossa stroke
- vestibular neuronitis.

Although older people more commonly present with recurrent dizzy spells and often find it difficult to describe the sensation they experience, the most effective way of establishing the cause(s) of the problem is nevertheless to determine which of the following is predominant (even if more than one is present):

- *lightheadedness*, suggestive of reduced cerebral perfusion
- *vertigo*, suggestive of labyrinthine or brain-stem disease
- *unsteadiness/poor balance*, suggestive of joint or neurological disease.

Lightheadedness

Structural cardiac disease (such as left ventricular dysfunction or aortic stenosis) and arrhythmia must be considered, but disorders of autonomic cardiovascular control, such as vasovagal syndrome and postural hypotension, are also very common in old age. Hypotensive medication may exacerbate these. Further investigation and treatment are described on page 1149.

Vertigo

This is most commonly due to benign positional vertigo in old age (p. 1151), but if other brain-stem symptoms or signs are present, magnetic resonance imaging (MRI) of the brain is required to exclude a cerebello-pontine angle lesion.

Unsteadiness

This may be caused by a wide range of joint and neurological conditions. Examination of the gait, joints and neurological system (Box 7.13) guides further specific investigation and treatment. Whatever the cause, gait and balance problems in old age can be improved by physiotherapy. If the patient is falling as a result of dizziness, interventions to prevent falls should be instigated (see Box 7.7, p. 170).

Other problems in old age

There is a vast range of other presenting problems in older people and they present to many medical specialties.

7.13 Abnormal gaits and probable causes

Gait abnormality	Probable cause
Antalgic	Arthropathy
Waddling	Proximal myopathy
Stamping	Sensory neuropathy
Foot drop	Peripheral neuropathy or radiculopathy
Ataxic	Sensory neuropathy or cerebellar disease
Shuffling/festination	Parkinson's disease
Marche à petits pas	Small-vessel cerebrovascular disease
Hemiplegic	Cerebral hemisphere lesion
Apraxic	Bilateral hemisphere lesions

7.14 Other presenting problems in old age

• Hypothermia	p. 101
• Under-nutrition	p. 121
• Infection	pp. 292 and 302
• Fluid balance problems	p. 437
• Heart failure	p. 543
• Hypertension	p. 551
• Dizziness and blackouts	pp. 551 and 1149
• Atrial fibrillation	p. 563
• Diabetes mellitus	p. 804
• Peptic ulceration	p. 874
• Anaemia	p. 997
• Painful joints	p. 1065
• Bone disease and fracture	pp. 1116–1124 and 1068
• Immobility	p. 1154
• Stroke	p. 1180
• Dementia	p. 1197

End-of-life care is an important facet of clinical practice in old age and is discussed in Chapter 12 (pp. 286–287). Relevant sections in other chapters are referenced in Box 7.14.

Within each chapter, 'In Old Age' boxes highlight the areas in which presentation or management differs from that in younger individuals. These are listed on page 176.

REHABILITATION

Rehabilitation aims to improve the ability of people of all ages to perform day-to-day activities, and to restore their physical, mental and social capabilities as far as possible. Acute illness in older people is often associated with loss of their usual ability to walk or care for themselves, and common disabling conditions such as stroke, fractured neck of femur, arthritis and cardio-respiratory disease become increasingly prevalent with advancing age.

Disability is an interaction between factors intrinsic to the individual and the context in which they live, and both medical and social interventions are needed to address this (Box 7.15). Doctors tend to focus on health conditions and impairments, but patients are more concerned with the effect on their activities and ability to participate in everyday life.

The rehabilitation process

Rehabilitation is a problem-solving process focused on improving the patient's physical, psychological and social function. It entails:

- **Assessment.** The nature and extent of the patient's problems are identified using the framework in Box 7.15. Specific assessment scales, such as the Elderly Mobility Scale or Barthel Index of Activities of Daily Living, can be used to quantify components of disability, but do not determine the underlying

7.15 International classification of functioning and disability	
Factor	Intervention required
Health condition Underlying disease, e.g. stroke, osteoarthritis	Medical or surgical treatment
Impairment Symptoms or signs of the condition, e.g. hemiparesis, visual loss	Medical or surgical treatment
Activity limitation Resultant loss of function, e.g. walking, dressing	Rehabilitation, assistance, aids
Participation restriction Resultant loss of social function, e.g. cooking, shopping	Adapted accommodation Social services

causes or the interventions required in individual patients.

- **Goal-setting.** Goals should be specific to the patient's problems, realistic, and agreed between the patient and the rehabilitation team.
- **Intervention.** This includes the active treatments needed to achieve the established goals and to maintain the patient's health and quality of life. 'Hard' interventions include hands-on treatment by therapists using a functional, task-orientated approach to improve day-to-day activities. 'Soft' interventions are just as important, and include psychological support and education (Fig. 7.5). The emphasis on the type of intervention will be different, depending on the patient's disabilities, psychological status and progress. The patient and his or her carer(s) must be active participants.

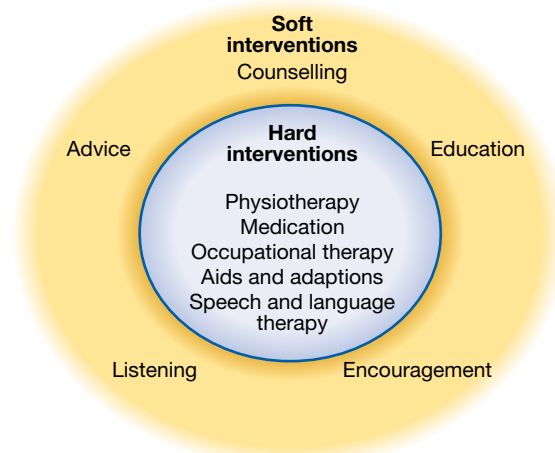

Fig. 7.5 Rehabilitation techniques.

- **Reassessment.** There is ongoing re-evaluation of the patient's function and progress towards the goals by the rehabilitation team, the patient and the carer. Interventions may be modified as a result.

Multidisciplinary team working

The core rehabilitation team includes members from several professional disciplines (Box 7.16). Others may be involved, e.g. audiometry to correct hearing impairment, podiatry for foot problems, and orthotics where a prosthesis or splinting is required. Good communication and mutual respect are essential. Regular team meetings allow sharing of assessments, agreement of rehabilitation goals and interventions, evaluation of progress and planning for the patient's discharge home. Rehabilitation is *not* when the doctor orders 'physio' or 'a home visit', and takes no further role.

Rehabilitation outcomes

There is evidence that rehabilitation improves functional outcomes in older people following acute illness, stroke and hip fracture. It also reduces mortality after stroke and hip fracture. These benefits accrue from complex multi-component interventions, but occupational therapy to improve personal ADLs, and individualised exercise interventions have now been shown to be effective in improving functional outcome in their own right.

7.16 The rehabilitation team	
Team member	Role
Physiotherapist	Promotion of balance, mobility and upper limb function
Occupational therapist	Promotion of ADLs, e.g. dressing, cooking Assessment of home environment and care needs
Speech and language therapist	Management of speech and swallowing problems
Dietitian	Management of nutrition
Social worker	Organisation of home support services or institutional care
Nurse	Encouragement towards independent function in all activities Promotion of continence Communication with relatives and other professionals
Doctor	Management of medical problems Coordinator of rehabilitation programme

RECOGNISING THE CRITICALLY ILL PATIENT

Respiratory signs

- Respiratory arrest
- Threatened or obstructed airway
- Stridor, intercostal recession, paradoxical breathing (seesaw pattern)
- Respiratory rate < 8 or > 35/min
- Respiratory distress: use of accessory muscles; unable to speak in complete sentences
- SpO₂ < 90% on high-concentration oxygen
- Rising PaCO₂ > 7 kPa (52.5 mmHg) or > 2 kPa (> 15 mmHg) above 'normal' with acidosis

Cardiovascular signs

- Cardiac arrest
- Pulse rate < 40 or > 140 bpm
- Systolic blood pressure < 100 mmHg
- Poor peripheral perfusion
- Evidence of inadequate oxygen delivery
- Metabolic acidosis
- Hyperlactataemia
- Poor response to volume resuscitation
- Oliguria < 0.5 mL/kg/hr (check urea, creatinine, K⁺)

Neurological signs

- Threatened or obstructed airway
- Absent gag or cough reflex
- Failure to maintain normal PaO₂ and PaCO₂
- Failure to obey commands
- GCS < 10
- Sudden fall in level of consciousness (GCS by > 2 points)
- Repeated or prolonged seizures

Recognition of critical illness: early warning scores

- Record standard observations:
 - Respiratory rate
 - SpO₂
 - Temperature
 - Blood pressure (BP)
 - Heart rate
 - Neurological response
- Note whether the observation falls in a shaded 'at-risk zone' (see SEWS key)
- Add the points scored and record total SEWS score on chart
- Do not add 'Pain' score to SEWS score

If SEWS score ≥ 4, a doctor should assess the patient within 20 minutes.

If SEWS score ≥ 6, a senior doctor should assess the patient within 10 minutes.

Clinical features of shock

Low-flow shock, e.g. hypovolaemia, cardiogenic shock

- Rapid, shallow respiration
- Cold, clammy skin
- Tachycardia (> 100/min)
- Hypotension (systolic BP < 100 mmHg)
- Drowsiness, confusion, irritability (usually occurs late)
- Oliguria
- Multi-organ failure

Vasodilated shock, e.g. sepsis, anaphylaxis

- Rapid, shallow respiration (very early)
- Warm peripheries*
- Tachycardia (> 100/min)
- Hypotension (systolic BP < 100 mmHg and disproportionately low diastolic BP—early)
- Drowsiness, confusion, irritability (can occur early)
- Oliguria
- Multi-organ failure

*Peripheries may be cool in severe hypovolaemia (low central venous pressure) or if myocardial depression is present (normal or raised central venous pressure).

A critically ill patient is one at imminent risk of death. Recognition, assessment and management of critical illness are fundamental to clinical care in any sphere of medicine. Acutely ill patients require rapid but careful assessment, and initiation of treatment often precedes or parallels acquisition of a definitive diagnosis. The principles underpinning intensive care management are the simultaneous assessment of severity of illness and stabilisation of life-threatening physiological abnormalities, with a view to preventing deterioration and effecting improvement as the diagnosis is established and treatment of the underlying definitive disease process(es) is initiated. Slavish attention to *either* resuscitation *or* diagnostic processes in isolation results in suboptimal outcomes and increased mortality; the two processes are inextricably interlinked. At the same time, wherever the clinical environment, appropriate physiological monitoring should be commenced to inform the continuing process of assessment and reassessment, including response to therapy.

PHYSIOLOGY OF CRITICAL ILLNESS

Oxygen transport

The major function of the heart, lungs and circulation is the provision of oxygen (and other nutrients) to the various organs and tissues of the body. During this process, carbon dioxide and other metabolic waste products are removed. The rate of supply and removal should match the specific metabolic requirements of the individual tissues. This requires adequate oxygen uptake in the lungs, global matching of delivery and consumption, and regional control of the circulation. Failure to supply sufficient oxygen to meet the metabolic requirements of the tissues is the cardinal feature of circulatory failure or 'shock', and optimisation of tissue oxygen delivery and consumption is the goal of resuscitation.

Atmospheric oxygen moves down a partial pressure gradient from air, through the respiratory tract, from alveoli to arterial blood and is then transported in the circulation to the capillary beds and cells, diffusing into the mitochondria and being utilised at cytochrome a_3 . Clinically important points to note in the management of a critically ill patient are that:

- The movement of oxygen from the left ventricle to the systemic tissue capillaries is referred to as oxygen delivery (DO_2), and is the product of cardiac output (flow) and arterial oxygen content (CaO_2). The latter is calculated from $CaO_2 = Hb \times \text{arterial oxygen saturation of haemoglobin (SaO}_2) \times 1.34$. By increasing cardiac output, arterial oxygen saturation or haemoglobin concentration, DO_2 will be increased.
- The regional distribution of oxygen delivery is also vital. If skin and muscle receive high blood flows but the splanchnic bed does not, the gut will become hypoxic even if overall DO_2 is high.
- The movement of oxygen from tissue capillary to cell occurs by diffusion and depends on the gradient of oxygen partial pressures, diffusion distance and the ability of the cell to take up and use oxygen. Thus microcirculatory, tissue diffusion and cellular factors, as well as DO_2 , influence the oxygen status of the cell.

Cardiovascular component of oxygen delivery: flow

A key determinant of DO_2 is cardiac output, which is determined by the ventricular 'preload', 'afterload', myocardial contractility and heart rate.

Preload

The atrial filling pressures or preload determine the end-diastolic ventricular volume which, according to Starling's Law and depending on the myocardial contractility, defines the force of cardiac contraction and the stroke volume (see Fig. 18.22, p. 544). The predominant factor influencing preload is venous return, which is determined by the intravascular volume, the venous 'tone' and the intrathoracic pressure (Box 8.1).

When volume is lost (e.g. major haemorrhage), venous 'tone' increases and this helps to offset the consequent fall in atrial filling pressure and stroke volume. If the equivalent volume is returned gradually, the right atrial pressure will return to normal as the intravascular volume is restored and the reflex increase in venous tone abates. However, if fluid is infused too rapidly, there will be insufficient time for the venous and arteriolar tone to fall and pulmonary oedema may occur, even though the intravascular volume has only been restored to the pre-morbid level.

If the preload is low, volume loading with intravenous fluids is the priority and this is the most appropriate means of improving cardiac output and tissue

i 8.1 Factors affecting level and measurement of central venous pressure (CVP)

Physiology-related

- Cardiac function
- Blood volume
- Ven constriction
- Intrathoracic pressure

Disease-related

- Superior vena cava occlusion
 - Chronic obstructive pulmonary disease (COPD)/cor pulmonale
 - Pulmonary embolism
 - Cardiac tamponade
- All increase CVP*

Intervention-related

- Positive pressure ventilation and positive end-expiratory pressure (PEEP)
 - Fluid resuscitation
 - Vasopressors
- All increase CVP*
- Venodilators *reduce* CVP

Artefactual levels caused by physical aberrations

- Malpositioned line: tip in right ventricle, internal jugular line in axillary vein, or subclavian line in internal jugular vein
- Transducer not in alignment with phlebostatic axis (mid-axillary line)
- Inaccurate calibration of transducer system
- Infusion attached to monitoring line
- Clot/occlusion in line

Fig. 8.1 The different responses observed in central venous pressure (CVP) after a fluid challenge of 250 mL, depending on the intravascular volume status of the patient.

perfusion. The choice of fluid for volume loading is controversial. No clear advantage of colloid over crystalloid has ever been demonstrated, but adequate filling is achieved with smaller volumes of colloid. Red cells have traditionally been transfused to achieve and maintain an Hb concentration of 100 g/L, but in the absence of significant heart disease, a target of 70–90 g/L may be preferable (p. 182). Fluid challenges of 200–250 mL should be titrated against clinical signs (heart rate, blood pressure (BP), peripheral circulation) and measurements of central venous pressure (CVP; Fig. 8.1).

When the preload is high due to excessive intravascular volume or impaired myocardial contractility, removing volume from the circulation (diuretics, haemofiltration) or increasing the capacity of the vascular bed using venodilator therapy (glyceryl trinitrate, morphine) often improves stroke volume.

Afterload

The tension in the ventricular myocardium during systole, termed 'afterload', is determined by the resistance to ventricular outflow, which is a function of the peripheral arteriolar resistance.

Understanding the reciprocal relationship between pressure, flow and resistance is crucial for appropriate circulatory management. High resistances produce lower flows at higher pressures for a given amount of ventricular work. Therefore, a systemic vasodilator such as sodium nitroprusside will allow the same cardiac output to be maintained for less ventricular work but with a reduced arterial BP. In hyperdynamic sepsis, the peripheral arteriolar tone and BP are low but the cardiac output is often high; therefore the vasoconstrictor nor-adrenaline (norepinephrine) is appropriate to restore BP, usually at the price of some reduction in cardiac output.

Myocardial contractility

This determines the work that the ventricle performs under given loading conditions, i.e. the stroke volume that the ventricle will generate against a given afterload for a particular level of preload.

The relationship between stroke work and filling pressure is shown in Figure 18.22 (p. 544). The ventric-

ular stroke work is the external work performed by the ventricle with each beat and is calculated from the stroke volume (SV) multiplied by the difference between afterload and preload pressures.

Consideration of ventricular work is important because it is desirable to maintain satisfactory perfusion and oxygen delivery to all organs at maximum cardiac efficiency, therefore minimising myocardial ischaemia. Myocardial contractility is frequently reduced in critically ill patients due either to pre-existing cardiac disease (usually ischaemic heart disease), drugs (β -blockers, verapamil) or to the disease process itself (particularly sepsis).

Oxygenation component of oxygen delivery: content

The major determinants of the oxygen content of arterial blood (CaO_2) are the arterial oxygen saturation of haemoglobin (SaO_2) and the haemoglobin (Hb) concentration. Over 95% of oxygen carried in the blood is attached to haemoglobin.

The oxyhaemoglobin dissociation curve (Fig. 8.2) describes the relationship between the saturation of haemoglobin (SO_2) and the partial pressure (PO_2) of oxygen in the blood. A shift in the curve will influence the uptake and release of oxygen by the Hb molecule; for example, if the curve moves to the right, the haemoglobin saturation will be lower for any given oxygen tension and therefore less oxygen will be taken up in the lungs but more will be released to the tissues. As capillary PCO_2 rises, the curve moves to the right, increasing unloading of oxygen in the tissues—a phenomenon known as the Bohr effect. In essence, a shift to the right beneficially increases capillary PO_2 .

Fig. 8.2 Oxyhaemoglobin dissociation curve: the relationship between oxygen tension (PO_2) and percentage saturation of haemoglobin with oxygen (SO_2). The dotted line illustrates the rightward shift of the curve (i.e. P_{50} increases) caused by increases in temperature, $PaCO_2$, metabolic acidosis and 2,3 diphosphoglycerate (DPG).

Due to the shape of the curve, a small drop in arterial PO_2 (PaO_2) below 8 kPa (60 mmHg) will cause a marked fall in SaO_2 . Its position and the effect of various physico-chemical factors are defined by the PO_2 at which 50% of the haemoglobin is saturated (P_{50}), which is normally 3.5 kPa (26 mmHg). The shape of the curve also dictates that increases in PaO_2 beyond the level that ensures SaO_2 is > 90% produce relatively small additional increases in CaO_2 (Fig. 8.3). Consider a patient who is both anaemic (Hb 60 g/L) and hypoxaemic (SaO_2 75%) when breathing air (fractional inspired oxygen concentration (FiO_2) 20%). Supplementary oxygen at FiO_2 40% will increase SaO_2 to 93%; CaO_2 will increase by 24% but further increases in FiO_2 , while raising PaO_2 , cannot produce any further useful increases in SaO_2 or CaO_2 . However, increasing Hb to 90 g/L by blood transfusion will result in a further 50% increase in CaO_2 .

Traditionally, the optimum haemoglobin concentration for critically ill patients was considered to be approximately 100 g/L, representing a balance between maximising the oxygen content of the blood and avoid-

ing regional microcirculatory problems due to increased viscosity. However, evidence suggests an improved outcome in critically ill patients if the haemoglobin concentration is maintained between 70 and 90 g/L, with the exception of the elderly and patients with coronary artery disease, cardiogenic shock or significant aortic stenosis, in whom 100 g/L remains appropriate.

Oxygen consumption

The sum of the oxygen consumed by the various organs represents the global oxygen consumption (VO_2) and is approximately 250 mL/min for an adult of 70 kg undertaking normal daily activities. VO_2 may be calculated:

- indirectly, from the product of cardiac output and the arterial mixed venous oxygen content difference ($CaO_2 - CvO_2$), as shown in Figure 8.3
- directly, by sampling the inspired and mixed-expired gases from the ventilator and measuring inspired and expired minute volume.

Equations:	Oxygen delivery (DO_2) = $CO \times CaO_2$	= 1000 mL/min
	Oxygen consumption (VO_2) = $CO \times (CaO_2 - CvO_2)$	= 250 mL/min
	Arterial oxygen content (CaO_2) = $Hb \times 1.34^* \times SaO_2/100 + (PaO_2 \times 0.23^{**})$	= 200 mL O_2 /L
	Oxygen extraction ratio (OER) = $VO_2/DO_2 \times 100$	= 25%
	Alveolar gas equation $PAO_2 = PiO_2 - PaCO_2/R$	

* 1 gram of 100% saturated Hb contains 1.34 mL O_2

** Oxygen dissolved in plasma = 3 mL/Litre

Fig. 8.3 The oxygen cascade in the transport of oxygen from inspired gas to the cell, with equations for calculation of arterial oxygen content, global oxygen delivery, consumption and extraction, and alveolar gas. Values are for a normal 70 kg individual (body surface area: 1.67 m²) breathing air (FiO_2 : 0.21) at standard atmospheric pressure (P_B : 101 kPa); contents (CaO_2 , CvO_2) in mL/L; Hb in g/L; cardiac output in L/min; oxygen delivery (DO_2), VO_2 and VCO_2 in mL/min. To convert kPa to mmHg, multiply by 7.5.

CaO_2 = arterial O_2 content

CO = cardiac output

CvO_2 = mixed venous O_2 content

FiO_2 = fractional inspired oxygen concentration

Hb = haemoglobin

PaO_2 = arterial PO_2

PAO_2 = alveolar PO_2

PiO_2 = inspired PO_2

PO_2 = oxygen partial pressure (kPa)

PvO_2 = venous PO_2

SaO_2 = arterial SO_2

SvO_2 = mixed venous SO_2

VCO_2 = CO_2 production

VO_2 = O_2 consumption

The oxygen saturation in the pulmonary artery, or 'mixed venous oxygen saturation' (SvO_2), is a measure of the oxygen not consumed by the tissues ($DO_2 - VO_2$). The saturation of venous blood from different organs varies considerably; for example, the hepatic venous saturation usually does not exceed 60% but the renal venous saturation may reach 90%, reflecting the great difference in both the metabolic requirements of these organs and the oxygen content of the blood delivered to them. The SvO_2 is a flow-weighted average measured in the mixed effluent blood from all of the perfused tissues, and is influenced by changes in both oxygen delivery (DO_2) and consumption (VO_2). Provided the microcirculation and the mechanisms for cellular oxygen uptake are intact, it can be used to monitor whether global oxygen delivery is adequate to meet overall demand, so is particularly useful in low-flow situations such as cardiogenic shock. Central venous oxygen saturation ($ScvO_2$) has been used in the same way and can be useful, but it only reflects part of the picture and does not represent hepatosplanchnic oxygen consumption, so may be quite different to SvO_2 .

The reoxygenation of the blood that returns to the lungs and the resulting arterial saturation (SaO_2) will depend on how closely pulmonary ventilation and perfusion are matched. If part of the pulmonary blood flow perfuses non-ventilated parts of the lung, there will be 'shunting', and the blood entering the left atrium will be desaturated in proportion to the size of this shunt and the level of SvO_2 .

Relationship between oxygen consumption and delivery

The tissue oxygen extraction ratio (OER), which is 20–25% in a normal subject at rest, rises as consumption increases or supply diminishes (Fig. 8.4). The maximum OER is approximately 60% for most tissues; at this point no further increase in extraction can occur and any further increase in oxygen consumption or decline in oxygen delivery will cause tissue hypoxia, anaerobic metabolism and increased lactic acid production.

Fig. 8.4 The effects of changing oxygen delivery on consumption. The solid line (ABC) represents the normal relationship and the dotted line (DEF) the altered relationship believed to exist in sepsis.

In sepsis, the slope of maximum OER decreases, reflecting the reduced ability of tissues to extract oxygen (DE cf. AB on Fig. 8.4), but the curve does not plateau and oxygen consumption continues to increase even at 'supranormal' levels of oxygen delivery. Although trials have demonstrated no benefit from pushing oxygen delivery to high levels in those with established organ failure, it may be worthwhile if applied before organ failure supervenes (Box 8.2). In practice, if there is a metabolic acidosis, hyperlactataemia and/or oliguria which could be due to inadequate oxygen delivery, a therapeutic trial of increasing oxygen delivery (with adequate BP secured) may be informative. If oxygen consumption rises, it may indicate an oxygen debt which is being repaid.

EBM 8.2 Early goal-directed therapy in severe sepsis

'In patients with severe sepsis or septic shock managed initially in A&E, early goal-directed therapy (EGT) reduced 60-day mortality from 57% to 44%. Both groups were resuscitated with similar targets for CVP, arterial blood pressure and urine output, but in the EGT group additional goals were central venous oxygen saturation > 70% and haematocrit > 30%, resulting in more rapid fluid resuscitation and higher red blood cell transfusion rates in the first 6 hours.'

• Rivers E, et al. *N Engl J Med* 2001; 345:1368–1377.

Pathophysiology of the inflammatory response

The mediators and clinical manifestations of the inflammatory response are described on pages 81–82. In critically ill patients, these processes have important consequences (Box 8.3).

Fever, tachycardia with warm peripheries, tachypnoea and a raised white cell count traditionally prompt a diagnosis of sepsis with the clinical picture caused by invading microorganisms and their breakdown products. However, other conditions such as pancreatitis, trauma, malignancy, tissue necrosis (e.g. burns), aspiration syndromes, liver failure, blood transfusion and drug reactions can all produce the same clinical picture in the absence of infection.

Local inflammation

The body's initial response to a noxious local insult is to produce a local inflammatory response with sequestration and activation of white blood cells and the release of a variety of mediators to deal with the primary 'insult' and prevent further damage either locally or in distant organs.

Normally, a delicate balance is achieved between pro- and anti-inflammatory mediators. However, if the inflammatory response is excessive, local control is lost and a large array of mediators, including prostaglandins, leukotrienes, free oxygen radicals and particularly pro-inflammatory cytokines (p. 72), are released into the circulation.

The inflammatory and coagulation cascades are intimately related. The process of blood clotting not only involves platelet activation and fibrin deposition but also causes activation of leucocytes and endothelial cells.

i

8.3 Terminology to describe the inflammatory state

Infection

- Invasion of normally sterile host tissue by microorganisms

Bacteraemia

- Viable bacteria in the blood

Systemic inflammatory response syndrome (SIRS)

- The inflammatory response to both infective and non-infective causes, e.g. pancreatitis, trauma, cardiopulmonary bypass, vasculitis etc.
- Defined by the presence of two or more of:
 - Respiratory rate > 20/min
 - Heart rate > 90/min
 - White blood count > $12 \times 10^9/L$ or < $4 \times 10^9/L$
 - Temperature > $38.0^\circ C$ or < $36.0^\circ C$
 - $PaCO_2$ < 4.3 kPa (< 32 mmHg) or ventilated
- Hypothermia and septic neutropenia are indicators of more severe infection
- A wide pulse pressure, e.g. 115/42 mmHg, may be an early pointer to systemic sepsis

Sepsis

- Systemic inflammatory response caused by documented infection

Severe sepsis/SIRS

- Sepsis/SIRS with evidence of early organ dysfunction *or* hypotension

Septic/SIRS shock

- Sepsis associated with organ failure *and* hypotension (systolic BP < 90 mmHg or > 40 mmHg fall from baseline) unresponsive to fluid resuscitation

Multiple organ dysfunction syndrome (MODS)

- Development of impaired organ function in critically ill patients with SIRS
- Multiple organ failure (MOF) will ensue if prompt treatment of underlying cause and suitable organ support are not achieved

Conversely, leucocyte activation induces tissue factor expression and initiates coagulation. Control of the coagulation cascade is achieved through the natural anticoagulants, antithrombin (AT III), activated protein C (APC) and tissue factor pathway inhibitor (TFPI), which not only regulate the initiation and amplification of the coagulation cascade but also inhibit the pro-inflammatory cytokines. Deficiency of AT III and APC (features of disseminated intravascular coagulation (DIC)) facilitates thrombin generation and promotes further endothelial cell dysfunction.

Systemic inflammation

During a severe inflammatory response, systemic release of cytokines and other mediators triggers widespread interaction between the coagulation pathways, platelets, endothelial cells and white blood cells, particularly the polymorphonuclear cells (PMNs). These 'activated' PMNs express adhesion factors (selectins), causing them initially to adhere to and roll along the endothelium, then to adhere firmly and migrate through the damaged and disrupted endothelium into the extravascular, interstitial space together with fluid

and proteins, resulting in tissue oedema and inflammation. A vicious circle of endothelial injury, intravascular coagulation, microvascular occlusion, tissue damage and further release of inflammatory mediators ensues.

All organs may become involved. This manifests in the lungs as the acute respiratory distress syndrome (ARDS) and in the kidneys as acute tubular necrosis (ATN), while widespread disruption of the coagulation system results in the clinical picture of DIC.

The endothelium itself produces mediators that control blood vessel tone locally: endothelin 1, a potent vasoconstrictor, and prostacyclin and nitric oxide (NO, p. 82), which are systemic vasodilators. NO (which is also generated outside the endothelium) is implicated in both the myocardial depression and the profound vasodilatation of both arterioles and venules that causes the relative hypovolaemia and systemic hypotension found in septic/systemic inflammatory response syndrome (SIRS) shock.

A major component of the tissue damage in septic/SIRS shock is the inability to take up and use oxygen at mitochondrial level, even if global oxygen delivery is supra-normal. This effective bypassing of the tissues results in a reduced arteriovenous oxygen difference, a low oxygen extraction ratio, a raised plasma lactate and a paradoxically high mixed venous oxygen saturation (SvO_2).

Role of splanchnic ischaemia

In shock, splanchnic hypoperfusion plays a major role in initiating and amplifying the inflammatory response, ultimately resulting in multiple organ failure (MOF). The processes involved include:

- increased gut mucosal permeability
- translocation of organisms from the gastrointestinal tract lumen into portal venous and lymphatic circulation
- Kupffer cell activation with production and release of inflammatory mediators.

RECOGNITION AND ASSESSMENT OF THE CRITICALLY ILL PATIENT

Recognition of severity of illness

All clinical staff should be aware of the fundamental physiological criteria which indicate critical illness.

The immediate appearance of the patient yields a wealth of information. Introducing yourself, shaking hands and asking 'How are you?' allows assessment of:

- the airway (for patency and noises, e.g. stridor, snoring, gurgling, none)
- breathing (rate, symmetry, work of breathing including accessory muscle use, paradoxical or seesaw pattern)
- peripheral circulation (temperature of the extremities)
- conscious level (the response of the patient).

Tachypnoea is often the earliest physiological abnormality to appear and the most sensitive to a worsening clinical state, but is the least well documented. A number of approaches have been adopted to improve

the recognition of critical illness, including the use of early warning scores and charts such as the Standard Early Warning System (SEWS, p. 179). This alerts staff to severely ill patients, complements clinical judgement and facilitates the prioritisation of clinical care. A patient with a SEWS score of 4 or greater requires urgent review and appropriate interventions to be commenced. An elevated score correlates with increased mortality.

Assessment and initial resuscitation of the critically ill patient

Airway and breathing

If the patient is talking, the airway is clear and breathing is adequate. A rapid history should be obtained whilst initial assessment is undertaken.

Assess breathing in the same way as the pulse: rate, volume, rhythm, character (work of breathing) and symmetry. Look for accessory muscle use and for the ominous sign of paradoxical chest/abdominal movement, manifest as a seesaw pattern of breathing. Supplemental oxygen should be administered to patients who are breathless, tachypnoeic or bleeding, or who have chest pain or reduced conscious level. The clinical state of the patient will determine how much oxygen to give, but the critically ill should receive at least 60% oxygen initially. High-concentration oxygen is best given using a mask with a reservoir bag which, at 15 L/min, can provide nearly 90% oxygen. Arterial blood gases (ABG) should be checked early to assess oxygenation, ventilation (P_{aCO_2}) and metabolic state (pH or H^+ , HCO_3^- and base deficit). Oxygen therapy should be adjusted in light of the ABG, remembering that oxygen requirements may subsequently increase or decrease. Early application of pulse oximeter monitoring is ideal, although this may not be reliable if the patient is peripherally shut down. Intubation, while often essential, may be hazardous in the patient with cardiorespiratory failure, and full monitoring and resuscitation facilities must be available.

Circulation

In the collapsed or unconscious patient, the carotid pulse should be palpated first, but in the conscious, peripheral pulses should be sought. The radial, brachial, foot and femoral pulses may disappear as shock progresses, so this gives information on the severity of circulatory compromise.

Venous access for the administration of drugs and/or fluids is pivotal to successful management but is often difficult in sick patients. The gauge of cannula needed is dictated by its purpose. Wide-bore cannulae are required for rapid fluid administration. Ideally, two 16G or larger cannulae should be inserted, one in each arm, in the severely hypovolaemic patient. If the two cannulae are of different sizes, the pulse oximeter should be placed on the same side as the larger, and the BP cuff on the same side as the smaller. This facilitates unimpeded volume resuscitation and uninterrupted oxygen saturation monitoring. Pressure infusors and blood warmers should be utilised for rapid, high-volume fluid resuscitation, particularly of blood products. An 18G cannula is usually adequate for drug administration.

Machine-derived cuff BP is inaccurate at extremes of BP and in tachycardia, especially atrial fibrillation. Manual sphygmomanometer BP readings tend to be more accurate in hypotension. If severe hypotension is not readily corrected with fluid, early consideration should be given to arterial line insertion and vasoactive drug therapy.

Disability

Conscious level should be assessed using the Glasgow Coma Scale (GCS; see Box 26.18, p. 1158). Best eye, verbal and motor responses should be accurately assessed and documented. A score of 8 or less denotes coma with associated airway compromise and loss of airway protection that necessitates intervention. Focal neurological signs may indicate unilateral cerebral pathology. Abnormal pupil size, symmetry or reaction to light may indicate either primary cerebral disease or global cerebral insults induced by drugs (e.g. opioids), hypoxia or hypoglycaemia.

Exposure, evidence and examination

The term exposure indicates the need for targeted clinical examination and evidence, the information provided by any recent investigations, prescription or monitoring charts.

Clinical decision-making and referral to critical care

During the initial assessment and resuscitation period, a number of decisions have to be made regarding ongoing patient care (Box 8.4). A decision about referral to the critical care service is a key part of the assessment of illness severity. It requires local knowledge of the clinical areas providing enhanced care, whether intermediate high-dependency or advanced intensive care, and the mechanism of referral.

- *High-dependency care* allows a greater degree of monitoring, physiological support and nursing/medical input than the standard ward, for patients

8.4 Clinical decision-making and critically ill patients

- How ill is the patient?
- How much help do I need and how quickly?
- Where would the patient be best managed?
- When should we move the patient?
- What do we need to achieve before transporting the patient?
ABCDE resuscitation, including endotracheal intubation and ventilation where appropriate
Monitoring, including invasive arterial \pm CVP plus volume resuscitation and vasoactive support
Imaging/diagnostic processes
- Do we need specialist involvement?
Transfer to another hospital may be necessary for specialised investigations, or to specialist liver, burns, neurosurgical or cardiac surgical units
Balance the urgency of specialist treatment against the stability of the patient's condition; it may be necessary to admit the patient to the local ICU for stabilisation first
All critically ill patients require an appropriately trained escort during transfer

8.5 Admission criteria for intensive care units (ICU) and high-dependency units (HDU)

ICU

- Patients requiring/likely to require endotracheal intubation and invasive mechanical ventilatory support
- Patients requiring support of two or more organ systems (e.g. inotropes and haemofiltration)
- Patients with chronic impairment of one or more organ systems (e.g. COPD or severe ischaemic heart disease) who *also* require support for acute reversible failure of another organ system

HDU

- Patients who require more detailed observation or monitoring than can be safely provided on a general ward:
 - Direct arterial BP monitoring
 - CVP monitoring
 - Fluid balance
 - Neurological observations, regular GCS recording
- Patients requiring support for a single failing organ system, excluding invasive ventilatory support:
 - CPAP or non-invasive (mask) ventilation (NIV)—see Box 8.19, p. 195
 - Moderate inotropic or vasopressor support
 - Renal replacement therapy in an otherwise stable patient
- Patients no longer requiring intensive care but who cannot be safely managed on a general ward

following major surgery, or for the septic patient requiring invasive haemodynamic monitoring and circulatory support alone, or for the patient with respiratory failure manageable with non-invasive ventilation or continuous positive airways pressure (CPAP).

- *Intensive care units* are staffed and equipped to allow management of the sickest patients who require invasive ventilation, multimodal monitoring and multiple organ system support (Box 8.5).

The mechanism of referral to critical care varies between hospitals but clinical staff in all areas and specialties must be aware of the local system and how to access it. Many hospitals have medical emergency or outreach teams to facilitate this.

A clear understanding of what is available in and what is achievable by critical care allows appropriate and early referral, and prevents referral of patients who have no realistic prospect of meaningful survival, due either to the overwhelming nature of their acute condition or to the lack of definitive therapy for the underlying disease process. Patients who do warrant admission should be identified early and admitted without delay, since this improves survival and reduces the length of stay.

PRESENTING PROBLEMS IN CRITICAL ILLNESS

Circulatory failure: 'shock'

The defining feature of 'shock' is a level of oxygen delivery (DO_2) which fails to meet the metabolic requirements of the tissues. 'Shock' is not synonymous with hypotension. While hypotension is a sinister development and

requires urgent attention, it is often a late manifestation of circulatory failure or shock, and also the cardiac output and oxygen delivery may be critically low even though the BP remains normal. The problem should be identified and treated before the BP falls. Objective markers of tissue oxygen delivery, such as base deficit, blood lactate and urine output, may aid earlier identification of shock.

The causes of circulatory failure or 'shock' may be categorised as either low flow (reduced stroke volume) or low peripheral arteriolar resistance (vasodilatation), which are the primary presenting circulatory abnormalities.

Low stroke volume

- *Hypovolaemic*: any condition provoking a major reduction in blood volume, e.g. internal or external haemorrhage, severe burns, salt and water depletion.
- *Cardiogenic*: severe mechanical impairment, e.g. myocardial infarction, acute mitral regurgitation.
- *Obstructive*: obstruction to blood flow around the circulation, e.g. major pulmonary embolism, cardiac tamponade, tension pneumothorax.

Vasodilatation

- *Septic/SIRS*: infection or other causes of a systemic inflammatory response that produce widespread endothelial damage with vasodilatation, arteriovenous shunting, microvascular occlusion, capillary leak and tissue oedema.
- *Anaphylactic*: inappropriate vasodilatation triggered by an allergen (e.g. bee sting), often associated with endothelial disruption and capillary leak.
- *Neurogenic*: caused by major brain or spinal injury which disrupts brain-stem and neurogenic vasomotor control.

Clinical assessment and complications

Clinical features depend upon the primary pathophysiological abnormality (p. 178). Hypovolaemic, cardiogenic and obstructive causes of circulatory failure produce the 'classical' image of shock with cold peripheries, reduced or absent peripheral pulses, weak central pulses and evidence of a low cardiac output. In early haemorrhagic shock, a narrowed pulse pressure, i.e. a raised diastolic (DBP) and reduced systolic (SBP) such as 105/95 mmHg, indicates the combination of hypovolaemia (reduced stroke volume, hence SBP) and activation of the sympathetic nervous system, with noradrenaline (norepinephrine)-induced vasoconstriction raising the DBP.

In contrast, septic shock and anaphylactic shock are usually associated with warm peripheries, bounding pulses and features of a high cardiac output. The BP pattern is again distinctive. In the early stages, peripheral vasodilatation results in a low DBP, but since the left ventricular afterload is reduced, stroke volume and hence systolic BP are maintained, e.g. 115/42 mmHg. These patients are usually warm peripherally. However, in more advanced septic or anaphylactic shock, SBP falls and the peripheries become cool. This is usually due to the hypovolaemia associated with capillary leak and will respond to fluid resuscitation. If it does not, it is possible that myocardial depression is present.

Neurogenic shock often results in vasodilated hypotension with a paradoxically slow heart rate.

All forms of shock require early identification and treatment because, if inadequate regional tissue perfusion and cellular dysoxia persist, multiple organ failure (MOF) will develop. Early institution of invasive haemodynamic monitoring (p. 190) is recommended.

Prognosis

If the precipitating cause and accompanying circulatory failure (hypotension and frequently severe hypovolaemia due to venodilatation and fluid loss through the leaky vascular endothelium) are dealt with promptly before significant organ failure occurs ('early' shock), the prognosis is good. If not, there is progressive deterioration in organ function and MOF ensues ('late' shock).

The mortality of MOF is high and increases with the number of organs that have failed, the duration of organ failure and the patient's age. Failure of four or more organs is associated with a mortality > 80%.

Respiratory failure, including ARDS

The majority of patients admitted to ICU/HDU have respiratory problems either as the primary cause of admission or secondary to pathology elsewhere.

Respiratory failure is classified on the basis of blood gas analysis as:

- *type 1*: hypoxaemia ($PaO_2 < 8$ kPa (< 60 mmHg) when breathing air) without hypercapnia caused by a failure of gas exchange due to mismatching of pulmonary ventilation and perfusion
- *type 2*: hypoxaemia with hypercapnia ($PaCO_2 > 6.5$ kPa (> 49 mmHg)) due to alveolar hypoventilation which occurs when the respiratory muscles cannot perform sufficient work to clear the carbon dioxide produced by the body.

Although this distinction is conceptually useful, it cannot be applied too rigidly in critically ill patients since they may change from type 1 to 2 as their illness progresses; hypercapnia may develop in pneumonia or pulmonary oedema as the patient tires and can no longer sustain the increased work of breathing.

Pulmonary problems in critically ill patients can also be classified according to the functional residual capacity (FRC, or the lung volume at the end of expiration). Examples of low FRC include lung collapse, pneumonia and pulmonary oedema; examples of high FRC (i.e. over-distended lungs) include asthma, COPD and bronchiolitis. This allows logical management directed at improving lung compliance and reducing the work of breathing.

The more common causes of acute respiratory failure presenting to ICU/HDU for respiratory support are shown in Box 8.6. The presentation, differential diagnosis and initial treatment of the primary respiratory conditions causing acute respiratory failure are covered in Chapter 19.

The assessment of respiratory failure in the critically ill patient should be guided by several important principles:

- The patient's appearance (tachypnoea, difficulty speaking in complete sentences, laboured breathing, exhaustion, agitation or increasing obtundation) is more important than measurement

8.6 Common causes of respiratory failure in critically ill patients

Type 1 respiratory failure

- Pneumonia
- Pulmonary oedema*
- Pulmonary embolism
- Pulmonary fibrosis
- ARDS*
- Aspiration
- Lung collapse*, e.g. retained secretions
- Asthma
- Pneumothorax
- Pulmonary contusion (blunt chest trauma)

Type 2 respiratory failure

- Reduced respiratory drive*, e.g. drug overdose, head injury
- Upper airway obstruction (oedema, infection, foreign body)
- Late severe acute asthma
- COPD
- Peripheral neuromuscular disease*, e.g. Guillain-Barré, myasthenia gravis
- Flail chest injury
- Exhaustion* (includes all type 1 causes)

*Secondary complications of other diseases.

of blood gases in deciding when it is appropriate to provide mechanical respiratory support or intubation.

- Adequate supplemental oxygen to maintain $SpO_2 > 94\%$ should be provided. If the inspired oxygen concentration required exceeds 60%, refer to the critical care team.
- Measurement of SpO_2 and ABGs is essential in monitoring progress.
- Restless patients dependent on supplementary oxygen or with deteriorating conscious level are at risk. If they remove the mask or vomit, the resulting hypoxaemia or aspiration may be catastrophic.
- An attempt should be made to reduce the work of breathing, e.g. by treating bronchoconstriction or using CPAP (see below).

Acute respiratory distress syndrome (ARDS)

This describes the acute, diffuse pulmonary inflammatory response to either direct (via airway or chest trauma) or indirect (blood-borne) insults that originate from extrapulmonary pathology (Box 8.7). It is characterised by:

- neutrophil sequestration in pulmonary capillaries
- increased capillary permeability
- protein-rich pulmonary oedema with hyaline membrane formation
- damage to type 2 pneumocytes leading to surfactant depletion
- alveolar collapse
- reduction in lung compliance.

If this early phase does not resolve with treatment of the underlying cause, a fibroproliferative phase ensues and causes progressive pulmonary fibrosis. It is frequently associated with other organ dysfunction as part of MOF. The term ARDS is often limited to patients requiring ventilatory support on the ICU, but less severe forms, conventionally referred to as acute lung injury (ALI) and with similar pathology, occur on acute medical and surgical wards.

8.7 Conditions predisposing to ARDS

Inhalation (direct)

- Aspiration of gastric contents
- Toxic gases/burn injury
- Pneumonia
- Blunt chest trauma
- Near-drowning

Blood-borne (indirect)

- Sepsis
- Necrotic tissue (particularly bowel)
- Multiple trauma
- Pancreatitis
- Cardiopulmonary bypass
- Severe burns
- Drugs (heroin, barbiturates, thiazides)
- Major transfusion reaction
- Anaphylaxis (wasp or bee stings, snake venom)
- Fat embolism
- Carcinomatosis
- Obstetric crises (amniotic fluid embolus, eclampsia)

Fig. 8.5 Chest X-ray in acute respiratory distress syndrome (ARDS).

This 22-year-old woman was involved in a road traffic accident. Note bilateral lung infiltrates, pneumomediastinum, pneumothoraces with bilateral chest drains, surgical emphysema, and fractures of the ribs, right clavicle and left scapula.

The clinical symptoms and signs are not specific, sharing many features with other pulmonary conditions. The criteria defining ARDS are:

- hypoxaemia, defined as $PaO_2/FiO_2 < 26.7$ kPa (< 200 mmHg) or < 40 kPa (< 300 mmHg) for ALI
- chest X-ray showing diffuse bilateral infiltrates (Fig. 8.5)
- absence of a raised left atrial pressure: pulmonary artery 'wedge' pressure (PAWP) < 15 mmHg
- impaired lung compliance.

The term ARDS has severe limitations as a diagnostic label since, like jaundice or a raised CVP, it represents a response to a variety of primary conditions.

Acute kidney injury

Acute renal failure has been renamed 'acute kidney injury' (AKI), defined as an abrupt and sustained decrease in kidney function (Box 8.8). AKI in the critically ill patient is often due to pre-renal elements such as hypovolaemia, hypotension and ischaemia resulting

in reduced renal DO_2 . Sepsis is often present. Potentially nephrotoxic drugs liable to contribute to AKI include non-steroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, radiological contrast media and some antibiotics. Oliguria is frequently an early sign of systemic problems in critical illness and successful resuscitation is associated with restoration of good urine output, an improving acid-base balance and correction of plasma potassium, urea and creatinine.

Oliguria is also a normal physiological component of the stress response to major surgery, and care should be taken not to overfill the post-operative patient with oliguria who is otherwise cardiovascularly and biochemically well.

In any patient with AKI, renal tract obstruction (including a blocked urinary catheter) must be excluded. Acute glomerulonephritis and vasculitis associated with connective tissue diseases such as microscopic polyarteritis or Goodpasture's disease must always be considered and appropriate investigations such as urine microscopy and immunopathological tests (p. 484) must be carried out early.

8.8 Diagnostic criteria for acute kidney injury*

An abrupt (within 48 hours) decline in kidney function defined as:

- An absolute increase in serum creatinine of ≥ 26.4 $\mu\text{mol/L}$ (0.3 mg/dL)
- A percentage increase in serum creatinine of $\geq 50\%$ (1.5-fold from baseline)
- A reduction in urine output (documented oliguria of < 0.5 mL/kg for > 6 consecutive hours)

*Mehta R, et al. <http://ccforum.com/content/11/2/R31>.

Neurological failure (coma)

Impaired consciousness or coma is often an early feature of severe systemic illness (Box 8.9). Prompt assessment of conscious level and management of airway, breathing and circulation are essential to prevent further brain injury, to allow diagnosis and to permit definitive treatment to be instituted. Any patient with confusion or reduced conscious level should have blood sugar measured and hypoglycaemia treated.

Impairment of conscious level is graded using the GCS, which is also used to monitor progress. Although necessarily limited, targeted neurological examination is very important in the unconscious patient. Pupil size and reaction to light, presence or absence of neck stiffness, focal neurological signs and evidence of other organ impairment should be noted. After cardiorespiratory stability is achieved, the cause of the coma must be sought from history (family, witness, general practitioner), examination and investigation, particularly computed tomography (CT) of the brain. The possibility of drug overdose should always be considered.

Sepsis

Any or all of the features of SIRS (see Box 8.3, p. 184) may be present, together with an obvious focus of infection, such as purulent sputum with chest X-ray shadowing

8.9 Causes of coma

Systemic causes

Cerebral hypoxia; hypercapnia

- Respiratory failure

Cerebral ischaemia

- Cardiac arrest
- Hypotension

Metabolic disturbance

- Diabetes mellitus
- Hypoglycaemia
- Ketoacidosis
- Hyperosmolar coma
- Hyponatraemia
- Myxoedema coma
- Uraemia
- Hepatic failure
- Hypothermia
- Drugs
- Sepsis

Primary neurological causes

Trauma

- Cerebral contusion
- Extradural haematoma
- Subdural haematoma

Infection

- Cerebral abscess
- Encephalitis
- Meningitis

Cerebrovascular disease

- Intracerebral haemorrhage
- Brain-stem infarction
- Subarachnoid haemorrhage
- Cerebral venous sinus thrombosis

Cerebral tumour

Epilepsy

Hydrocephalus

or erythema around an intravenous line. However, severe sepsis may present with unexplained hypotension (i.e. septic shock), and the speed of onset may mimic a major pulmonary embolus or myocardial infarction.

Box 8.10 gives the common sites of infection in critically ill patients and appropriate investigations to consider. The most important objective is to identify and treat the underlying cause.

The patient may be admitted with infection from home ('community-acquired') or develop infection after admission ('nosocomial'). The likely causative micro-organism and antibiotic sensitivities will depend on this and direct the initial choice of antibiotics. Initial investigations include:

- cultures of blood, sputum, intravascular lines, urine and any wound discharge
- ABGs, plasma lactate, coagulation profile
- urinalysis
- chest X-ray.

Only 10% of ICU patients with a clinical diagnosis of 'septic' shock will have positive blood cultures, due to prior antibiotic treatment and the fact that an inflammatory state is not always due to infection. Specific investigations will be driven by the history and examination (see Box 8.10).

Nosocomial infections are an increasing problem in critical care units (Box 8.11). Cross-infection is a major concern, particularly with meticillin-resistant *Staphylococcus aureus* (MRSA), multidrug-resistant Gram-negative organisms and *Clostridium difficile*. If cross-infection occurs frequently, it should prompt a review of the unit's infection control policies. The most important preventive measure is thorough hand-washing before and after every patient contact (p. 145). The choice of broad-spectrum antibiotics used may influence the development of *C. difficile*-induced pseudomembranous colitis. Limiting antibiotic use helps to prevent the emergence of multidrug-resistant bacteria.

8.10 Sites of infection in critically ill patients

Sites of infection

Investigations and comments

Major

Intravenous lines (particularly central)	Always suspect; if the patient develops evidence of sepsis and lines have not been changed for > 4 days, they must be replaced
Lungs	High risk of nosocomial pneumonia in intubated patients; after being in ICU for > 3–4 days, particularly if treated with antibiotics, the nasopharynx becomes colonised with Gram-negative bacteria which migrate to the lower respiratory tract. Prophylaxis with both parenteral and enteral antibiotics (selective decontamination of the digestive tract) reduces the incidence of nosocomial pneumonia
Abdomen	Consider intra-abdominal abscess or necrotic gut in patients who have had abdominal surgery. Pancreatitis, acute cholecystitis or perforated peptic ulcer may develop as a complication of critical illness. Ultrasound, CT, aspiration of collections of fluid/pus and laparotomy may be required
Urinary tract	Always culture a catheter specimen of urine in unexplained sepsis, although the lower urinary tract is a relatively unusual source

Other

Heart valves	Transthoracic or transoesophageal echocardiogram
Meninges	Lumbar puncture but check coagulation and platelet count first
Joints and bones	X-ray, gallium or technetium white cell scan
Nasal sinuses, ears, retropharyngeal space	Clinical examination, plain X-ray, CT
Genitourinary tract (particularly post-partum)	Per vaginam examination, ultrasound
Gastrointestinal tract	Per rectum examination, stool culture, <i>Clostridium difficile</i> toxin, sigmoidoscopy

8.11 Risk factors for nosocomial infection

- Invasive ventilation
- Trauma
- Invasive catheters: i.v., urinary, nasogastric tubes
- Stress ulcer prophylaxis with H₂-antagonists
- Prolonged length of stay

Disseminated intravascular coagulation (DIC)

Also known as consumptive coagulopathy, this is an acquired disorder of haemostasis (p. 1050); it is common in critically ill patients and often heralds the onset of MOF. It is characterised by an increase in prothrombin time, partial thromboplastin time and fibrin degradation products, and a fall in platelets and fibrinogen. The clinically dominant feature may be widespread bleeding from vascular access points, gastrointestinal tract, bronchial tree and surgical wound sites, or widespread microvascular and even macrovascular thrombosis. Management is supportive with infusions of fresh frozen plasma and platelets, while the underlying cause is treated.

GENERAL PRINCIPLES OF CRITICAL CARE MANAGEMENT

Essential aspects of the management of critically ill patients on admission to the ICU are shown in Box 8.12.

8.12 Management of patients on admission to ICU

- Handover from transferring team to ICU staff
- Full clinical assessment
- Ongoing resuscitation/stabilisation
- Establishment of monitoring
- Review of medical and social history
- Communication (including explanation) with relatives
- Investigations to establish or confirm the definitive diagnosis
- Formulation and implementation of a management plan

Monitoring

Monitoring in ICU represents a mixture of clinical and automated recordings. Electrocardiogram (ECG), SpO₂ (oxygen saturation derived from a pulse oximeter), BP (generally invasive arterial pressure) and usually CVP are established at an early stage, and recordings made at least hourly, on either a 24-hour chart or a computerised system. All invasive haemodynamic monitoring should be referenced to the mid-axillary line as 'zero'. Urine output is a sensitive measure of renal perfusion and early catheterisation is required in most patients. Clinical monitoring is particularly important. Physical signs such as respiratory rate, the appearance of the patient, restlessness, conscious level and indices of peripheral perfusion (pale, cold skin; delayed capillary refill in the nailbed) are just as important as a set of blood gases or monitor readings.

Monitoring the circulation

Electrocardiogram (ECG)

Standard monitors display a single-lead ECG, record heart rate and identify rhythm changes. More sophisticated machines can print out rhythm strips and monitor ST segment shift, which may be useful in patients with ischaemic heart disease.

Blood pressure

In critically ill patients, continuous intra-arterial monitoring is necessary, using a line placed in the radial artery (or the femoral in vasoconstricted patients or where access is difficult). Remember that, when there is systemic vasoconstriction, the mean arterial pressure (MAP) may be normal or even high, although the cardiac output is low. Conversely, if there is peripheral vasodilatation, as in sepsis, the MAP may be low, although the cardiac output is high.

Central venous pressure (CVP)

CVP or right atrial pressure (RAP) is monitored using a catheter inserted via either the internal jugular or the subclavian vein, with the distal end sited in the upper right atrium. The CVP may help in assessing the need for intravascular fluid replacement and the rate at which this should be given (Box 8.13). If the CVP is low in the presence of a low MAP or cardiac output, fluid resuscitation is necessary. However, a raised level does not necessarily mean that the patient is adequately volume-resuscitated. Right heart function, pulmonary artery pressure, intrathoracic pressure and venous 'tone' also influence CVP, and may lead to a raised CVP even when the patient is hypovolaemic (see Box 8.1, p. 180). In addition, positive pressure ventilation raises intrathoracic pressure and causes marked swings in atrial pressures and systemic BP in time with respiration. Pressure measurements should be recorded at end-expiration.

In severe hypovolaemia, the RAP may be sustained by peripheral venoconstriction, and transfusion may initially produce little or no change in the CVP (see Fig. 8.1, p. 181).

8.13 Central venous pressure

Normal	0–5 mmHg
Target (usual) of volume resuscitation	6–10 mmHg
Normal if ventilated	5–10 mmHg
Target of volume resuscitation if ventilated	10–15 mmHg

Pulmonary artery catheterisation and pulmonary artery 'wedge' pressure (PAWP)

In most situations, the CVP is an adequate guide to the filling pressures of both sides of the heart. However, certain conditions, such as pulmonary hypertension or right ventricular dysfunction, may lead to raised CVP levels, even in the presence of hypovolaemia. If this is the case, it may be appropriate to insert a pulmonary artery flotation catheter (Fig. 8.6) so that pulmonary artery pressure and PAWP, which approximates to left atrial pressure, can be measured.

The mean PAWP normally lies between 6 and 12 mmHg (measured from the mid-axillary line), but

Fig. 8.6 A pulmonary artery catheter. **A** There is a small balloon at the tip of the catheter and pressure can be measured through the central lumen. The catheter is inserted via an internal jugular, subclavian or femoral vein and advanced through the right heart until its tip lies in the pulmonary artery. When the balloon is deflated, the pulmonary artery pressure can be recorded. **B** Advancing the catheter with the balloon inflated will 'wedge' the catheter in the pulmonary artery. In this position blood cannot flow past the balloon, so the tip of the catheter will now record the pressure transmitted from the pulmonary veins and left atrium. This is known as the pulmonary artery wedge pressure and provides an indirect measure of the left atrial pressure. (LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle)

in left heart failure it may be grossly elevated and even exceed 30 mmHg. Provided the pulmonary capillary membranes are intact, the optimum PAWP when managing acute circulatory failure in the critically ill patient is generally 12–15 mmHg because this will ensure good left ventricular filling without risking hydrostatic pulmonary oedema.

Pulmonary artery catheters also allow measurement of cardiac output and sampling of blood from the pulmonary artery ('mixed venous' samples), allowing continuous monitoring of the mixed venous oxygen saturation (SvO_2) by oximetry. Measurement of SvO_2 gives an indication of the adequacy of cardiac output (and hence DO_2) in relation to the body's metabolic requirements and is especially useful in low cardiac output states.

Cardiac output

Measurement of cardiac output is important particularly where large doses of vasopressor are being administered, where there is underlying cardiac disease (acute or chronic), and where volume resuscitation and vasoactive drug therapy are not achieving resolution of lactic acidosis or oliguria. It is most accurately measured by techniques which use an indicator dilution method. Most PA catheters incorporate a heating element, which raises blood temperature at frequent intervals, with the resultant temperature change detected by a thermistor at the tip of the catheter.

Oesophageal Doppler ultrasonography provides a rapid and clinically useful assessment of volume status and cardiac performance to guide early fluid and vasoactive therapy. A 6 mm probe is inserted into the distal oesophagus, allowing continuous monitoring of the aortic flow signal from the descending aorta

(Fig. 8.7). Using the stroke distance (area under velocity/time waveform) and a correction factor that incorporates the patient's age, height and weight, an estimate of left ventricular stroke volume and hence cardiac output can be made. Peak velocity is an indicator of left ventricular performance, while flow time is an indicator of left ventricular filling and peripheral resistance.

Fig. 8.7 Oesophageal Doppler ultrasonography.

Analysis of arterial pressure waveform is another means of continuously estimating cardiac output, and can be calibrated either by transpulmonary thermodilution (PiCCO) or lithium dilution methods (LidCO). The Vigileo/Flotrac system derives cardiac output from arterial pressure waveform analysis with no external calibration.

Urine output

This is a sensitive measure of renal perfusion, provided that the kidneys are not damaged (e.g. ATN) or affected by drugs (e.g. diuretics, dopamine), and can be monitored accurately if a urinary catheter is in place. Output is measured hourly and the lower limit of normal is 0.5 mL/hr/kg body weight. It is not measured in real time and reflects renal perfusion over the hours preceding measurement.

Peripheral skin temperature

In general, resuscitation is not complete until the patient's feet are warm and well perfused.

Blood lactate, hydrogen ion and base excess/deficit

Acid-base balance is discussed on page 442. Base excess or deficit is calculated as the difference between the patient's bicarbonate and the normal bicarbonate after the PCO_2 has been maintained in the blood gas machine at 5.33 kPa (40 mmHg). This is especially useful in critically ill patients as it describes the underlying metabolic status independently of the current respiratory status. A metabolic acidosis with base deficit > 5 mmol/L requires investigation (p. 443). It often indicates increased lactic acid production in poorly perfused, hypoxic tissues and impaired lactate metabolism due to poor hepatic perfusion. Serial lactate measurements may therefore be helpful in monitoring tissue perfusion and the response to treatment. Other conditions, such as acute renal failure, ketoacidosis and poisoning, may be the cause (p. 443). Large-volume infusions of fluids containing sodium chloride may lead to a hyperchloraemic acidosis.

Monitoring respiratory function

Oxygen saturation (SpO_2)

This is measured by a probe, attached to a finger or earlobe. Spectrophotometric analysis determines the relative proportions of saturated and desaturated haemoglobin.

It is unreliable if peripheral perfusion is poor and may produce erroneous results in the presence of nail polish, excessive movement or high ambient light. In general, arterial oxygenation is satisfactory if SpO_2 is $> 90\%$. Box 8.14 gives the potential causes of sudden falls in SpO_2 .

Arterial blood gases (ABGs)

These are usually measured several times a day in a ventilated patient so that inspired oxygen (FiO_2) and minute volume can be adjusted to achieve the desired PaO_2 and $PaCO_2$ respectively. ABG results are also used to monitor disturbances of acid-base balance (Ch. 16).

Lung function

In ventilated patients, lung function is monitored by:

- arterial PO_2 taken in relation to the fractional inspired oxygen concentration (PO_2/FiO_2 ratio) and level of end-expiratory pressure
- arterial and end-tidal CO_2 , reflecting alveolar ventilation
- airway pressures and tidal volumes reflecting lung compliance and airways resistance.

Capnography

The CO_2 concentration in inspired gas is zero, but during expiration, after clearing the physiological dead space, it rises progressively to reach a plateau which represents the alveolar or end-tidal CO_2 concentration. This cyclical change in CO_2 concentration, or capnogram, is measured using an infrared sensor inserted between the ventilator tubing and the endotracheal tube. In normal lungs, the end-tidal CO_2 closely mirrors $PaCO_2$, and can be used to assess the adequacy of alveolar ventilation. However, its use is limited, as there may be marked discrepancies in lung disease or impaired pulmonary perfusion (e.g. due to hypovolaemia). In combination with the gas flow and respiratory cycle data from the ventilator, CO_2 production and hence metabolic rate may be calculated. In clinical practice, end-tidal CO_2 is used to confirm correct placement of an endotracheal tube, in the management of head injury, and during the transport of ventilated patients.

Transcutaneous PCO_2

Monitors now exist which measure transcutaneous PCO_2 , usually using an earlobe probe which incorporates both pulse oximeter and CO_2 electrode. The transcutaneous PCO_2 closely approximates to $PaCO_2$ and gives continuous monitoring, which is useful in patients with no arterial cannula but who require close monitoring: for example, during ventilatory weaning (see below).

Daily clinical management in the ICU

Regular clinical examination is essential if changes in a patient's condition are to be recognised. Detailed clinical examination is performed at least daily, with additional focused and systematic assessment on ward rounds at least twice daily:

- Review of progress reports from ICU nursing and medical staff, and any specialist opinions.
- Review of 24-hour charts.
- Examination: general (including skin, line sites, wounds etc.) and specific:

8.14 Causes of sudden changes in oxygen saturations

Patient factors

- Bronchospasm
- Lung collapse due to thick secretions blocking the proximal bronchial tree
- Pneumothorax
- Circulatory collapse causing a poor signal due to impaired peripheral perfusion

Equipment factors

- Displacement of the endotracheal tube (extubation, endobronchial intubation)
- Blockage of the endotracheal tube
- Disconnection from the ventilator
- Oxygen supply failure
- Error, e.g. detached probe

cardiovascular, including haemodynamics, fluids and inotropes
respiratory, including ventilator settings and ABGs
gastrointestinal, including nutrition (calorie, protein intake, route), nasogastric aspirate and bowel function
renal, including urine output, overall fluid balance, urea and electrolytes, and renal replacement therapy
neurological, including sedation level, GCS and pupil responses where appropriate.

- Laboratory results: haematology, including coagulation, and biochemistry.
- Microbiology: temperature, white blood count, line sites and other possible sources of infection, results of cultures, antibiotic therapy.
- Drug therapy: review with pharmacist, consider side-effects and interactions, and identify therapy that can be discontinued.
- Imaging: review X-rays and other specialist investigations.
- Monitoring: are all measures still required?
- Management plan: formulate an integrated plan, with specific goals for each organ system.

Sedation and analgesia

Intensive care is an extremely stressful experience for the patient, with pain, discomfort and anxiety related to endotracheal intubation, invasive monitoring and other procedures.

Sedation is required for most patients in order to relieve anxiety, allow tolerance of an endotracheal tube, mechanical ventilation and invasive procedures, and control intracranial pressure in neurological disease. The level of sedation can usually be lightened as the ICU stay progresses. Over-sedation is a common occurrence, and can delay weaning from ventilation and prolong ICU stay. Daily sedation 'pauses' can allow better patient assessment, prevent sedative accumulation and have been shown to reduce ICU stay.

Standard sedation consists of a mixture of either the short-acting anaesthetic agent propofol or the benzodiazepine midazolam, and an opioid analgesic, traditionally morphine. Morphine is metabolised to the active metabolite morphine-6-glucuronide, which accumulates in renal failure; alfentanil is a good alternative in MOF, and for patients in whom frequent neurological assessment is essential.

Analgesia is required to relieve post-operative and other pain.

Muscle relaxants

Muscle relaxants are used less now than previously. They are required to facilitate endotracheal intubation, to facilitate ventilation in patients with critical oxygenation and/or poor lung compliance, and to aid control of critically increased intracranial pressure.

Delirium

Delirium is a feature of severe illness, especially when patients are subjected to major organ dysfunction, metabolic derangement and polypharmacy. Haloperidol in 2.5–5 mg doses (i.v.) and the α_2 -adrenergic agonist clonidine are useful in immediate management.

MANAGEMENT OF MAJOR ORGAN FAILURE

Circulatory support

The primary goals (Box 8.15) are to:

- Restore global oxygen delivery (DO_2) by ensuring adequate cardiac output.
- Maintain an MAP that ensures adequate perfusion of vital organs. The target will be patient-specific depending on pre-morbid factors (e.g. hypertension or coronary artery disease) and may range from 60 to 90 mmHg.

The first objective is to ensure that an 'appropriate' ventricular preload is restored. Vasoactive drugs should *not* be used as a substitute for adequate volume resuscitation.

Therapeutic options to optimise cardiac function

If the cardiac output is inadequate and myocardial contractility is poor, the available treatment options are to:

8.15 Initial management of circulatory collapse

Correct hypoxaemia

- Oxygen therapy
- Consider ventilation
 - Intractable hypoxaemia
 - Hypercapnia: $PaCO_2 > 6.7$ kPa (50 mmHg)
 - Respiratory distress
 - Impaired conscious level

Assess circulation

- Heart rate
- BP: direct arterial pressure
- CVP
- Peripheral perfusion

Optimise volume status

- Fluid challenge(s)
 - CVP < 6 mmHg: 250 mL 0.9% saline or colloid
 - CVP > 6 mmHg or poor ventricular function suspected: 100 mL boluses and consider measuring cardiac output, e.g. PA catheter or oesophageal Doppler

Optimise haemoglobin concentration

- 70–90 g/L; 100 g/L if ischaemic heart disease
- Red cells as required
- Septic patients can become profoundly anaemic with crystalloid/colloid resuscitation due to haemodilution and require blood transfusion

Achieve target BP

- Use vasopressor/inotrope once hypovolaemia is corrected

Achieve adequate CO and DO_2

- Inotropic agent if fluid alone inadequate

Other measures

- Establish monitoring, including invasive measures, as resuscitation starts
- Trends in haemodynamics, ABG, H^+ , base deficit and lactate guide further treatment

- **Reduce afterload.** This can be achieved by using an arteriolar dilator (e.g. nitrates), which may be limited by the consequent fall in systemic pressure. A counterpulsation balloon pump offers the ideal physiological treatment because it reduces LV afterload while increasing cardiac output, diastolic pressure and coronary perfusion; it is particularly valuable in treating myocardial ischaemia.
- **Increase preload.** If there is significant impairment of myocardial contractility, giving intravascular volume to increase filling pressures will only produce a small increase in stroke volume and cardiac output, and risks precipitating pulmonary oedema.
- **Improve myocardial contractility.** An inotrope may be required to ensure adequate cardiac output and peripheral blood flow sufficient to secure adequate oxygen delivery. Box 8.16 lists some characteristics of the commonly used vasoactive agents.
- **Control heart rate and rhythm** (pp. 559–577). The optimum heart rate is usually between 90 and 110 per minute. Correction of low serum potassium and magnesium concentrations should be the first stage in treating tachyarrhythmias in the critically ill. Atrial fibrillation is particularly common and troublesome in septic and critically ill patients; intravenous amiodarone 300 mg over 30–60 minutes, followed by 900 mg over 24 hours, can be successful in controlling ventricular rate and in restoring and maintaining sinus rhythm.

The management of tamponade and pulmonary embolism is described on pages 639 and 719 respectively. Circulatory support in the context of sepsis is described below.

Respiratory support

Respiratory support is indicated to maintain the patency of the airway, correct hypoxaemia and hypercapnia (Boxes 8.17 and 8.18), and reduce the work of breathing. It ranges from oxygen therapy by facemask, through non-invasive techniques such as continuous positive airways pressure (CPAP) and non-invasive positive pressure ventilation (NIV), to invasive ventilation via an endotracheal tube or tracheostomy (Box 8.19).

Oxygen therapy

Oxygen is given to treat hypoxaemia and ensure adequate arterial oxygenation ($SpO_2 > 90\%$). It should initially be given by facemask or nasal cannulae and the inspired oxygen concentration (FiO_2) can then be adjusted according to the results of pulse oximetry and ABG analysis. The risk of progressive hypercapnia in patients with COPD who are dependent on hypoxic drive has been overstated. If administration of oxygen to ensure $SpO_2 > 90\%$ results in unacceptable hypercapnia, the patient requires some form of mechanical respiratory support. The theoretical risks of oxygen toxicity are not relevant if the patient is acutely hypoxaemic. It is vital to maintain cerebral oxygenation even at the risk of pulmonary toxicity because hypoxic cerebral damage is irreversible. More detail on oxygen therapy is given on page 660.

Non-invasive respiratory support

If a patient remains hypoxaemic on high-concentration oxygen, other measures are required to improve oxygenation and to reduce the work of breathing. If the patient has respiratory failure associated with decreased lung volume, application of CPAP by mask or hood (see Box 8.19)

8.16 Circulatory effects of commonly used vasoactive drug infusions

Drug	Receptor activity	Cardiac contractility	Heart rate	BP	Cardiac output	Splanchnic blood flow	SVR	PVR
Dopamine								
< 5 µg/kg/min	DA ₁ , β ₁ , α	↑	→/↑	→/↑	↑	→/↑	→/↑	→/↑
> 5 µg/kg/min	β ₁ , α, DA ₁ , β ₂	↑↑	↑	↑	↑↑	→	↑	↑
Adrenaline (epinephrine)	β ₁ , α, β ₂	↑↑	↑	↑↑	↑↑↑	↓	↑	↑
Noradrenaline (norepinephrine)	α, β ₁	→/↑	→/↓	↑↑	→/↓	→/↓	↑↑	↑↑
Isoprenaline	β ₁ , β ₂	↑	↑↑	→/↓	↑	→/↑	→/↓	↓
Dobutamine	β ₁ , β ₂ , α	↑	↑	→/↓	↑↑	→	↓	↓
Dopexamine	β ₂ , DA ₁ , DA ₂	↑	↑↑	→/↓	↑	↑	↓	↓
Glyceryl trinitrate	NO	→	↑	↓	↑	↑	↓	↓
Nitroprusside	NO	→	↑	↓	↑	↑	↓	↓
Epoprostenol	Prostacyclin	→	↑	↓	↑	↑	↓	↓
Milrinone	PDEI	→/↑	↑	↓	↑↑	↑	↓	↓

Receptors through which each drug works are listed in order of the extent of receptor stimulation produced. The global circulatory effects listed are guidelines only. The magnitude of the response will depend on the circulatory state of the patient, the dose of the drug administered, and the receptor distribution and density in specific vascular beds. Dopamine acts more like adrenaline at high doses.

(α = α-adrenoceptor; β₁, β₂ = β-adrenoceptors 1 and 2; DA₁, DA₂ = dopaminergic receptors 1 and 2; NO = acts via local nitric oxide release; PDEI = phosphodiesterase inhibitor; PVR = pulmonary vascular resistance; SVR = systemic vascular resistance.)

8.17 Clinical conditions requiring mechanical ventilation*

Post-operative

- e.g. After major abdominal or cardiac surgery

Respiratory failure

- ARDS
- Pneumonia
- COPD
- Acute severe asthma
- Aspiration
- Smoke inhalation, burns

Circulatory failure

- Low cardiac output: cardiogenic shock
- Pulmonary oedema
- Following cardiac arrest

Neurological disease

- Coma of any cause
- Status epilepticus
- Drug overdose
- Respiratory muscle failure (e.g. Guillain-Barré syndrome, poliomyelitis, myasthenia gravis)
- Head injury: to avoid hypoxaemia and hypercapnia, and reduce intracranial pressure
- Bulbar abnormalities causing risk of aspiration (e.g. cerebrovascular accident, myasthenia gravis)

Multiple trauma

* Additional considerations:

Metabolic rate: ventilatory requirements rise as metabolic rate increases
 Nutritional reserve: low potassium or phosphate reduces respiratory muscle power
 Condition of the abdomen: distension due to surgery or tense ascites causes discomfort and splinting of the diaphragm, compromising spontaneous respiratory effort and promoting bilateral basal lung collapse.

8.18 Indications for tracheal intubation and mechanical ventilation

- Protection of airway
- Respiratory arrest or rate < 8/min
- Tachypnoea > 35/min
- Inability to tolerate oxygen mask/CPAP/NIV, e.g. agitation, confusion
- Removal of secretions
- Hypoxaemia ($\text{PaO}_2 < 8 \text{ kPa}$ (< 60 mmHg); $\text{SpO}_2 < 90\%$) despite CPAP with $\text{FiO}_2 > 0.6$
- Hypercapnia if conscious level impaired or risk of raised intracranial pressure
- Worsening respiratory acidosis
- Vital capacity falling below 1.2 L in patients with neuromuscular disease
- Removing the work of breathing in exhausted patients

will both improve oxygenation by recruitment of under-ventilated alveoli, and reduce the work of breathing by improving lung compliance. CPAP is most successful in clinical situations where alveoli are readily recruited, such as in pulmonary oedema and post-operative collapse/atelectasis. It is also helpful in correcting hypoxaemia in pneumonia, especially in immunocompromised patients. The risk of nosocomial infection is reduced by avoiding endotracheal intubation. A CPAP mask often becomes uncomfortable and gastric distension may occur; the Castar hood which fits tightly around the neck enclosing the patient's head in a clear plastic hood is much better tolerated (Fig. 8.8). Patients must be cooperative, be able to protect their airway, and have the strength to breathe spontaneously and cough effectively. Failure to improve clinically after 48–72 hours or more of CPAP is a case for consideration of invasive ventilation.

8.19 Modes and terms used in mechanical ventilatory support

Intermittent positive pressure ventilation (IPPV)

- Generic term for all types of positive pressure ventilation

Controlled mandatory ventilation (CMV)

- Most basic form of ventilation; may be volume- or pressure-controlled
- Pre-set rate and tidal volume or pressure
- Assist/control mode allows patient triggering of full ventilator breaths
- Appropriate for initial control of patients with little respiratory drive, severe lung injury or circulatory instability

Synchronised intermittent mandatory ventilation (SIMV)

- Pre-set rate of mandatory breaths generally with pre-set tidal volume
- Allows spontaneous breaths between mandatory breaths
- Spontaneous breaths may be pressure-supported (PS)
- Allows patient to settle on ventilator with less sedation

Pressure-controlled ventilation (PCV)

- Pre-set rate; pre-set inspiratory pressure; pre-set inspiratory time
- Tidal volume depends on pre-set pressure, lung compliance and airways resistance
- Used in management of severe acute respiratory failure to avoid high airway pressure, often with prolonged inspiratory to expiratory ratio (pressure-controlled inverse ratio ventilation, PCIRV)

Pressure support ventilation (PSV)/Assisted spontaneous breathing (ASB)

- Breaths are triggered by patient; spontaneous cycling to expiration
- Provides positive pressure to augment patient's breaths; useful for weaning
- Usually combined with CPAP; may be combined with SIMV
- Pressure support is titrated against tidal volume and respiratory rate

Positive end-expiratory pressure (PEEP)

- Positive airway pressure applied during expiratory phase in patients receiving mechanical ventilation
- Improves oxygenation by recruiting atelectatic or oedematous lung

Continuous positive airways pressure (CPAP)

- Positive airway pressure applied throughout the respiratory cycle, via either an endotracheal tube or a tight-fitting facemask or a hood
- Fresh gas flow must exceed patient's peak inspiratory flow (> 30–40 L/min) to maintain positive pressure
- Improves oxygenation by recruitment of atelectatic or oedematous lung
- Mask CPAP discourages coughing and clearance of lung secretions; may increase the risk of aspiration

Bi-level positive airway pressure (BiPAP/BiPAP)

- Two levels of positive airway pressure (higher level in inspiration)
- In fully ventilated patients, BiPAP is essentially the same as PCV with PEEP
- If used non-invasively, BiPAP is essentially PSV with CPAP

Non-invasive positive pressure ventilation (NIPPV/NIV)

- Most modes of ventilation may be applied via a facemask or nasal mask
- Usually PSV/BiPAP (typically 15–20 cmH₂O) often with back-up mandatory rate
- Indications include acute exacerbations of COPD

Fig. 8.8 CPAP delivery with a Castar hood.

Non-invasive ventilation (NIV) refers to ventilatory support by nasal or full facemask. NIV can be delivered by a simple bi-level (BiPAP) turbine ventilator which delivers a higher pressure (approximately 15–25 cmH₂O) for inspiration and a lower pressure (4–10 cmH₂O) to allow expiration. A simple breathing circuit with a leak rather than an expiratory valve is generally used, and ventilation can be spontaneous (PSV) or timed (PCV). In more seriously hypoxaemic patients, NIV can be delivered using a complex ICU ventilator which allows higher oxygen concentrations to be administered. NIV has been shown to improve the outcome of patients with type 2 respiratory failure secondary to acute exacerbation of COPD, and in hypercapnia associated with left ventricular failure and pulmonary oedema. It may also be used during weaning from conventional invasive ventilation, either electively to facilitate earlier extubation, notably in COPD, or after failed extubation with a view to prevention of re-intubation. As with mask CPAP, NIV requires the patient to be conscious and cooperative.

Endotracheal intubation and mechanical ventilation

Over 60% of patients appropriately admitted to ICU require endotracheal intubation and mechanical ventilation, mostly for respiratory failure (see Boxes 8.18 and 8.19). The final decision to perform tracheal intubation and ventilate a patient should be taken on clinical grounds rather than depending on the results of investigations, such as ABG.

In the conscious patient, intubation requires induction of anaesthesia and muscle relaxation, while in more obtunded patients, sedation alone may be adequate. This can be hazardous in the critically ill patient with respiratory and often cardiovascular failure.

Capnography should be used to confirm correct endotracheal tube placement. Continuous monitoring, particularly of heart rate and BP (preferably invasively), is essential and resuscitation facilities and drugs must be immediately available. Hypotension commonly follows sedation or anaesthesia because of direct cardiovascular effects of the drugs and loss of sympathetic drive; positive pressure ventilation may compound this problem by increasing intrathoracic pressure, thereby reducing venous return and hence cardiac output.

There are different types of ventilatory support (Fig. 8.9). Modern ventilators allow flexibility in the level of support from controlled mandatory ventilation to partial ventilatory support modes, and assisted spontaneous breathing which allows the ventilator to respond to patients' demands (see Box 8.19). Use of partial ventilatory support avoids the requirement for and hazards of paralysis and deep sedation, and allows the patient to be conscious and yet comfortable.

General considerations in the management of the ventilated/intubated patient

Beware of the restless patient. Try to establish the cause of the problem before simply administering sedation. Possibilities include pneumothorax, hypoxaemia, hypercapnia due to inadequate ventilation, pain, onset of sepsis, cardiac decompensation (pulmonary oedema, dysrhythmia, infarction) and proximal airway obstruction, e.g. secretions.

Patients who are breathing spontaneously adjust their ventilation to compensate for metabolic derangements; this cannot occur in patients who are ventilated using mandatory modes, so either the underlying metabolic abnormality must be corrected or appropriate changes must be made to the ventilator settings. For example, a patient with severe diabetic ketoacidosis will hyperventilate to compensate for the metabolic acidosis; if mechanical ventilation is instituted,

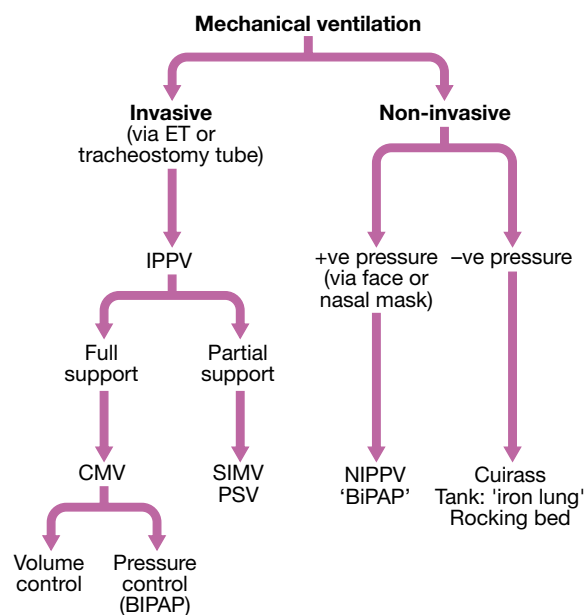

Fig. 8.9 Different types of invasive and non-invasive ventilatory support. (ET = endotracheal; see Box 8.19 for other abbreviations.)

there will be a potentially catastrophic increase in acidemia due to reduced minute ventilation, and this should be taken into account when choosing ventilator settings.

The ventilator should be set to detect:

- minimum acceptable minute volume to identify inadvertent disconnection
- maximum acceptable airway pressure to prevent barotrauma.

If in PCV mode, a minimum acceptable tidal volume should be an alarm limit.

Humidify and warm inspired gas to prevent inspissation of secretions, normally with a heat and moisture exchanger, but occasionally with a hot water humidifier. Arrange regular positioning, physiotherapy and suctioning to clear secretions and prevent proximal airway obstruction and distal alveolar collapse. The patient should be in a 30° head-up position to avoid aspiration. A chest X-ray to check the position of the endotracheal tube following intubation is required (the appropriate position is 4 cm above the carina).

Bronchoscopy should be readily available to:

- investigate upper airways obstruction (plugging of the proximal bronchial tree by inspissated mucus is the most common cause)
- investigate lobar/segmental collapse, and aspirate mucus plug obstructing proximal bronchial tree
- assist in cases of difficult intubation or tracheostomy tube change
- obtain broncho-alveolar lavage specimens for microbiology
- identify the cause of haemoptysis (not always easy)
- exclude tracheobronchial disruption after thoracic trauma.

Ventilation strategy

The selection of ventilator mode and settings for tidal volume, respiratory rate, positive end-expiratory pressure (PEEP) and inspiratory to expiratory ratio is dependent on the cause of the respiratory failure. The objectives are to:

- improve gas exchange
- minimise damage to the lung by avoiding high lung volumes, pressures and FiO_2
- avoid adverse circulatory effects
- make the patient comfortable without heavy sedation or muscle paralysis by reducing the work of breathing and harmonising interaction between patient and ventilator.

In asthma and conditions with increased lung volumes (high FRC), a prolonged expiratory phase is necessary to prevent progressive lung over-inflation; PEEP and large tidal volumes exacerbate over-distension, produce high alveolar pressures and increase the risk of pneumothorax. High intrathoracic pressures compromise circulatory function, particularly if there is intravascular volume depletion, so that oxygen delivery may actually fall in spite of improved arterial oxygenation.

In patients with alveolar collapse (low FRC), such as those with ARDS, it is appropriate to use a prolonged inspiratory to expiratory ratio and high levels of PEEP (+10 to +15 cmH_2O) to recruit alveoli and improve compliance and gas exchange.

Ventilation and ARDS

Recent studies have shown that, in ARDS, damage to the lungs can be exacerbated by mechanical ventilation, possibly by over-distension of alveoli and repeated opening and closure of distal airways. The ventilator strategy for ARDS encompasses limiting tidal volumes and airway pressures (Boxes 8.20 and 8.21). Other strategies which may be of benefit in severe ARDS include prone ventilation, nitric oxide inhalation and corticosteroids.

Prone positioning improves oxygenation significantly in two-thirds of patients with ARDS by reducing thoraco-abdominal compliance and the vertical pleural pressure gradient so that ventilation is more evenly distributed and better matched to perfusion. Multicentre trials using manual proning have failed to show a survival benefit, and trials using an automatic rotating bed are under way. Nevertheless it remains a very useful rescue therapy in patients with critical oxygenation.

Nitric oxide is a very short-acting pulmonary vasodilator. Delivered to the airway in concentrations of between 1 and 20 parts per million, it improves blood flow to ventilated alveoli, thus improving ventilation-perfusion matching. Oxygenation can be improved markedly in some patients but the evidence indicates that this benefit lasts for only 48 hours and outcome is not improved. Its role, like that of prone ventilation, is as a rescue therapy in patients with critical oxygenation. It may also be useful in patients with severe pulmonary hypertension.

There is conflicting evidence that corticosteroids improve outcome if given in the fibroproliferative stage of ARDS. A trial of corticosteroids may be considered if a patient has consistent gas exchange impairment and ventilator dependence at 7–10 days after diagnosis. The recommended dose of methylprednisolone is 2–3 mg/kg/day, decreasing after 7 days and as gas exchange

8.20 Principles of mechanical ventilation in ARDS

- Optimum ventilator settings are:
 - Pressure-controlled or limited
 - Small tidal volumes (ideally < 6 mL/kg)
 - Long inspiratory to expiratory time
 - Positive end-expiratory pressure (PEEP)
- Allow PaCO_2 to rise (permissive hypercapnia) and tolerate lower oxygen saturations than normal (e.g. 88–90%)
- Avoid:
 - Large tidal volumes
 - Airway pressure of > 35 cmH_2O
 - FiO_2 of > 0.8 if possible
- Maintain a balance between improving gas exchange, minimising the risk of subsequent pulmonary fibrosis due to lung injury, and avoiding adverse circulatory effects

EBM 8.21 Optimal ventilation in ARDS

'Ventilation using positive end-expiratory pressure but limiting tidal volumes to 5–7 mL/kg and accepting high PaCO_2 levels improves outcome in ARDS.'

- Acute Respiratory Distress Syndrome Network. *N Engl J Med* 2000; 342:1301–1308.

improves. Bronchoscopy and broncho-alveolar lavage should be performed to identify or exclude pulmonary infection before commencing corticosteroid therapy.

Weaning from respiratory support

This is the process of progressively reducing and eventually removing all external ventilatory support and associated apparatus. The majority of patients require mechanical ventilatory support for only a few days and do not need weaning; simple trials of spontaneous breathing via the endotracheal tube will usually indicate whether the patient can be successfully extubated or not.

In contrast, patients who have required long-term ventilatory support for severe lung disease, such as ARDS, may initially be unable to sustain even a modest degree of respiratory work because of residual decreased lung compliance and hence increased work of breathing, compounded by respiratory muscle weakness. These patients require weaning until respiratory muscle strength improves to the point that all support can be discontinued.

Weaning techniques involve the patient breathing spontaneously for increasing periods of the day and a gradual reduction in the level of ventilatory support. This often involves graduation to partial support modes and then non-invasive modes of ventilatory support.

The process of identifying patients able to progress to spontaneous breathing and extubation is carried out according to a 'weaning protocol'. This entails deciding whether a patient can be safely subjected to a spontaneous breathing trial (Box 8.22). If the patient meets these criteria, he/she undergoes the breathing trial for 2–5 minutes. The ratio of the respiratory rate to tidal volume is calculated. If it is < 105 breaths/min/L, the patient continues the trial for a further 30-minute to 2-hour period before extubation.

In the event of failure (increased respiratory rate; decreased tidal volume), gradual weaning of ventilation continues using synchronised intermittent mandatory ventilation (SIMV), pressure support ventilation (PSV) or intermittent periods of spontaneous breathing. Non-invasive ventilation via a facemask can allow earlier extubation in certain groups, such as patients with COPD, with weaning continuing after removal of the endotracheal tube.

Despite the development of objective tests and indices of the patient's ability to sustain spontaneous ventilation, the decision to extubate and the speed of weaning from mechanical ventilation still rely largely on clinical judgement.

8.22 Factors in deciding whether a ventilated patient can be weaned and safely extubated

- Has the original indication for mechanical ventilation resolved?
- Is the patient conscious and able to cough and protect his/her airway?
- Is the circulation stable, with a normal or reasonably low left atrial pressure?
- Is gas exchange satisfactory ($PaO_2 > 10$ kPa (> 75 mmHg) on $FiO_2 < 0.5$; $PaCO_2 < 6$ kPa (< 45 mmHg))?
- Is analgesia adequate?
- Are any metabolic problems well controlled?

Tracheostomy

Tracheostomy is usually performed electively when endotracheal intubation is likely to be required for over 14 days. Box 8.23 describes the advantages and disadvantages.

Tracheostomy is usually carried out using a percutaneous technique in the ICU, avoiding the need for transfer to the operating theatre. This has led to its earlier and more frequent use. A recent multicentre RCT found that early tracheostomy (< 3 days) did not lead to earlier weaning or shorter ICU stay.

Mini-tracheostomy

The passage of a smaller (4.5 mm internal diameter) tube through the cricothyroid membrane is a useful technique to clear airway secretions in spontaneously breathing patients with a poor cough effort. It can be particularly useful in the HDU and in post-operative patients.

8.23 Advantages and disadvantages of tracheostomy

Advantages

- Patient comfort
- Improved oral hygiene
- Reduced sedation requirement
- Enables speech with cuff deflated and a speaking valve attached
- Earlier weaning and ICU discharge
- Access for tracheal toilet
- Reduces vocal cord damage

Disadvantages

- Immediate complications: hypoxia, haemorrhage
- Tracheal damage; late stenosis
- Tracheostomy site infection

Renal support

Oliguria (< 0.5 mL/kg/hr for several hours) requires investigation and early intervention to correct hypoxaemia, hypovolaemia, hypotension and renal hypoperfusion. There is little evidence that specific treatments aimed at inducing a diuresis, such as low-dose dopamine, furosemide or mannitol, have renoprotective action or additional beneficial value in restoring renal function beyond aggressive haemodynamic resuscitation to achieve normovolaemia, normotension and an appropriate cardiac output. Sepsis is frequently implicated in the development of AKI, and the focus must be promptly and adequately treated by surgical drainage and antibiotics if renal function is to be restored. Obstruction of the renal tract should always be excluded by abdominal ultrasound and, if present, relieved.

If renal function cannot be restored following resuscitation, renal replacement therapy (p. 492) is indicated (Box 8.24). The preferred renal replacement therapy in ICU patients is pumped venovenous haemofiltration. This is associated with fewer osmotic fluid shifts and hence greater haemodynamic stability than haemodialysis. It is carried out using a double-lumen central venous catheter placed percutaneously. Haemofiltration

8.24 Indications for renal replacement therapy

- Hyperkalaemia: potassium > 6 mmol/L despite medical treatment
- Fluid overload; pulmonary oedema
- Metabolic acidosis: H^+ > 56 nmol/L (pH < 7.25)
- Uraemia:
 - Urea > 30–35 mmol/L (180–210 mg/dL)
 - Creatinine > 600 μ mol/L (> 6.78 mg/dL)
- Drug removal in overdose
- Sepsis: tentative evidence for mediator removal

should be continuous in the early phase of treatment; higher rates of filtration (preferably > 35 mL/kg/hr) are associated with improved outcome. Intermittent treatment may be used when the patient is recovering from the primary insult and return of normal renal function is expected. Provided the precipitating cause can be successfully treated, renal failure due to ATN usually recovers between 5 days and several weeks later.

Survival rates from MOF including AKI have been around 50% for many years, but evidence suggests that modern haemofiltration techniques are producing better outcomes.

Gastrointestinal and hepatic support

The gastrointestinal tract and liver play an important role in the evolution of MOF, even when the primary diagnosis is not related to the abdomen. Gastrointestinal symptoms, such as nausea, vomiting and large nasogastric aspirates, may be the earliest signs of regional circulatory failure, and when associated with a tender, distended, silent abdomen, indicate the probable site of the primary pathology. Ischaemic bowel is difficult to diagnose in the critically ill patient but in the context of an otherwise unexplained lactic acidosis, hyperkalaemia and coagulopathy, urgent laparotomy must be considered (p. 906).

The gut has a rapid cell turnover rate and fasting alone can produce marked changes in mucosal structure and function. In hypovolaemia and frank shock states, splanchnic vasoconstriction produces gut mucosal ischaemia, damaging the mucosal barrier and allowing toxins to enter the portal circulation and lymphatics. Although equipped to cope with moderate portal toxemia, the liver may be overwhelmed and then augments the inflammatory response by releasing cytokines into the systemic circulation. For this reason the gut has been described as the 'undrained abscess' or 'motor' of MOF.

Manifestations of MOF within the gastrointestinal tract include loss of gastric acid production, erosive gastritis, stress ulceration, bleeding, ischaemia, pancreatitis and acalculous cholecystitis.

Early institution of enteral nutrition is the most effective strategy for protecting the gut mucosa and providing nutritional support. Evidence suggests that nasogastric feeds supplemented with arginine, omega 3 fatty acids and nucleotides ('immunonutrition') may improve outcome in critical illness. Glutamine supplementation is logical, although not of proven benefit, since it is a 'conditionally essential' amino acid (see Box 5.15, p. 111) and the principal energy substrate used by the gut mucosa in

critical illness. Total parenteral nutrition (TPN) should be started if attempts at implementing enteral feeding fail, but should only be necessary in < 20% of ICU patients.

Tight glycaemic control has been shown to improve outcomes in critically ill surgical patients, but subsequent studies have not replicated this benefit in a mixed critically ill population and have highlighted the dangers of inadvertent hypoglycaemia when using insulin to maintain blood sugars between 4.5 and 6.5 mmol/L (80–120 mg/dL). A rather higher level of glucose, such as 5.5–8 mmol/L (100–144 mg/dL), is thus now the target.

Ranitidine and sucralfate are both used to reduce the risk of gastrointestinal haemorrhage, although ranitidine is the more effective. Both agents are associated with an increased incidence of nosocomial pneumonia. Treatment should be stopped when full enteral nutrition has been established and is probably only necessary in patients with a history of peptic ulcer and those who have evidence of MOF, particularly severe coagulopathy. Proton pump inhibitors are only required if upper GI bleeding due to ulceration occurs.

The hepatic circulation, 80% of which is derived from the portal venous system, is compromised by the same factors which lead to splanchnic vasoconstriction. Hepatic ischaemia leads to impaired filtering of endotoxin from the portal circulation, and as SIRS develops, inflammatory mediators (e.g. cytokines interleukin (IL)-1, IL-6 and tumour necrosis factor (TNF)) are released from activated Kupffer cells (hepatic macrophages) into the systemic circulation, increasing the risk of AKI and the other manifestations of MOF. Increased metabolic activity in the liver as a result of sepsis, and the need for vasoconstricting agents to maintain BP increase hepatic ischaemia. The synthetic inodilator dopexamine, with dopaminergic 1 and 2 and β -adrenergic effects, may enhance splanchnic blood flow but has not been shown to improve outcome.

Three distinctive hepatic dysfunction syndromes occur in the critically ill:

- *Shock liver or ischaemic hepatitis* results from extreme hepatic tissue hypoxia and is characterised by centrilobular hepatocellular necrosis. Transaminase levels are often massively raised (> 1000–5000 U/L) at an early stage, followed by moderate hyperbilirubinaemia (< 100 μ mol/L or < 5.8 mg/dL). There is often associated hypoglycaemia, coagulopathy and lactic acidosis. Following successful resuscitation, hepatic function generally returns to normal.
- *Hyperbilirubinaemia ('ICU jaundice')* frequently develops following trauma or sepsis, particularly if there is inadequate control of the inflammatory process. There is a marked rise in bilirubin (predominantly conjugated) but only mild elevation of transaminase and alkaline phosphatase. This results from failure of bilirubin transport within the liver and produces the histological appearance of intrahepatic cholestasis. Extrahepatic cholestasis must be excluded by abdominal ultrasound and potentially hepatotoxic drugs should be stopped. Treatment is non-specific and should include early institution of enteral feeding. Therapy that compromises splanchnic blood flow, particularly high doses of vasoconstrictor agents, should be avoided.
- *Transaminitis* is most commonly due to drug toxicity: for example, antibiotics.

Recognition and management of patients with acute liver failure is described on page 933.

Neurological support

A diverse range of neurological conditions require management in the ICU. These include the various causes of coma, spinal cord injury, peripheral neuromuscular disease and prolonged seizures. Intensive care is required to:

- manage acute brain injury with control of raised intracranial pressure (ICP)
- protect the airway, if necessary by endotracheal intubation
- provide respiratory support to correct hypoxaemia and hypercapnia
- treat circulatory problems, e.g. neurogenic pulmonary oedema in subarachnoid haemorrhage, autonomic disturbances in Guillain-Barré syndrome, spinal shock following high spinal cord injuries
- manage status epilepticus using anaesthetic agents such as thiopental or propofol.

The aim of management in acute brain injury is to optimise cerebral oxygen delivery by maintaining a normal arterial oxygen content and a cerebral perfusion pressure > 60 mmHg. Avoiding secondary insults to the brain, such as hypoxaemia and hypotension, improves outcome in head injury. ICP rises in acute brain injury as a result of haematoma, contusions, oedema or ischaemic swelling. Raised ICP is damaging both directly to the cerebral cortex and by producing downward pressure on the brain stem, and indirectly by reducing cerebral perfusion pressure, thereby threatening cerebral blood flow and oxygen delivery:

Cerebral perfusion pressure (CPP) = mean BP – ICP

ICP is generally measured via pressure transducers inserted directly into the brain tissue. The normal upper limit for ICP is 15 mmHg and management should be directed at keeping ICP < 20 mmHg (Box 8.25). Sustained pressures > 30 mmHg are associated with a poor prognosis.

8.25 Strategies to control intracranial pressure

- Prevent coughing with sedation, analgesia and occasionally paralysis
- Nurse with 30° head-up tilt and avoid excessive flexion of the head or pressure around the neck that may impair cerebral venous drainage
- Control epileptiform activity with appropriate anticonvulsant therapy; an electroencephalogram (EEG) may be necessary to ensure that this is achieved
- Maintain good glycaemic control with blood glucose between 5.5 and 8 mmol/L (~99–144 mg/dL)
- Aim for a core body temperature of between 36 and 37°C
- Maintain sodium > 140 mmol/L using i.v. 0.9% saline
- Avoid volume depletion or fluid overload
- Provide ventilation aiming to reduce the P_{aCO_2} to 4–4.5 kPa (~30–34 mmHg) for the first 24 hours
- Osmotic diuretic, mannitol 20% 100–200 mL (0.25–0.5 g/kg), coupled with volume replacement
- Hypnotic infusion, thiopental, titrated to 'burst suppression' on EEG
- Surgery: drainage of haematoma or ventricles; lobectomy, decompressive craniectomy

CPP should be maintained > 60 mmHg by ensuring adequate fluid replacement and, if necessary, by treating hypotension with a vasopressor such as noradrenaline (norepinephrine).

Complex neurological monitoring must be combined with frequent clinical assessment of GCS, pupil response to light and focal neurological signs. The motor response to pain is an important prognostic sign. No response or extension of the upper limbs is associated with severe injury, and unless there is improvement within a few days, prognosis is very poor. A flexor response is encouraging and indicates that a good outcome is still possible.

Neurological complications in intensive care

Neurological complications also occur as a result of systemic critical illness. Sepsis may be associated both with an encephalopathy characterised by delirium and with cerebral oedema and loss of vasoregulation. Hypotension and coagulopathy may provoke cerebral infarction or haemorrhage. Neurological examination is very difficult if patients are sedated or paralysed, and it is important to stop sedation regularly to reassess their underlying level of consciousness. If there is evidence of a focal neurological deficit or a markedly declining level of consciousness, CT of the brain should be performed.

Critical illness polyneuropathy is another potential complication in patients with sepsis and MOF. It is due to peripheral nerve axonal loss and can result in areflexia, gross muscle-wasting and failure to wean from the ventilator, thus prolonging the duration of intensive care. Recovery can take many weeks.

Management of sepsis

Prompt resuscitation with early cultures, administration of appropriate antibiotics and eradication of the source of infection (e.g. surgical drainage) is required. Antibiotics should exhibit a spectrum wide enough to cover probable causative organisms, based on an analysis of the likely site of infection, previous antibiotic therapy and known local resistance patterns. The haemodynamic changes in septic shock are very variable and not specific for the Gram status of the infecting organism. The first feature is often tachypnoea and the early stages are often dominated by hypotension with relative volume depletion due to vasodilatation. Sufficient intravenous fluid should be given to ensure that the intravascular volume is not the limiting factor in determining global oxygen delivery. The type of fluid that should be administered and what constitutes 'adequate' volume resuscitation remain controversial. The response to therapy is crucial and frequently unpredictable, so rigid protocols cannot be used. Depending on haemoglobin concentration, blood or synthetic colloid should be given as 100–200 mL boluses to assess BP response to volume (see Fig. 8.1, p. 181).

Although ventricular function is frequently impaired, the characteristically low SVR usually ensures a high cardiac output (once the patient is adequately volume-resuscitated), albeit with low BP.

The choice of the most appropriate vasoactive drug to use should be based on a full analysis of the circulation

8.26 Factors that increase metabolic rate in critically ill patients

- Fever (10–15% increase in $\dot{V}O_2$ for every 1°C rise)
- Sepsis
- Trauma
- Burns
- Surgery
- Sympathetic activation (pain, agitation, shivering)
- Interventions (e.g. nursing procedures, physiotherapy, visitors)
- Drugs (e.g. β -blockers, amphetamines, tricyclics)

N.B. Sedatives, analgesics and muscle relaxants will reduce metabolic rate.

and knowledge of the different inotropic, dilating or constricting properties of these drugs (see Box 8.16, p. 194). In most cases, a vasoconstrictor such as nor-adrenaline (norepinephrine) is necessary to increase SVR and BP, while an inotrope (dobutamine) may be necessary to maintain cardiac output. In the later stages of severe sepsis, the essential problem is at the micro-circulatory level. Oxygen uptake and utilisation are impaired due to failure of the regional distribution of flow and direct cellular toxicity despite adequate global oxygen delivery. Tissue oxygenation may be improved and aerobic metabolism sustained by reducing demand, i.e. metabolic rate (Box 8.26).

Corticosteroids

Assessment of the pituitary–adrenal axis is difficult in the critically ill, but in some series up to 30% of patients have adrenal insufficiency as assessed by baseline cortisol levels and the response to adrenocorticotrophic hormone (ACTH). Corticosteroid replacement therapy is controversial; recent evidence suggests that, although treatment is associated with earlier resolution of shock, it has no effect on survival.

Activated protein C

Administration of activated protein C (levels of which frequently fall in critical illness) may reduce mortality in patients with severe sepsis. Further trials are in progress.

DISCHARGE FROM INTENSIVE CARE

Discharge is appropriate when the original indication for admission has resolved and the patient has sufficient physiological reserve to continue recovery without the facilities available in intensive care. For long-stay ICU patients who have been ventilator-dependent, 'step-down' to the HDU is appropriate. Discharges from ICU/HDU to standard wards should preferably take place within normal working hours, as there is frequently a lack of sufficient medical and nursing support out of hours and at weekends. The shortage of ICU and HDU beds in most hospitals in the UK creates pressure for early discharge, but it has been shown that readmission rates and hospital mortality increase if discharge occurs prematurely or out of hours.

The critical care team should give the receiving team a detailed handover, a written summary with relevant recent investigations, remain available for advice, and

ideally visit the patient on the ward within the 24 hours after discharge.

Withdrawal of care

Withdrawal of support is appropriate when it is clear that the patient has no realistic prospect of recovery or of surviving with a quality of life that he or she would value. In these situations intensive care will only prolong the dying process and is therefore both futile and an inhumane waste of resources. Nevertheless, when intensive support is withdrawn, management should remain active and be directed towards allowing the patient to die with dignity and as free from distress as possible (p. 286). Patients' wishes in this regard are paramount and increasing use is being made of advance directives or 'living wills'. Communication with the patient, if possible, with the family and the referring clinicians, and between members of the critical care team is crucial (p. 175). Failure in this area damages working relations, causes stress and unrealistic expectations, and leads to subsequent unhappiness, anger and litigation.

Brain-stem death

Recent advances in resuscitation and intensive care management of brain-injured patients have inevitably increased the survival of patients who remain ventilated on ICU where progression of brain injury results in brain-stem death. The preconditions for considering brain-stem death and the criteria for establishing the diagnosis are listed on page 1158.

When formal criteria for brain-stem death are met, it is clearly inappropriate to continue supporting life with mechanical ventilation, and the possibility of organ donation should be considered. All intensive care clinicians have a responsibility to approach relatives to seek consent for organ donation, provided there is no contra-indication to the use of the organs. This can be very difficult, but is easier if the patient carried an organ donor card or was registered with an organisation such as the UK Organ Donor Register. In the UK, each region has a team of transplant coordinators who provide help with the process of organ donation and care of the potential organ donor.

SCORING SYSTEMS IN INTENSIVE CARE

Admission and discharge criteria vary between units, so it is important to define the characteristics of the patients admitted (case mix) in order to assess the effects of the care provided on the outcome achieved (Box 8.27).

Two systems are widely used to measure severity of illness:

- 'APACHE' II: Acute Physiology Assessment and Chronic Health Evaluation
- 'SAPS' 2: Simplified Acute Physiology Score.

These scores include assessment of certain admission characteristics (e.g. age and pre-existing organ dysfunction) and a variety of routine physiological measurements

8.27 Uses of critical care scoring systems

- Comparison of the performance of different units
- Assessment of new therapies
- Assessment of changes in unit policies and management guidelines
- Measurement of the cost-effectiveness of care

(e.g. temperature, BP, GCS) that reflect the response of the patient to his or her illness. When combined with the admission diagnosis, scoring systems have been shown to correlate well with the risk of hospital death. Such outcome predictions can never be 100% accurate and should be viewed as only one of many factors that the clinician considers when deciding whether or not further intervention is appropriate. Patient age is included in many scoring systems (Box 8.28).

Predicted mortality figures by diagnosis have been calculated from large databases generated from a range of ICUs. These allow a particular unit to evaluate its performance compared to the reference ICUs by calculating standardised mortality ratios (SMRs) for each diagnostic group:

$$\text{SMR} = \text{observed mortality} \div \text{predicted mortality}$$

8.28 The critically ill older patient

- **ICU demography:** increasing numbers of critically ill older patients are admitted to the ICU; more than 50% of patients in many general ICUs are over 65 years old.
- **Outcome:** affected to some extent by age, as reflected in APACHE II, but age should not be used as the sole criterion for withholding or withdrawing ICU support.
- **Cardiopulmonary resuscitation (CPR):** age does affect outcome. Successful hospital discharge following in-hospital CPR is rare in patients over 70 years old in the presence of significant chronic disease.
- **Functional independence:** tends to be lost during an ICU stay and prolonged rehabilitation may subsequently be necessary.
- **Specific problems:**
 - Skin fragility and ulceration
 - Poor muscle strength: difficulty in weaning from ventilator and in mobilising
 - Delirium: compounded by sedatives and analgesics
 - High prevalence of underlying nutritional deficiency.

A value of unity indicates the same performance as the reference ICUs while a value < 1 indicates a better than predicted outcome. If a unit has a high SMR in a certain diagnostic category, this would prompt investigation into how such patients were managed, in order to identify aspects of care that could be improved.

OUTCOME OF INTENSIVE CARE

The most widely used measure to assess outcome from intensive care is mortality. This is quoted at hospital discharge and at 28 days because mortality at the time of discharge from the ICU will be influenced by the unit discharge policy. Mortality is also influenced by case mix, length of stay and organisational issues.

It is important to demonstrate long-term benefit to justify the increasing costs of intensive care provision. Quality of life following discharge should be included but this is difficult to measure and interpret, not least because no objective pre-morbid assessment is possible in emergency admissions. However, several units in the UK now run follow-up clinics and have identified that there is a high incidence of physical and psychological problems affecting patient and family following ICU discharge.

Taking a history in poisoning

- What toxin(s) have been taken and how much?
- What time were they taken and by what route?
- Has alcohol or any drug of misuse been taken as well?

- Obtain details of the circumstances of the overdose from family, friends and ambulance personnel
- Ask the general practitioner for background and details of prescribed medication
- Assess suicide risk (full psychiatric evaluation

when patient has physically recovered)

- Capacity to make decisions about accepting or refusing treatment?
- Past medical history, drug history and allergies, social and family history?
- Record all information carefully

Clinical signs of poisoning by pharmaceutical agents and drugs of misuse.

EVALUATION OF THE ENVENOMED PATIENT

Assessment of type and extent of envenoming

Neurotoxic paralysis

- 'Sleepy' or drooping eyelids
- Difficulty swallowing, dysarthria and drooling
- Limb weakness
- Respiratory distress

Excitatory neurotoxicity

- Sweating, salivation, piloerection
- Tingling around mouth, tongue or muscle twitching
- Dyspnoea (pulmonary oedema)

Myolysis

- Muscle pain or weakness

Coagulopathy

- Blood oozing from bite site and/or gums
- Bruising
- Melaena, haematemesis

Local effects

- Pain, sweating, blistering, bruising etc.

Taking a history in envenoming

- When was the patient exposed to a bite/sting?
- Was the organism causing it seen and what did it look like (size, colour)?
- What were the circumstances (on land, in water etc.)?
- Was there more than one bite/sting?
- What first aid was used, when and for how long?
- What symptoms has the patient had (local and systemic)?
- Are there symptoms suggesting systemic envenoming (paralysis, myolysis, coagulopathy etc.)?
- Past medical history and medications?
- Past exposure to antivenom/venom and allergies?

Bites showing puncture marks, blistering, bruising and bleeding.

Acute poisoning is common, accounting for about 10% of hospital admissions in the UK. Important substances involved are shown in Box 9.1. In developed countries, the most frequent cause is intentional drug overdose in the context of self-harm and usually involves prescribed or 'over-the-counter' medicines. Accidental poisoning is also common, especially in children and the elderly (Box 9.2). Toxicity also may occur as a result of alcohol or recreational substance use, or following occupational or environmental exposure. Poisoning is a major cause of death in young adults, but most deaths occur before patients reach medical attention, and mortality is much lower than 1% in those admitted to hospital.

In developing countries, the frequency of self-harm is more difficult to estimate because patients may be reticent in admitting to deliberate poisoning. Household and agricultural products such as pesticides and herbicides are more freely available, are common sources of poisoning and are associated with a much higher case fatality. In China and South-east Asia, pesticides account for about 300 000 suicides each year.

9.1 Important substances involved in poisoning

In the UK

- Analgesics, e.g. paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs)
- Antidepressants, e.g. tricyclic antidepressants (TCAs), selective serotonin re-uptake inhibitors (SSRIs) and lithium
- Cardiovascular agents, e.g. β -blockers, calcium channel blockers and cardiac glycosides
- Drugs of misuse, e.g. opiates, benzodiazepines, stimulants (e.g. amphetamines, MDMA, cocaine)
- Carbon monoxide*
- Alcohol

In South and South-east Asia

- Organophosphorus* and carbamate insecticides
- Aluminium and zinc phosphide
- Oleander
- Snake venoms
- Antimalarial drugs, e.g. chloroquine
- Antidiabetic medication

*The most common causes of death by poisoning.

9.2 Poisoning in old age

- **Aetiology:** commonly results from accidental poisoning (e.g. due to confusion or dementia) or drug toxicity as a consequence of impaired renal or hepatic function or drug interaction. Toxic prescription medicines are more likely to be available.
- **Psychiatric illness:** self-harm is less common than in younger adults but more frequently associated with depression and other psychiatric illness, as well as chronic illness and pain. There is a higher risk of subsequent suicide.
- **Severity of poisoning:** increased morbidity and mortality result from reduced renal and hepatic function, reduced functional reserve, increased sensitivity to sedative agents and frequent comorbidity.

GENERAL APPROACH TO THE POISONED PATIENT

A general approach to the poisoned patient is shown on pages 204–205.

Triage and resuscitation

Patients who are seriously poisoned must be identified early so that appropriate management is not delayed. Triage involves:

- immediate measurement of vital signs
- identifying the poison(s) involved and obtaining adequate information about them
- identifying patients at risk of further attempts at self-harm and removing any remaining hazards from them.

Those with possible external contamination with chemical or environmental toxins should undergo appropriate decontamination (Fig. 9.1). Critically ill patients must be resuscitated (p. 178).

The Glasgow Coma Scale (GCS) is commonly employed to assess conscious level, although it has not been specifically validated in poisoned patients. The AVPU (alert/verbal/painful/unresponsive) scale is

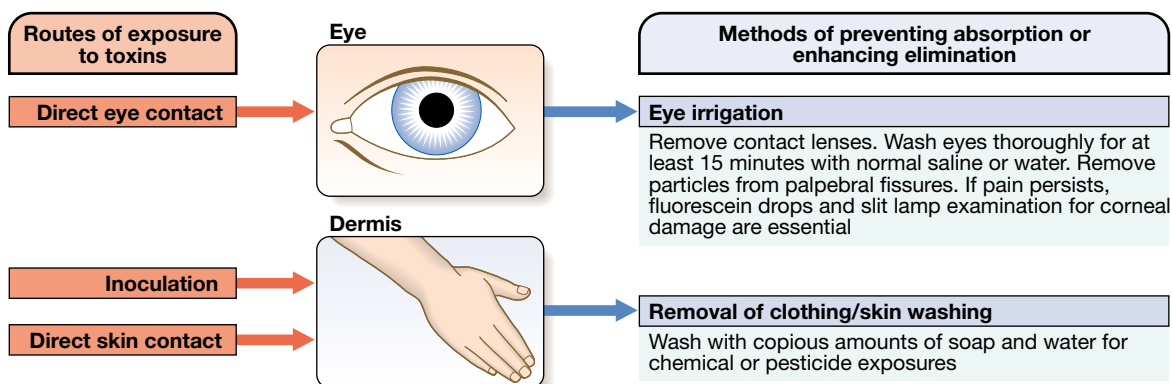

Fig. 9.1 Methods of external decontamination.

9.3 Substances of very low toxicity

- Writing/educational materials
- Decorating products
- Cleaning/bathroom products (except dishwasher tablets which are corrosive)
- Pharmaceuticals: oral contraceptives, most antibiotics (but not tetracyclines and antituberculous drugs), H₂-blockers, proton pump inhibitors, emollients and other skin creams, baby lotion
- Miscellaneous: plasticine, silica gel, household plants, plant food

also a rapid and simple method. An electrocardiogram (ECG) should be performed and cardiac monitoring instituted in all patients with cardiovascular features or where exposure to potentially cardiotoxic substances is suspected. Patients who may need antidotes should be weighed when this is feasible, so that appropriate doses can be prescribed.

Substances that are unlikely to be toxic in humans should be identified so that inappropriate admission and intervention are avoided (Box 9.3).

Clinical assessment and investigations

History and examination are described on page 204. Occasionally, patients may be unaware or confused about what they have taken, or may exaggerate (or less commonly underestimate) the size of the overdose, but rarely mislead medical staff deliberately. In some parts of the world, such as Asia, patients may not readily admit to deliberate self-poisoning.

Toxic causes of abnormal physical signs are shown on page 205. The patient may have a cluster of clinical features ('toxidrome') suggestive of poisoning with a particular drug type (Box 9.4). Poisoning is a common cause of coma, especially in younger people, but it is important to exclude other potential causes (p. 1158), unless the aetiology is certain.

Urea, electrolytes and creatinine should be measured in most patients. Arterial blood gases should be checked in those with significant respiratory or circulatory compromise, or when poisoning with substances likely to affect acid-base status is suspected (Box 9.5). Calculation of anion and osmolar gaps may help to inform diagnosis and management (Box 9.6).

9.4 Feature clusters in poisoning

Features	Cross-reference
Serotonin syndrome	Box 9.12, p. 211
Anticholinergic	Box 9.12, p. 211
Stimulant	Box 9.13, p. 215
Sedative hypnotic	Box 9.13, p. 215
Opioid	Box 9.13, p. 215
Cholinergic muscarinic	Box 9.15, p. 219
Cholinergic nicotinic	Box 9.15, p. 219

9.5 Causes of acidosis in the poisoned patient

Cause	Normal lactate*	High lactate
Toxic	Salicylates Methanol Ethylene glycol Paraldehyde	Metformin Iron Cyanide Sodium valproate Carbon monoxide
Other	Renal failure Ketoacidosis Severe diarrhoea	Shock

*Unless circulatory shock is present, when it will be high in any case.

9.6 Anion and osmolar gaps in poisoning

	Anion gap	Osmolar gap
Calculation	$[\text{Na}^+ + \text{K}^+] - [\text{Cl}^- + \text{HCO}_3^-]$	Osm (measured) – [2Na + K + Urea + Glucose]
Normal range	12–16 mmol/L	< 10 mOsm/kg
Common toxic causes of elevation*	Ethanol Ethylene glycol Methanol Salicylates Iron Cyanide	Ethanol Ethylene glycol Methanol

*Box 16.19 (p. 443) gives non-toxic causes.

For a limited number of specific substances, management may be facilitated by measurement of the amount of toxin in the blood (Box 9.7). Qualitative urine screens for potential toxins including near-patient testing kits have a limited clinical role. Occasionally, for medico-legal reasons, it is useful to save blood and urine for subsequent measurement of drug concentrations.

Psychiatric assessment

All patients presenting with deliberate drug overdose should undergo psychosocial evaluation by a health professional with appropriate training prior to discharge (p. 236). This should take place once the patient has recovered from any features of poisoning, unless there is an urgent issue such as uncertainty about his or her capacity to decline medical treatment.

General management

Patients presenting with eye or skin contamination should undergo appropriate local decontamination procedures (see Fig. 9.1).

Gastrointestinal decontamination

Patients who have ingested potentially life-threatening quantities of toxins may be considered for gastrointestinal decontamination if poisoning has been

9.7 Laboratory analysis in poisoning

Acetylcholinesterase

- Plasma cholinesterase is reduced more rapidly but is less specific than red cell cholinesterase (p. 219) in organophosphorus poisoning
- Antidote use should not be delayed pending results

Carboxyhaemoglobin

- > 20% indicates significant carbon monoxide exposure

Digoxin

- Therapeutic range usually 1–2 µg/L
- Concentrations > 4 µg/L usually associated with toxicity, especially with chronic poisoning

Ethanol

- Toxicity at concentrations > 1.8 g/L

Iron

- Take sample at least 4 hrs after overdose or if there are clinical features of toxicity
- Concentrations > 5 mg/L suggest severe toxicity

Lithium

- Take sample at least 6 hrs after overdose or if there are clinical features of toxicity
- Usual therapeutic range 0.4–1.0 mmol/L

Methaemoglobin

- Methaemoglobinaemia associated with toxicity due to nitrites, benzocaine, dapsone, chloroquine, aniline dyes
- Concentrations > 20% may require treatment with methylthioninium chloride (methylene blue)

Paracetamol

- Take sample at least 4 hrs after overdose
- Use nomogram to determine need for antidotal treatment (see Fig. 9.2, p. 211)

Salicylate

- Take sample at least 2 hrs (symptomatic patients) or 4 hrs (asymptomatic patients) after overdose
- Concentrations > 500 mg/L suggest serious toxicity
- Repeat after 2 hrs if severe toxicity is suspected

Theophylline

- Take sample at least 4 hrs after overdose or if there are clinical features of toxicity
- Repeat after 2 hrs if severe toxicity is suspected
- Concentrations > 60 mg/L suggest severe toxicity

recent (Box 9.8). Induction of emesis using ipecacuanha is now never recommended.

Activated charcoal

Given orally as slurry, activated charcoal absorbs toxins in the bowel as a result of its large surface area. If given sufficiently early, it can prevent absorption of an important proportion of the ingested dose of toxin. However, efficacy decreases with time and current guidelines do not advocate use more than 1 hour after overdose in most circumstances (see Box 9.8). However, use after a longer interval may be reasonable when a delayed-release preparation has been taken or when gastric emptying may be delayed. Some toxins do not

EBM 9.8 Use of gastric decontamination methods

Single-dose activated charcoal

'The administration of activated charcoal may be considered if a patient has ingested a potentially toxic amount of a poison (which is known to be adsorbed to charcoal) up to 1 hr previously.'¹

Multiple-dose activated charcoal

'Multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine or theophylline.'²

Gastric lavage

'Gastric lavage should not be employed routinely, if ever, in the management of poisoned patients.'³

Whole bowel irrigation (WBI)

'WBI should be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs, particularly for those patients presenting more than 2 hrs after drug ingestion. WBI should be considered for patients who have ingested substantial amounts of iron, as the morbidity is high and there is a lack of other options for gastrointestinal decontamination. The use of WBI for the removal of ingested packets of illicit drugs is also a potential indication.'⁴

- American Academy of Clinical Toxicology and European Association of Poison Centres and Clinical Toxicologists Joint Position Statements on Gastric Decontamination Methods:

¹AACT and EAPCCT. Clin Toxicol 2005; 43:61–87.

²AACT and EAPCCT. Clin Toxicol 1999; 37:731–751.

³AACT and EAPCCT. Clin Toxicol 2004; 42:933–943.

bind to activated charcoal (Box 9.9) so it will not affect their absorption. In patients with an impaired swallow or a reduced level of consciousness, the use of activated charcoal, even via a nasogastric tube, carries a risk of aspiration pneumonitis. This risk can be reduced but not completely removed by protecting the airway with a cuffed endotracheal tube.

Multiple doses of oral activated charcoal (50 g every 4 hours) may enhance the elimination of some drugs at any time after poisoning and are recommended for serious poisoning with some substances (see Box 9.8). They achieve their effect by interrupting enterohepatic circulation or by reducing the concentration of free drug in the gut lumen, to the extent that drug diffuses from the blood back into the bowel to be absorbed on to the charcoal: so-called 'gastrointestinal dialysis'. A laxative is generally given with the charcoal to reduce the risk of constipation or intestinal obstruction by charcoal 'briquette' formation in the gut lumen.

9.9 Substances poorly adsorbed by activated charcoal

Medicines

- Iron
- Lithium

Chemicals

- Acids*
- Alkalis*
- Ethanol
- Ethylene glycol
- Mercury
- Methanol
- Petroleum distillates*

*Gastric lavage contraindicated.

Recent evidence suggests that single or multiple doses of activated charcoal do not improve clinical outcomes after poisoning with pesticides or oleander.

Gastric aspiration and lavage

Gastric aspiration and/or lavage is now very infrequently indicated in acute poisoning, as it is no more effective than activated charcoal, and complications are common, especially aspiration. Use may be justified for life-threatening overdoses of some substances that are not absorbed by activated charcoal (see Box 9.9).

Whole bowel irrigation

This is occasionally indicated to enhance the elimination of ingested packets or slow-release tablets that are not absorbed by activated charcoal (e.g. iron, lithium), but use is controversial. It is performed by administration of large quantities of polyethylene glycol and electrolyte solution (1–2 L/hr for an adult), often via a nasogastric tube, until the rectal effluent is clear. Contraindications include inadequate airway protection, haemodynamic instability, gastrointestinal haemorrhage, obstruction or ileus. Whole bowel irrigation does not cause osmotic changes but may precipitate nausea and vomiting, abdominal pain and electrolyte disturbances.

Urinary alkalinisation

Urinary excretion of weak acids and bases is affected by urinary pH, which changes the extent to which they are ionised. Highly ionised molecules pass poorly through lipid membranes and therefore little tubular reabsorption occurs and urinary excretion is increased. If the urine is alkalinised (pH > 7.5) by the administration of sodium bicarbonate (e.g. 1.5 L of 1.26% sodium bicarbonate over 2 hrs), weak acids (e.g. salicylates, methotrexate and the herbicides 2,4-dichlorophenoxyacetic acid and mecoprop) are highly ionised and so their urinary excretion is enhanced. This technique should be distinguished from forced alkaline diuresis, in which large volumes of fluid with diuretic are given in addition to alkalinisation. This is no longer used because of the risk of fluid overload.

Urinary alkalinisation is currently recommended for patients with clinically significant salicylate poisoning when the criteria for haemodialysis are not met (see below). It is also sometimes used for poisoning with methotrexate. Complications include alkalaemia, hypokalaemia and occasionally alkalotic tetany (p. 444). Hypocalcaemia is rare.

Haemodialysis and haemoperfusion

These can enhance the elimination of poisons that have a small volume of distribution and a long half-life after overdose, and are useful when the episode of poisoning is sufficiently severe to justify invasive elimination methods. The toxin must be small enough to cross the dialysis membrane (haemodialysis) or must bind to activated charcoal (haemoperfusion) (Box 9.10). Haemodialysis may also correct acid-base and metabolic disturbances associated with poisoning (p. 207).

Antidotes

Antidotes are available for some poisons and work by a variety of mechanisms: for example, by specific antagonism (e.g. isoproterenol for β -blockers), chelation (e.g.

9.10 Poisons effectively eliminated by haemodialysis or haemoperfusion

- Carbamazepine
- Phenobarbital
- Amobarbital

desferrioxamine for iron) or reduction (e.g. methylene blue for dapsone). The use of some antidotes is described in the management of specific poisons below.

Supportive care

For most poisons, antidotes and methods to accelerate elimination are inappropriate, unavailable or incompletely effective. Outcome is dependent on appropriate nursing and supportive care, and on treatment of complications (Box 9.11). Patients should be monitored carefully until the effects of any toxins have dissipated.

POISONING BY SPECIFIC PHARMACEUTICAL AGENTS

Analgesics

Paracetamol

Paracetamol (acetaminophen) is the drug most commonly used in overdose in the UK. Toxicity results from formation of an intermediate reactive metabolite which binds covalently to cellular proteins, causing cell death. This results in hepatic and occasionally renal failure. In therapeutic doses, the toxic intermediate metabolite is detoxified in reactions requiring glutathione, but in overdose, glutathione reserves become exhausted.

Management

Management is summarised in Figure 9.2. Activated charcoal may be used in patients presenting within 1 hour. Antidotes for paracetamol act by replenishing hepatic glutathione. Acetylcysteine given intravenously (or orally in some countries) is highly efficacious if administered within 8 hours of the overdose. However, since efficacy declines thereafter, administration should not be delayed in patients presenting after 8 hours to await a paracetamol blood concentration result. The antidote can be stopped if the paracetamol concentration is shown to be below the appropriate treatment line. The most important adverse effect of acetylcysteine is related to dose-related histamine release, the 'anaphylactoid' reaction, which causes itching and urticaria, and in severe cases, bronchospasm and hypotension. Most cases can be managed by temporary discontinuation of acetylcysteine and administration of an antihistamine. An alternative antidote in paracetamol poisoning is methionine 2.5 g orally 4-hourly to a total of four doses, but it is less effective, especially after delayed

9.11 Complications of poisoning and their management

	Examples of causative agents	Management
Coma	Sedative agents	Appropriate airway protection and ventilatory support Pressure area and bladder care Identification and treatment of aspiration pneumonia
Seizures	NSAIDs Anticonvulsants TCAs Theophylline	Appropriate airway and ventilatory support I.v. benzodiazepine (e.g. diazepam 10–20 mg, lorazepam 2–4 mg) Correction of hypoxia, acid–base and metabolic abnormalities
Acute dystonias	Typical antipsychotics Metoclopramide	Procyclidine, benzatropine or diazepam
Hypotension		
Due to vasodilatation	Vasodilator antihypertensives Anticholinergic agents TCAs	I.v. fluids Vasopressors (rarely indicated; see pp. 193–194)
Due to myocardial suppression	β -blockers Calcium channel blockers TCAs	Optimisation of volume status Inotropic agents (pp. 193–194)
Ventricular tachycardia		
Monomorphic, associated with QRS prolongation	Sodium channel blockers	Correction of electrolyte and acid–base abnormalities and hypoxia Sodium bicarbonate
Torsades de pointes, associated with QT _c prolongation	Anti-arrhythmic drugs (quinidine, amiodarone, sotalol) Antimalarials Organophosphate insecticides Antipsychotic agents Antidepressants Antibiotics (erythromycin)	Magnesium sulphate, 2 g i.v. over 1–2 mins, repeated if necessary

presentation. If a patient presents more than 15 hours after ingestion, liver function tests, prothrombin time (or international normalised ratio – INR), renal function tests and a venous bicarbonate should be measured, the antidote started, and a poisons information centre or local liver unit contacted for advice if results are abnormal. An arterial blood gas sample should be taken in patients with severe liver function abnormalities; metabolic acidosis indicates severe poisoning. Liver transplantation should be considered in individuals who develop life-threatening liver failure due to paracetamol poisoning (p. 933).

If multiple ingestions of paracetamol have taken place over several hours or days (i.e. a staggered overdose), acetylcysteine should be given when the paracetamol dose exceeds 150 mg/kg body weight in any one 24-hour period or 75 mg/kg body weight in 'high-risk groups' (see Fig. 9.2).

Salicylates (aspirin)

Clinical features

Salicylate overdose commonly causes nausea, vomiting, sweating, tinnitus and deafness. Direct stimulation of the respiratory centre produces hyperventilation and respiratory alkalosis. Peripheral vasodilatation with bounding pulses and profuse sweating occurs in moderately severe poisoning. Serious salicylate poisoning is

associated with metabolic acidosis, hypoprothrombinaemia, hyperglycaemia, hyperpyrexia, renal failure, pulmonary oedema, shock and cerebral oedema. Agitation, confusion, coma and fits may occur, especially in children. Toxicity is enhanced by acidosis, which increases salicylate transfer across the blood–brain barrier.

Management

Activated charcoal should be administered if the patient presents early. Multiple doses of activated charcoal may enhance salicylate elimination but currently are not routinely recommended.

The plasma salicylate concentration should be measured at least 2 (in symptomatic patients) or 4 hours (asymptomatic patients) after overdose and repeated in patients with suspected serious poisoning, since concentrations may continue to rise some hours after overdose. In adults, concentrations above 500 mg/L and 700 mg/L suggest serious and life-threatening poisoning respectively, although clinical status is more important than the salicylate concentration in assessing severity.

Dehydration should be corrected carefully, as there is a risk of pulmonary oedema, and metabolic acidosis should be identified and treated with intravenous sodium bicarbonate (8.4%), once plasma potassium has been corrected. Urinary alkalinisation is indicated for adult patients with salicylate concentrations above 500 mg/L.

Fig. 9.2 The management of a paracetamol overdose.

Haemodialysis is very effective at removing salicylate and correcting acid-base and fluid balance abnormalities, and should be considered when serum concentrations are above 700 mg/L in adult patients with severe toxic features, or when there is renal failure, pulmonary oedema, coma, convulsions or refractory acidosis.

Non-steroidal anti-inflammatory drugs (NSAIDs)

Clinical features

Overdose of most NSAIDs (e.g. ibuprofen, diclofenac, naproxen, indometacin) usually causes little more than minor abdominal discomfort, vomiting and/or diarrhoea, but convulsions occur occasionally, especially with mefenamic acid. Coma, prolonged seizures,

apnoea, liver dysfunction and renal failure can occur after substantial overdose but are rare. Features of toxicity are unlikely to develop more than 6 hours after overdose.

Management

Electrolytes, liver function tests and a full blood count should be checked in all but the most trivial cases. Activated charcoal may be given if the patient presents sufficiently early. Symptomatic treatment for nausea and gastrointestinal irritation may be necessary.

Antidepressants

Tricyclic antidepressants (TCAs)

TCAs continue to be used frequently in overdose and carry a high morbidity and mortality relating to their sodium channel-blocking, anticholinergic and α -adrenoceptor-blocking effects.

Clinical features

Anticholinergic effects are common (Box 9.12). Life-threatening complications are frequent, including convulsions, coma, arrhythmias (ventricular tachycardia, ventricular fibrillation and, less commonly, heart block) and hypotension, which results from inappropriate vasodilatation or impaired myocardial contractility.

9.12 Anticholinergic and serotonergic feature clusters

	Anticholinergic	Serotonin syndrome

Mouth	Dry	
Skin	Flushing, hot, dry	Flushing, sweating
Complications	Seizures	Seizures Rhabdomyolysis Renal failure Metabolic acidosis Coagulopathies

Fig 9.3 ECG in severe tricyclic antidepressant poisoning. This rhythm strip shows a broad QRS complex due to impaired conduction.

Serious complications appear to occur more commonly with dosulepin and amitriptyline.

Management

Activated charcoal should be administered if the patient presents sufficiently early. All patients with possible tricyclic overdose should have a 12-lead ECG and ongoing cardiac monitoring for at least 6 hours. Prolongation of the QRS interval (especially if > 0.16 s) indicates severe sodium channel blockade and is associated with an increased risk of arrhythmia (Fig. 9.3). Arterial blood gases should be measured in patients with suspected severe poisoning.

In patients with arrhythmias, severe ECG effects or acidosis, intravenous sodium bicarbonate (50 mL of 8.4% solution) should be administered and repeated to correct pH. The correction of the acidosis and the sodium loading that result is often associated with rapid improvement in ECG features and arrhythmias. Hypoxia and electrolyte abnormalities should also be corrected. Anti-arrhythmic drugs should only be given on specialist advice. Prolonged convulsions should be treated with intravenous benzodiazepines (see Box 9.11).

Selective serotonin re-uptake inhibitors (SSRIs)

The SSRIs, including fluoxetine, paroxetine, fluvoxamine, sertraline and citalopram, are commonly used to treat depression, in part because they are less toxic than TCAs.

Clinical features and management

Overdose may produce nausea and vomiting, tremor, insomnia and sinus tachycardia. Agitation, drowsiness and convulsions occur infrequently and may be delayed for several hours after ingestion. Occasionally, features of serotonin syndrome may develop (see Box 9.12), especially if SSRIs are taken in combination or with other serotonergic agents. Cardiac arrhythmias, e.g. junctional bradycardias, occur infrequently. Most patients require supportive care only.

Lithium

Severe lithium toxicity is uncommon after intentional overdose and is more often encountered in patients taking therapeutic doses as a result of drug interactions (e.g. with diuretics or NSAIDs), deteriorating renal function or dehydration, or because an excessive dose has been prescribed.

Clinical features

Nausea, diarrhoea, polyuria, dizziness and tremor may progress to muscular weakness, drowsiness, confusion, myoclonus, fasciculations, choreoathetosis and renal

failure. Coma, convulsions, ataxia, cardiac dysrhythmias (e.g. heart block), blood pressure disturbances and renal failure may occur in severe poisoning.

Management

Activated charcoal is ineffective. Gastric lavage is of theoretical benefit if used early after overdose, but lithium tablets are likely to remain intact in the stomach and may be too large for aspiration via a lavage tube. Some advocate whole bowel irrigation after substantial overdose but efficacy is unknown.

Lithium concentrations should be measured immediately in symptomatic patients or after at least 6 hours in asymptomatic patients following acute overdose. Adequate hydration should be maintained with intravenous fluids. Convulsions should be treated as in Box 9.11.

In patients with features suggesting severe toxicity associated with high lithium concentrations (e.g. > 4.0 mmol/L after chronic poisoning or > 7.5 mmol/L after acute poisoning), haemodialysis should be considered. Lithium concentrations are lowered substantially during dialysis but rebound increases occur after discontinuation, and multiple sessions may be required.

Cardiovascular medications

β -blockers

These have negative inotropic and chronotropic effects. Some have additional properties that may increase toxicity, such as blockade of sodium channels (e.g. propranolol) or potassium channels (e.g. sotalol).

Clinical features

The major features of toxicity are bradycardia and hypotension. Heart block, pulmonary oedema and cardiogenic shock occur in severe poisoning. Beta-blockers with sodium channel-blocking effects may cause seizures, confusion and coma, while sotalol may be associated with repolarisation abnormalities (including QT_c prolongation) and torsades de pointes (p. 567).

Management

Intravenous fluids may reverse hypotension but care is required to avoid pulmonary oedema. Bradycardia and hypotension may respond to high doses of atropine (up to 3 mg in an adult). The adrenoceptor agonist isoproterenol (isoprenaline) may also be effective but high doses are often needed. Glucagon (5–10 mg over 10 mins, then 1–5 mg/hr by infusion), which does not act via adrenoceptors, is now more commonly used.

Calcium channel blockers

Calcium channel blockers are highly toxic in overdose via blockade of L-type calcium channels. Dihydropyridines such as nifedipine or amlodipine affect vascular smooth muscle in particular, resulting in vasodilatation. 'Rate-limiting' calcium channel blockers such as diltiazem and verapamil have direct cardiac effects, resulting in bradycardia and reduced myocardial contractility.

Clinical features

Hypotension is associated with vasodilatation and myocardial depression. Bradycardias and heart block may also occur, especially with verapamil and diltiazem.

Non-cardiac effects include gastrointestinal disturbances, confusion, metabolic acidosis, hyperglycaemia and hyperkalaemia.

Management

Hypotension should be corrected with intravenous fluids, taking care to avoid pulmonary oedema. Persistent hypotension may respond to intravenous calcium gluconate (10 mg i.v. over 5 mins, repeated as required). Isoproterenol and glucagon may also be useful. Successful use of intravenous insulin with glucose (10–20% dextrose with insulin at 0.5–1.0 U/kg/hr), so-called 'hyperinsulinaemia euglycaemic therapy', has been reported in patients unresponsive to other strategies. Cardiac pacing may be needed for severe unresponsive bradycardias or heart block.

Cardiac glycosides (including oleander)

Poisoning with digoxin is usually accidental, arising from prescription of an excessive dose, impairment of renal function or drug interactions. In South Asia, deliberate self-poisoning with yellow oleander (*Thevetia peruviana*), which contains cardiac glycosides, is common.

Clinical features

Characteristic cardiac effects of toxicity are tachyarrhythmias (either atrial or ventricular) and bradycardias, with or without atrioventricular block. Ventricular bigeminy is common and atrial tachycardia with evidence of atrioventricular block is highly suggestive of the diagnosis. Severe poisoning is associated with hyperkalaemia. Non-cardiac features include confusion, headache, nausea, vomiting, diarrhoea and (rarely) altered colour vision.

Management

Activated charcoal is commonly administered to patients presenting early after ingestion of an acute overdose, although evidence of benefit is lacking. Urea, electrolytes and creatinine should be measured, a 12-lead ECG performed and cardiac monitoring instituted. Hypoxia, hypokalaemia (sometimes associated with concurrent diuretic use), hypomagnesaemia and acidosis increase the risk of arrhythmias and should be corrected. Significant bradycardias may respond to atropine, although temporary pacing is sometimes needed. Ventricular arrhythmias may respond to intravenous magnesium (see Box 9.11). If available, digoxin-specific antibody fragments should be administered when there are severe ventricular arrhythmias or unresponsive bradycardias. This antidote has been shown to be effective for both digitalis and yellow oleander poisoning.

Antimalarials

Chloroquine

Chloroquine is highly toxic; doses of 5 g or more of chloroquine base are likely to be fatal in an adult.

Clinical features

Features of toxicity occur within 1 hour of ingestion and include nausea, vomiting, agitation, drowsiness, hypokalaemia, acidosis, headaches and blurred vision.

Coma, convulsions and hypotension may occur in severe poisoning. ECG changes indicating conduction and repolarisation delay (prolonged QRS and QT_c intervals) occur and are associated with ventricular tachycardia (including torsades de pointes), ventricular fibrillation and sudden death.

Management

Activated charcoal should be given to all patients presenting within 1 hour of ingestion of chloroquine in amounts greater than 15 mg/kg. The cardiac rhythm should be monitored and dysrhythmias managed as in Box 9.11. The arterial pH should be corrected, but hypokalaemia is thought to have a protective effect and should not be corrected in the first 8 hours after poisoning. High-dose diazepam (2 mg/kg body weight i.v. over 30 mins) has been suggested as having a protective effect, especially if given in the early stages of severe chloroquine poisoning, but evidence is limited as yet. Respiratory support may be required.

Quinine

Quinine salts are widely used for treating malaria and leg cramps. Deaths have been reported with as little as 1.5 g in an adult and 900 mg in a child.

Clinical features

Features of toxicity include nausea, vomiting, tremor, tinnitus and deafness. Hypotension, haemolysis, renal failure, ataxia, convulsions and coma are features of serious poisoning. Conduction and repolarisation delay results in prolonged QRS and QT_c intervals on the ECG, and ventricular tachycardia (including torsades de pointes), ventricular fibrillation and sudden death may occur. Quinine-induced retinal vasoconstriction and retinal photoreceptor cell toxicity may result in blurred vision and impaired colour perception. This usually develops a few hours after overdose and progresses to constriction of the visual field, scotoma and complete blindness associated with pupillary dilatation and unresponsiveness to light. Fundoscopy may show retinal artery spasm, disc pallor and retinal oedema. Although visual loss can be permanent, some degree of recovery often occurs over several weeks.

Management

Multiple-dose activated charcoal should be commenced in patients who have taken quinine in amounts greater than 15 mg/kg. Gastric lavage may also be considered if patients have presented within 1 hour. All patients should have a 12-lead ECG and cardiac monitoring, and their urea, electrolytes and glucose checked. Dysrhythmias, hypotension, seizures and coma should be managed as in Box 9.11.

There are no effective treatments for the visual effects of quinine. Stellate ganglion block and retrobulbar or intravenous injections of vasodilators such as nitrates were previously used but are ineffective, as are haemodialysis and haemoperfusion.

Iron

The toxicity of iron preparations is related to their elemental iron content.

Clinical features

Early clinical features include gastrointestinal disturbance with the passage of grey or black stools. Haematemesis or rectal bleeding may occur. Hyperglycaemia and leucocytosis suggest significant toxicity. Drowsiness, convulsions, coma, metabolic acidosis and cardiovascular collapse may occur in severe poisoning.

Early symptoms may improve or even resolve within 6–12 hours, but hepatocellular necrosis may develop 12–24 hours after overdose and occasionally this progresses to hepatic failure. Gastrointestinal strictures are late complications of iron poisoning.

Management

Gastric lavage may be considered in patients presenting within 1 hour of overdose but efficacy has not been established. Activated charcoal is ineffective since iron is not bound. Serum iron concentration should be measured (see Box 9.7, p. 208). The antidote desferrioxamine chelates iron and should be administered immediately in patients with severe features, without waiting for serum iron concentrations to be available. Symptomatic patients with high serum iron concentrations (e.g. > 5 mg/L) should also receive desferrioxamine. Desferrioxamine may cause hypotension, allergic reactions and occasionally pulmonary oedema. Otherwise treatment is supportive and directed at complications.

Antipsychotic drugs

Antipsychotic drugs (p. 245) are often prescribed for patients at high risk of self-harm or suicide, and are commonly encountered in overdose.

Clinical features

Drowsiness, tachycardia and hypotension are frequently found. Anticholinergic features (see Box 9.12) and acute dystonias (e.g. oculogyric crisis, torticollis and trismus) may occur after overdose with typical antipsychotics such as haloperidol or chlorpromazine. QT interval prolongation and torsades de pointes may occur with some antipsychotics, either typical (e.g. thioridazine, haloperidol) or atypical (e.g. quetiapine, ziprasidone). Convulsions may occur.

Management

Activated charcoal may be of benefit if given sufficiently early. Cardiac monitoring should be undertaken for at least 6 hours. Management is largely supportive, with treatment directed at complications (see Box 9.11, p. 210).

Antidiabetic agents

Antidiabetic agents commonly causing toxicity in overdose include the sulphonylureas (e.g. chlorpropamide, glibenclamide, gliclazide, glipizide and tolbutamide), biguanides (metformin and phenformin) and insulins.

Clinical features

Sulphonylureas and parenteral insulin cause hypoglycaemia when taken in overdose, although insulin is

non-toxic if ingested. The duration of hypoglycaemia depends on the half-life or release characteristics of the preparation and may be prolonged over several days with long-acting agents such as chlorpropamide, insulin zinc suspension or insulin glargine.

Features of hypoglycaemia include nausea, agitation, sweating, aggression and behavioural disturbances, confusion, tachycardia, hypothermia, drowsiness, coma or convulsions (p. 812). Permanent neurological damage can occur if the hypoglycaemia is prolonged. Hypoglycaemia can be diagnosed using bedside glucose strips but venous blood should also be sent for laboratory confirmation.

Metformin is uncommonly associated with hypoglycaemia. Its major toxic effect in overdose is lactic acidosis, which can be associated with a high mortality, and is particularly common in older patients and those with renal or hepatic impairment, or when ethanol is co-ingested. Other features of metformin overdose are nausea and vomiting, diarrhoea, abdominal pain, drowsiness, coma, hypotension and cardiovascular collapse.

Management

Activated charcoal should be considered for all patients who present within 1 hour of ingestion of a substantial overdose of an oral hypoglycaemic agent. Venous blood glucose, urea and electrolytes should be measured and tests repeated regularly. Hypoglycaemia should be corrected using oral or intravenous glucose (50 mL of 50% dextrose); an infusion of 10–20% dextrose may be required to prevent recurrence. Intramuscular glucagon can be used as an alternative, especially if intravenous access is unavailable. Failure to regain consciousness within a few minutes of normalisation of the blood glucose can indicate that a central nervous system (CNS) depressant has also been ingested, the hypoglycaemia has been prolonged, or there is another cause for the coma (e.g. cerebral haemorrhage or oedema).

Arterial blood gases should be taken after metformin overdose to assess the extent of acidosis. If present, plasma lactate should be measured and acidosis should be corrected with intravenous sodium bicarbonate (e.g. 250 mL 1.26% solution or 50 mL 8.4% solution, repeated as necessary). In severe cases haemodialysis or haemodiafiltration is used.

DRUGS OF MISUSE

Cannabis

Cannabis is derived from the dried leaves and flowers of *Cannabis sativa*. When smoked, the onset of effect occurs within 10–30 minutes; after ingestion the onset is 1–3 hours. The duration of effect is 4–8 hours. Cannabis produces euphoria, perceptual alterations and conjunctival injection, followed by enhanced appetite, relaxation, and occasionally hypertension, tachycardia, slurred speech and ataxia. High doses may produce anxiety, confusion, hallucinations and psychosis (Box 9.13). Psychological dependence is common, but tolerance and withdrawal symptoms are unusual. Long-term use is thought to increase the lifetime

²i.v. use.

risk of developing schizophrenia. Ingestion or smoking of cannabis rarely results in serious poisoning and supportive treatment is all that is required.

Benzodiazepines

Benzodiazepines may be prescribed or used illicitly. They are of low toxicity when taken alone in overdose, but can enhance CNS depression when taken with other sedative agents, including alcohol. They may also cause significant toxicity in the elderly and those with chronic lung or neuromuscular disease.

Clinical features

Clinical features of toxicity include drowsiness, ataxia and confusion (see Box 9.13). Respiratory depression and hypotension may occur with severe poisoning in susceptible groups, especially after intravenous administration of short-acting agents.

Management

Activated charcoal may be useful after ingestion in susceptible patients or after mixed overdose, if given

within 1 hour. Conscious level and oxygen saturation should be monitored for at least 6 hours after substantial overdose.

The specific benzodiazepine antagonist flumazenil increases conscious level in patients with overdose but carries a risk of seizures, and is contraindicated in patients co-ingesting proconvulsant agents such as TCAs and in those with a history of seizures.

Stimulants

Amphetamines, ecstasy and cocaine are sympathomimetic amines and, as a result, some clinical features of poisoning are similar (see Box 9.13).

Cocaine

Cocaine is available as a water-soluble hydrochloride salt suitable for nasal inhalation ('snorting'), or as an insoluble free base ('crack' cocaine) which, unlike the hydrochloride salt, vaporises at high temperature and can be smoked, giving a more rapid and intense effect. Cocaine hydrochloride is usually purchased as a white crystalline powder while crack cocaine is usually sold in 'rocks'.

Clinical features

Cocaine's toxic effects appear rapidly after inhalation and especially after smoking. Sympathomimetic stimulant effects are common (see Box 9.13). Serious complications usually occur within 3 hours of use, and include coronary artery spasm which may result in myocardial ischaemia or infarction, even in patients with normal coronary arteries. This may lead to hypotension, cyanosis and ventricular arrhythmias. Cocaine toxicity should be considered in young adults who present with ischaemic chest pain. Hyperpyrexia may be associated with rhabdomyolysis, acute renal failure and disseminated intravascular coagulation.

Management

All patients should be observed with ECG monitoring for a minimum of 4 hours. A 12-lead ECG should be performed, although ECG changes can be misleading. Troponin T estimations are the most sensitive and specific markers of myocardial damage. Benzodiazepines and intravenous nitrates are useful for managing patients with chest pain or hypertension, but β -blockers are best avoided because of the risk of unopposed α -adrenoceptor stimulation. Coronary angiography should be considered in patients with myocardial infarction or acute coronary syndromes. Acidosis should be corrected. Physical cooling measures may be required for hyperthermia (p. 103).

Amphetamines and ecstasy

These include amphetamine sulphate ('speed'), methylamphetamine ('crystal meth') and 3,4-methylenedioxymethamphetamine (MDMA, 'ecstasy'). Tolerance to amphetamines is common, leading regular users to seek progressively higher doses.

Clinical features

Toxic features usually appear within a few minutes of use and last 4–6 hours or substantially longer after a large overdose. Sympathomimetic stimulant effects are common (see Box 9.13). A proportion of ecstasy users develop hyponatraemia as a result of drinking large amounts of water and inappropriate antidiuretic hormone secretion. Muscle rigidity, pain and trismus (jaw-clenching) may occur. Hyperpyrexia, rhabdomyolysis, metabolic acidosis, acute renal failure, disseminated intravascular coagulation, hepatocellular necrosis, acute respiratory distress syndrome (ARDS) and cardiovascular collapse have all been described following MDMA use but these are rare. Strokes, due to either cerebral infarction or haemorrhage, have been reported, especially after intravenous amphetamine use.

Management

Management is supportive and directed at complications (see Box 9.11, p. 210).

Gammahydroxybutyrate (GHB)

GHB is a sedative agent with psychedelic and body-building effects, which is easily manufactured from commonly available industrial chemicals. These include 1,4-butanediol, which is metabolised to GHB in vivo and

has similar effects after ingestion. GHB solution is drunk by users, who titrate the dose until the desired effects are achieved.

Clinical features

Toxic features are those of a sedative hypnotic (see Box 9.13). Nausea, diarrhoea, vertigo, tremor, myoclonus, extrapyramidal signs, euphoria, bradycardia, convulsions, metabolic acidosis, hypokalaemia and hyperglycaemia may also occur. As the drug may be produced in batches and shared amongst a number of individuals, several patients may present with coma at the same time. The sedative effects are potentiated by other CNS depressants, e.g. alcohol, benzodiazepines, opioids and neuroleptic drugs. Coma usually resolves spontaneously and abruptly within a few hours, but may occasionally persist for several days.

Management

Activated charcoal is recommended within 1 hour for ingestion of GHB in amounts greater than 20 mg/kg. Urea, electrolytes and glucose should be measured in all but the most trivial of cases. All patients should be observed for a minimum of 2 hours, with monitoring of blood pressure, heart rate, respiratory rate and oxygenation. Patients who remain symptomatic should be observed in hospital until symptoms resolve, but require supportive care only.

LSD

d-Lysergic acid diethylamide (LSD) is a synthetic hallucinogen usually ingested as small squares of impregnated absorbent paper, which are often printed with a distinctive design, or as 'microdots'. The drug causes perceptual effects, such as heightened visual awareness of colours, distortion of images, and hallucinations which may be pleasurable or terrifying ('bad trip') and associated with panic, confusion, agitation or aggression. Dilated pupils, hypertension, pyrexia and metabolic acidosis may occur and psychosis may sometimes last several days.

Patients with psychotic reactions or CNS depression should be observed in hospital, preferably in a quiet, dimly lit room to minimise external stimulation. Where sedation is required, diazepam is the drug of choice. Antipsychotics should be avoided if possible, as they may precipitate cardiovascular collapse or convulsions.

Opioids

Commonly encountered opioids are shown in Box 9.13. Toxicity may result from drug misuse (e.g. heroin) or after overdose of medicinal opiates (e.g. dextropropoxyphene). Intravenous use of heroin or morphine gives a rapid, intensely pleasurable experience, often accompanied by heightened sexual arousal. Physical dependence occurs within a few weeks of regular high-dose injection; as a result, the dose is escalated and the user's life becomes increasingly centred on obtaining and taking the drug. Withdrawal, which can start within 12 hours, presents with intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting,

diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

Accidental overdose with prescribed strong opioid preparations is common, especially in the elderly.

Clinical features

These are shown in Box 9.13. Needle tracks may be visible in intravenous drug misusers and drug-related paraphernalia may be found amongst their possessions. Severe poisoning results in respiratory depression, hypotension, non-cardiogenic pulmonary oedema and hypothermia, leading to respiratory arrest or aspiration of gastric contents. Dextropropoxyphene (the opioid component of co-proxamol) may also cause cardiac conduction effects, particularly QRS prolongation, ventricular arrhythmias and heart block. Excess deaths caused by these complications have prompted the withdrawal of co-proxamol (dextropropoxyphene and paracetamol combination) in the UK. Methadone may cause QT_c prolongation and torsades de pointes.

Symptoms of opioid poisoning can be prolonged for up to 48 hours after use of long-acting agents (e.g. methadone, dextropropoxyphene and oxycodone).

Management

The airway should be cleared and, if necessary, respiratory support and oxygen given. Oxygen saturation monitoring and measurement of arterial blood gases should be performed. Prompt use of the specific opioid antagonist naloxone (0.8–2 mg i.v., repeated if necessary) may obviate the need for intubation, although excessive doses may precipitate acute withdrawal in opiate misusers. An infusion may be required in some cases because the half-life of the antidote is short compared to that of most opiates, especially those with prolonged elimination. It is important that patients are monitored for at least 4 hours after the last naloxone dose. Other complications of naloxone therapy include fits and ventricular arrhythmias, although these appear to be rare. Box 9.11 (p. 210) describes the management of coma, fits and hypotension. Non-cardiogenic pulmonary oedema does not usually respond to diuretic therapy, and continuous positive airways pressure (CPAP) or positive end-expiratory pressure (PEEP) ventilatory support (p. 195) may be required.

Bodypackers

Bodypackers ('mules') attempt to smuggle illicit drugs (usually cocaine, heroin or amphetamines) by ingesting multiple small packages wrapped in multiple layers of clingfilm or in condoms. They are at risk of developing severe toxicity if these packages rupture.

Patients suspected of bodypacking should be admitted for observation. A careful history taken in private is important, but for obvious reasons patients may withhold details of the drugs involved. The mouth, rectum and vagina should be examined as possible sites for concealed drugs. Packages may be visible on plain abdominal films (Fig. 9.4), but this is not always the case, and ultrasound and computed tomography (CT) provides more sensitive methods of visualisation.

Antimotility agents are often used by bodypackers to prevent premature passage of packages, so it can take

Fig. 9.4 Abdominal X-ray of a bodypacker showing multiple drug-filled condoms.

a number of days for packages to pass spontaneously; during this period the carrier is at risk from package rupture. Whole bowel irrigation is commonly used to accelerate passage and is continued until all packages have passed. Surgery may be required for mechanical bowel obstruction or when evolving clinical features suggest package rupture.

CHEMICALS AND PESTICIDES

Carbon monoxide (CO)

CO is a colourless and odourless gas produced by faulty appliances burning organic fuels. It is also present in vehicle exhaust fumes and sometimes in smoke from house fires. It causes toxicity by binding with haemoglobin and cytochrome oxidase, which reduces tissue oxygen delivery and inhibits cellular respiration. It is a common cause of death by poisoning and most patients who die of CO poisoning do so before reaching hospital.

Clinical features

The early clinical features of acute severe carbon monoxide poisoning are headache, nausea, irritability, weakness and tachypnoea. Because these are non-specific, the correct diagnosis will not be obvious if the exposure is occult, e.g. from a faulty domestic appliance. Subsequently, ataxia, nystagmus, drowsiness and hyperreflexia may develop, progressing to coma, convulsions, hypotension, respiratory depression, cardiovascular collapse and death. Myocardial ischaemia may occur and result in arrhythmias or myocardial infarction. Cerebral

oedema is common and rhabdomyolysis may lead to myoglobinuria and renal failure. In those who recover from acute toxicity, longer-term neuropsychiatric effects are common, such as personality change, memory loss and concentration impairment. Extrapyramidal effects, urinary or faecal incontinence, and gait disturbance may also occur. Poisoning during pregnancy may cause fetal hypoxia and intrauterine death.

Management

Patients should be removed from exposure as soon as possible and the patient resuscitated as necessary. Oxygen should be administered in as high a concentration as possible via a tightly fitting facemask, as this reduces the half-life of carboxyhaemoglobin from 4–6 hours to about 40 minutes. Measurement of carboxyhaemoglobin is useful for confirming exposure (see Box 9.7, p. 208) but results do not correlate well with the severity of poisoning, partly because concentrations fall rapidly after removal of the patient from exposure, especially if supplemental oxygen has been given.

An ECG should be performed in all patients with acute poisoning, especially those with pre-existing heart disease. Arterial blood gas analysis should be checked in those with serious poisoning. Oxygen saturation readings by pulse oximetry are misleading since both carboxyhaemoglobin and oxyhaemoglobin are measured. Excessive intravenous fluid administration should be avoided, particularly in the elderly, because of the risk of pulmonary and cerebral oedema. Convulsions should be controlled with diazepam.

Hyperbaric oxygen therapy is controversial. In theory, at 2.5 atmospheres, it reduces the half-life of carboxyhaemoglobin to 20 minutes and increases the amount of dissolved oxygen by a factor of 10. The logistical difficulties of transporting sick patients to hyperbaric chambers and managing them therein should not be underestimated and recent systematic reviews have shown no improvement in clinical outcomes.

Organophosphorus (OP) insecticides/ nerve agents

OP compounds (Box 9.14) are widely used as pesticides, especially in developing countries. The case fatality rate following deliberate ingestion of OP pesticides in developing countries in Asia is 5–20%.

Nerve agents developed for chemical warfare are derived from OP insecticides but are much more toxic.

9.14 Organophosphorus compounds	
Nerve agents	
• G agents: sarin, tabun, soman	• V agents: VX, VE
Insecticides	
Dimethyl compounds	Diethyl compounds
• Dichlorvos	• Chlorpyrifos
• Fenthion	• Diazinon
• Malathion	• Parathion-ethyl
• Methamidophos	• Quinalphos

'G' agents are volatile, are absorbed by inhalation or via the skin, and dissipate rapidly after use. 'V' agents are contact poisons unless aerosolised, and contaminate ground for weeks or months.

The toxicology and management of nerve agent and pesticide poisoning are similar.

Mechanism of toxicity

OP compounds phosphorylate the active site of acetylcholinesterase (AChE), inactivating the enzyme and leading to the accumulation of acetylcholine (ACh) in cholinergic synapses (Fig. 9.5). Spontaneous hydrolysis of the OP-enzyme complex allows reactivation of the enzyme. However, loss of a chemical group from the OP-enzyme complex prevents further enzyme reactivation, a process termed 'ageing'. After ageing has taken place, new enzyme needs to be synthesised before function can be restored. The rate of ageing is an important determinant of toxicity and is more rapid with dimethyl compounds (3.7 hours) than diethyl compounds (31 hours), and especially rapid after exposure to nerve agents (soman in particular), which cause ageing within minutes.

Clinical features and management

OP poisoning causes an acute cholinergic phase, which may occasionally be followed by the intermediate syndrome or organophosphate-induced delayed polyneuropathy (OPIDN). The onset, severity and duration of poisoning depend on the route of exposure and agent involved.

Acute cholinergic syndrome

The acute cholinergic syndrome usually starts within a few minutes of exposure. Nicotinic or muscarinic features may be present (Box 9.15). Vomiting and profuse diarrhoea are typical following oral ingestion. Bronchoconstriction, bronchorrhoea and salivation may cause severe respiratory compromise. Miosis is characteristic and the presence of muscle fasciculations strongly suggests the diagnosis, although this feature is often absent, even in serious poisoning. Subsequently, the patient may develop generalised flaccid paralysis which can affect respiratory and ocular muscles and result in respiratory failure. Ataxia, coma and convulsions may occur. In severe poisoning, cardiac repolarisation abnormalities and torsades de pointes may occur. Other early complications of OP poisoning include extrapyramidal features, pancreatitis, hepatic dysfunction and pyrexia.

Management

In the event of external contamination, further exposure should be prevented, contaminated clothing and contact lenses removed, the skin washed with soap and water, and the eyes irrigated. The airway should be cleared of excessive secretions and high-flow oxygen administered. Intravenous access should be obtained. Gastric lavage or activated charcoal may be considered within 1 hour of ingestion. Convulsions should be treated as described in Box 9.11, p. 210. The ECG, oxygen saturation, blood gases, temperature, urea and electrolytes, amylase and glucose should be monitored closely.

Early use of sufficient doses of atropine is potentially life-saving in patients with severe toxicity. Atropine reverses ACh-induced bronchospasm, bronchorrhoea,

Fig. 9.5 Mechanism of toxicity of organophosphorus compounds and treatment with oxime.

bradycardia and hypotension. When the diagnosis is uncertain, a marked increase in heart rate associated with skin flushing after a 1 mg intravenous dose makes OP poisoning unlikely. In OP poisoning, atropine should

be administered in doses of 0.6–2 mg i.v., repeated every 10–25 mins until secretions are controlled, the skin is dry and there is a sinus tachycardia. Large doses may be needed but excessive doses may cause anticholinergic effects (see Box 9.12, p. 211).

In patients requiring atropine, an oxime such as pralidoxime chloride (or obidoxime), if available, should also be administered, as this may reverse or prevent muscle weakness, convulsions or coma, especially if administered rapidly after exposure. The dose for an adult is 2 g i.v. over 4 mins, repeated 4–6-hourly. Oximes work by reactivating AChE that has not undergone 'ageing' and are therefore less effective with dimethyl compounds and nerve agents, especially soman. Oximes may provoke hypotension, especially if administered rapidly.

Ventilatory support should be instituted before the patient develops respiratory failure (p. 194). Benzodiazepines may be used to reduce agitation and fasciculations, treat convulsions and sedate patients during mechanical ventilation.

Exposure is confirmed by measurement of plasma (butyrylcholinesterase) or red blood cell cholinesterase activity. These correlate poorly with the severity of clinical features, although values are usually less than 10% in severe poisoning, 20–50% in moderate poisoning and > 50% in subclinical poisoning.

The acute cholinergic phase usually lasts 48–72 hours, with most patients requiring intensive cardiorespiratory support and monitoring.

The intermediate syndrome

About 20% of patients with OP poisoning develop weakness rapidly spreading from the ocular muscles

9.15 Cholinergic features in poisoning*

	Cholinergic muscarinic	Cholinergic nicotinic
Respiratory	Bronchorrhoea, bronchoconstriction	Reduced ventilation
Cardiovascular	Bradycardia, hypotension	Tachycardia, hypertension
CNS	Confusion	–
Muscle	–	Fasciculation, paralysis
Temperature	Fever	–
Eyes	Diplopia, mydriasis	Lacrimation, miosis
Abdomen	Ileus, palpable bladder	Vomiting, profuse diarrhoea
Mouth	Dry	Salivation
Skin	Flushing, hot, dry	Sweating
Complications	Seizures	Seizures

*Both muscarinic and nicotinic features occur in OP poisoning. Nicotinic features occur in nicotine poisoning and black widow spider bites. Cholinergic features are sometimes seen in poisoning with some mushrooms.

to those of the head and neck, proximal limbs and the muscles of respiration, resulting in ventilatory failure. This 'intermediate syndrome' (IMS) generally develops quite rapidly between 1 and 4 days after exposure, often after resolution of the acute cholinergic syndrome, and may last 2–3 weeks. There is no specific treatment but supportive care, including maintenance of airway and ventilation, is important.

Organophosphate-induced delayed polyneuropathy (OPIDN)

This is a rare complication that usually occurs 2–3 weeks after acute exposure. It is a mixed sensory/motor polyneuropathy, especially affecting long myelinated neurons, and appears to result from inhibition of enzymes other than AChE. It is a feature of poisoning with some OPs (e.g. trichlorocresylphosphate), while others, including nerve agents, are not thought to have this effect. Early clinical features are muscle cramps followed by numbness and paraesthesiae, proceeding to flaccid paralysis of the lower and subsequently the upper limbs. Paralysis of the lower limbs is associated with foot drop and a high-stepping gait, progressing to paraplegia. Paralysis of the arms leads to wrist drop. Sensory loss may also be present but is variable. Initially, tendon reflexes are reduced or lost, but later mild spasticity may develop.

There is no specific therapy for OPIDN. Regular physiotherapy may limit deformity caused by muscle-wasting. Recovery is often incomplete and may be limited to the hands and feet, although substantial functional recovery after 1–2 years may occur, especially in younger patients.

Carbamate insecticides

Carbamate insecticides (e.g. aldicarb, carbofuran, methomyl) inhibit a number of tissue esterases, including AChE. The mechanism of action, clinical features and management are similar to those of OP compounds. However, clinical features tend to be less severe and of shorter duration, because the carbamate/AChE complex dissociates quickly, with a half-life of 30–40 minutes, and does not undergo ageing. Also, carbamates penetrate the CNS poorly. Pancreatitis has been reported as a sequel, and deaths have occurred.

Atropine may be given intravenously in frequent small doses (0.6–2.0 mg i.v. for an adult) until signs of atropinisation develop. Diazepam may be used to relieve anxiety. The use of oximes is unnecessary.

Methanol and ethylene glycol

Ethylene glycol (1,2-ethanediol) is found in antifreeze, brake fluids and, in lower concentrations, windscreen washes. Methanol is present in some antifreeze products and commercially available industrial solvents, and in low concentrations in some screen washes and methylated spirits. It may also be an adulterant of illicitly produced alcohol. Both are rapidly absorbed after ingestion. Although methanol and ethylene glycol are not of high intrinsic toxicity, they are converted via alcohol dehydrogenase to toxic metabolites that are largely responsible for their clinical effects (Fig. 9.6).

Fig. 9.6 Metabolism of methanol and ethylene glycol.

Clinical features

Early features with either methanol or ethylene glycol include ataxia, drowsiness, dysarthria and nystagmus, often associated with vomiting. As the toxic metabolites are formed, metabolic acidosis, tachypnoea, coma and seizures may develop.

Toxic effects of ethylene glycol toxicity include ophthalmoplegia, cranial nerve palsies, hyporeflexia and myoclonus. Renal pain and acute tubular necrosis occur because of precipitation of calcium oxalate in the kidneys. Hypocalcaemia, hypomagnesaemia and hyperkalaemia are common.

Features of methanol poisoning include headache, confusion and vertigo. Visual impairment and photophobia develop, associated with optic disc and retinal oedema and impaired pupil reflexes. Blindness may be permanent, although some recovery may occur over several months. Pancreatitis and abnormal liver function have also been reported.

Management

Urea, electrolytes, chloride, bicarbonate, glucose, calcium, magnesium, albumin and plasma osmolality and arterial blood gases should be measured in all patients with suspected methanol or ethylene glycol toxicity. The osmolal and anion gaps should be calculated (see Box 9.6, p. 207). Initially, poisoning is associated with an increased osmolal gap, but as toxic metabolites are produced, an increased anion gap associated with metabolic acidosis will develop. The diagnosis can be confirmed by measurement of ethylene glycol or methanol concentrations, but these assays are not widely available.

An antidote, either ethanol or fomepizole, should be administered to all patients with suspected significant exposure while awaiting the results of laboratory investigations. These block alcohol dehydrogenase and delay the formation of toxic metabolites until the parent drug is eliminated either naturally or by dialysis. The antidote should be continued until ethylene glycol or methanol concentrations are undetectable. Metabolic acidosis should be corrected with sodium bicarbonate (e.g. 250 mL of 1.26% solution, repeated as necessary).

Convulsions should be treated with an intravenous benzodiazepine. In ethylene glycol poisoning, hypocalcaemia should only be corrected if there are severe ECG features or seizures occur, since this may increase calcium oxalate crystal formation.

Haemodialysis or haemodiafiltration should be used in severe poisoning, especially if renal failure is present or there is visual loss in the context of methanol poisoning. It should be continued until acute toxic features are no longer present and ethylene glycol or methanol concentrations are no longer detectable.

Aluminium and zinc phosphide

These rodenticides and fumigants are a common means of self-poisoning in northern India, where the mortality rate has been estimated at 60%. When ingested, both compounds react with gastric water to form phosphine, a potent pulmonary and gastrointestinal toxicant. Clinical features include severe gastrointestinal disturbances, chest tightness, cough and breathlessness progressing to ARDS and respiratory failure, tremor, paraesthesiae, convulsions, coma, tachycardia, metabolic acidosis, electrolyte disturbances, hypoglycaemia, myocarditis, liver and renal failure, and leucopenia. Just a few tablets can be fatal.

Detection of phosphine in the exhaled air or stomach aspirate using either a silver nitrate-impregnated strip or specific phosphine detector tube is diagnostic, but gas chromatography provides the most sensitive indicator. Treatment is supportive and directed at correcting electrolyte abnormalities and treating complications; there is no specific antidote. Early gastric lavage is sometimes used, often with vegetable oil to reduce the release of toxic phosphine, but the benefit is uncertain.

ENVIRONMENTAL POISONING AND ILLNESS

Arsenism

Chronic arsenic exposure from drinking water has been reported in many countries, especially India, Bangladesh, Nepal, Thailand, Taiwan, China, Mexico and South America, where a large proportion of the drinking water (ground water) has a high arsenic content, placing large population groups at risk. The World Health Organization (WHO) guideline value for arsenic content in tube well water is 10 µg/L.

Health effects associated with chronic exposure to arsenic in drinking water are shown in Box 9.16. In exposed individuals, high concentrations of arsenic are present in bone, hair and nails. Specific treatments are of no benefit in chronic arsenic toxicity and recovery from the peripheral neuropathy may never be complete. The emphasis should be on the prevention of exposure to arsenic in drinking water.

Fluorosis

Though water-borne fluorides at levels of 1 part per million (ppm) are associated with significant immunity

9.16 Clinical features of chronic arsenic poisoning

GI tract

- Anorexia, vomiting, weight loss, diarrhoea, increased salivation, metallic taste

Neurological

- Peripheral neuropathy (sensory and motor) with muscle wasting and fasciculation, ataxia

Skin

- Hyperpigmentation, palmar and plantar keratosis, alopecia, multiple epitheliomas, Mee's lines (transverse white lines on finger nails)

Eyes

- Conjunctivitis, corneal necrosis and ulceration

Bone marrow

- Aplastic anaemia

Other

- Low-grade fever, vasospasm and gangrene, jaundice, hepatomegaly, splenomegaly

Increased risk of malignancy

- Lung, liver, bladder, kidney, larynx and lymphoid system

to dental caries, the presence of excessive quantities of fluoride (> 10 ppm) in drinking water, e.g. from deep bore wells, leads to characteristic changes in teeth, bone and periarticular tissues. Fluorosis may also result from industrial exposure to fluoride dust and consumption of brick teas. Yellowish-brown staining and pitting of permanent teeth particularly are early and easily recognisable features of chronic toxicity. Damage of the enamel may ensue. Skeletal involvement is not clinically apparent unless advanced, but radiological changes are present at an early stage. Early symptoms include stiffness and back pain. Later, deformities (e.g. kyphosis), calcification of ligaments and joint ankylosis may occur and result in severe disability. Changes in the bones of the thoracic cage may lead to rigidity that causes dyspnoea on exertion. Very high doses of fluoride may cause abdominal pain, nausea, vomiting, seizures and muscle spasm. In calcium-deficient children, the toxic effects of fluoride manifest even at marginally high exposures to fluoride.

In endemic areas, such as Jordan, Turkey, Chile, India, Bangladesh, China and Tibet, fluorosis is a major public health problem. The maximum impact is seen in communities engaged in physically strenuous agricultural or industrial activities. Dental fluorosis is endemic in East Africa and some West African countries.

SUBSTANCES LESS COMMONLY TAKEN IN OVERDOSE

Box 9.17 gives an overview of the clinical features and management for some substances that are less often encountered in overdose.

9.17 Substances taken less commonly in overdose

Drug/substance	Features	Specific management
Anticonvulsants Carbamazepine, phenytoin Sodium valproate	Cerebellar signs Convulsions Cardiac arrhythmias Coma Coma Metabolic acidosis	Multiple-dose activated charcoal (carbamazepine) Haemodialysis for severe poisoning
Isoniazid	Peripheral neuropathy Convulsions	Activated charcoal I.v. pyridoxine
Theophylline	Cardiac arrhythmias Convulsions Coma	Multiple-dose activated charcoal
Corrosives and bleach	Injuries to stomach (esp. acids) and oesophagus (esp. alkali) GI perforation and late strictures Aspiration pneumonitis	Gastric lavage and neutralising chemicals are contraindicated Chest X-ray to exclude perforation Consider early endoscopy or Gastrografin studies to assess extent of damage and need for surgery
Lead , e.g. chronic occupational exposure, leaded paint, water contaminated by lead pipes, use of kohl cosmetics	Abdominal pain Microcytic anaemia with basophilic stippling Headache and encephalopathy Motor neuropathy Nephrotoxicity Hypertension Hypocalcaemia	Prevent further exposure Measure blood lead concentration, full blood count and blood film, urea and electrolytes, liver function tests and calcium Abdominal X-ray in children to detect pica Bone X-ray for 'lead lines' Chelation therapy with dimercaprol, DMSA, DMPS or sodium calcium edetate for severe poisoning (esp. in children)
Petroleum distillates, white spirit, kerosene	Vomiting Aspiration pneumonitis	Gastric lavage contraindicated Activated charcoal ineffective Oxygen and nebulised bronchodilators Chest X-ray to assess pulmonary effects
Paraquat	Buccal ulceration Progressive respiratory fibrosis with respiratory failure Renal failure	Urine screen for paraquat Multiple-dose activated charcoal Check blood paraquat concentration and compare with survival curve for prognosis
Organochlorines, e.g. DDT, lindane, dieldrin, endosulfan	Nausea, vomiting Agitation Fasciculation Paraesthesiae (face, extremities) Convulsions Coma Respiratory depression Cardiac arrhythmias Hyperthermia Rhabdomyolysis Pulmonary oedema Disseminated intravascular coagulation	Activated charcoal (with nasogastric aspiration for liquid preparations) within 1 hour of ingestion Cardiac monitoring
Pyrethroid insecticides, e.g. cypermethrin, permethrin, imiprothrin	Skin contact: dermatitis, skin paraesthesiae Eye contact: lacrimation, photophobia and oedema of the eyelids Inhalation: dyspnoea, nausea, headaches Ingestion: epigastric pain, nausea, vomiting, headache, coma, convulsions, pulmonary oedema	Symptomatic and supportive care Washing contaminated skin makes irritation worse
Anticoagulant rodenticides (e.g. brodifacoum, bromodialone) and warfarin	Abnormal bleeding (prolonged)	Monitor INR/prothrombin time Vitamin K ₁ by slow i.v. injection if coagulopathy Fresh frozen plasma or specific clotting factors for bleeding

(DMPS = 2,3-dimercapto-1-propane sulphonate; DMSA = 2,3-dimercaptosuccinic acid)

ENVENOMING

Envenoming occurs when a venomous animal injects sufficient venom into a prey item or perceived predator. This may be by a bite or a sting, and results in local and/or systemic toxic effects. Venomous animals generally use their venom to acquire and in some cases predigest prey, with defensive use a secondary function. Accidental encounters between venomous animals and humans occur frequently, particularly in the rural tropics, with millions of cases of venomous bites and stings annually. Globally, an increasing number of exotic venomous animals are kept privately, so cases of envenoming may present to hospitals where doctors have insufficient knowledge to manage potentially complex presentations. Doctors everywhere should thus be aware of the basic principles of management of envenoming and how to seek expert support.

Venom

Venom is a complex mixture of diverse components, often with several separate toxins that can cause adverse effects in humans, and each potentially capable of multiple effects (Box 9.18). Venom is produced at considerable metabolic cost, so is used sparingly; thus only some bites/stings by venomous animals result in significant envenoming, the remainder being 'dry bites'. The concept of dry bites is important in understanding approaches to management.

Venomo us animals

There are many animal groups that contain venomous species (Box 9.19). The epidemiology estimates shown reflect the importance of snakes and scorpions as causes of severe or lethal envenoming, and social insect stings (e.g. bees, wasps) as causes of sometimes lethal

anaphylaxis. Other venomous animals may commonly envenom humans but cause mostly non-lethal effects. A few rarely envenom humans, but have a high potential for severe or lethal envenoming (e.g. box jellyfish, cone shells, blue-ringed octopus, paralysis ticks, Australian funnel web spiders). Within any given group, particularly snakes, there may be a wide range of clinical presentations. Some are described here but for a more detailed discussion of the types of venomous animal, their venoms and effects on humans see www.toxinology.com.

Clinical effects

With the exception of dry bites where no significant effects occur, venomous bites/stings can result in three broad classes of effect.

Local effects

These vary from trivial to severe (Box 9.20). There may be minimal or no local effects with some snakebites (not even pain), yet lethal systemic envenoming may still be present. For other species, local effects predominate over systemic, and for others, e.g. many snakes, both are important.

General systemic effects

By definition, these are non-specific (see Box 9.20). Shock is an important complication of major local envenoming by some snake species and, if inadequately treated, can prove lethal, especially in children.

Specific systemic effects

These are important in both diagnosis and treatment.

- *Neurotoxic flaccid paralysis* can develop very rapidly, progressing from mild weakness to full respiratory paralysis in less than 30 minutes (blue-ringed octopus bite, cone shell sting), or may develop far more slowly, over hours (some snakes) to days (paralysis tick). For neurotoxic snakes, the cranial nerves are usually involved first, with ptosis a common initial

9.18 Key venom effects*

Venom component	Clinical effects	Type of venomous animal
Neurotoxin		
Paralytic	Flaccid paralysis	Some snakes Paralysis ticks Cone shells Blue-ringed octopus
Excitatory	Neuroexcitation: autonomic storm, cardiotoxicity, pulmonary oedema	Some scorpions, spiders, jellyfish
Myotoxins	Systemic or local myolysis	Some snakes
Cardiotoxins	Direct or indirect cardiotoxicity	Some snakes, scorpions, spiders, and jellyfish
Haemostasis system toxins	Vary from rapid coagulopathy and bleeding to thrombosis, DVT and pulmonary emboli	Many snakes and a few scorpions Brazilian caterpillars
Nephrotoxins	Renal damage	Some snakes
Necrotoxins	Local tissue injury/necrosis, shock	Some snakes, a few scorpions, spiders, jellyfish and stingrays
Allergic toxins	Induce acute allergic response	Almost all venoms, but particularly those of social insects (i.e. bees, wasps, ants)

*All venom components have lethal potential.

i

9.19 Venomous animals and human envenoming

Phyla	Principal venomous animal groups	Estimated number of human cases/year	Estimated number of human deaths/year
Chordata	Snakes	> 2.5 million	> 100 000
	Spiny fish	? > 100 000	Close to zero
	Stingrays	? > 100 000	? < 10
Arthropoda	Scorpions	> 1 million	? < 5000
	Spiders	? > 100 000	? < 100
	Paralysis ticks	? > 1000	? < 10
	Insects	? > 1 million	? > 1000*
Mollusca	Cone shells	? < 1000	? < 10
	Blue-ringed octopus	? < 100	? < 10
Coelenterata	Jellyfish	? > 1 million	? < 10

*Social insect stings cause death by anaphylaxis rather than primary venom toxicity, except for massive multiple sting attacks.

9.20 Local and systemic effects of envenoming

Local effects

- Pain
- Sweating
- Swelling
- Erythema
- Bleeding and bruising
- Blistering
- Necrosis
- Major direct tissue trauma (e.g. stingray injuries)

Non-specific systemic effects

- Headache
- Nausea
- Vomiting and diarrhoea
- Abdominal pain
- Tachycardia or bradycardia
- Hypertension or hypotension
- Dizziness
- Collapse
- Convulsions
- Shock
- Cardiac arrest

sign (Fig. 9.7). From this, paralysis may extend to the limbs, with weakness and loss of deep tendon reflexes, then finally respiratory paralysis.

- *Excitatory neurotoxins* cause an 'autonomic storm', with profuse sweating, variable cardiac effects and cardiac failure, sometimes with pulmonary oedema (notably Australian funnel web spider bite). This type of envenoming can be rapidly fatal (many scorpions, funnel web spiders), or may cause distressing symptoms but constitute a lesser risk of death (widow spiders, banana spiders).
- *Myotoxicity* can initially be silent, then present with generalised muscle pain, tenderness,

myoglobinuria and huge rises in serum creatine kinase (CK). Secondary renal failure can precipitate potentially lethal hyperkalaemic cardiotoxicity.

- *Cardiotoxicity* is often secondary, and symptoms and signs are non-specific in most cases.
- *Haemostasis system toxins* cause a variety of effects, depending on the type of toxin, and the specific features can be diagnostic. Coagulopathy may present as bruising and bleeding from the bite site, gums and intravenous sites. Surgical interventions are high-risk in such cases. Other venoms cause thrombosis, usually presenting as deep venous thrombosis (DVT), pulmonary embolus or stroke (particularly Caribbean/Martinique vipers).
- *Renal damage* in envenoming is mostly secondary, although some species can cause primary damage (e.g. Russell's vipers). Presentation is similar, with changes in urine output (polyuria, oliguria or anuria) or rises in creatinine and urea. In cases with intravascular haemolysis, secondary renal damage is likely.

The clinical effects of specific animals in different regions of the world are shown in Boxes 9.21–9.23.

Management

It is important to determine an accurate diagnosis and the degree of risk, so that potentially severe/lethal cases are identified quickly and managed as a priority. With correct care, even severe cases are treatable, but delays in initiating effective treatment can severely compromise outcomes. Expert advice should thus be sought at the earliest opportunity.

First aid

Pre-hospital first aid (Box 9.24) can be critical in major envenoming. It depends on the type of envenoming, but the key principles are:

- supporting vital systems
- delaying or preventing the onset of envenoming
- avoiding harmful 'treatments' (e.g. electric shock, cut and suck, tourniquets, cryotherapy in snakebite).

Fig. 9.7 Ptosis following neurotoxin envenomation.

9.21 Important venomous animals in Asia

Scientific name ¹	Common name	Clinical effects	Antivenom/antidote/treatment
Indian subcontinent			
<i>Bungarus</i> spp. (E)	Kraits	Flaccid paralysis ^{2,3}	Indian PV or specific
<i>Naja</i> spp. (E)	Cobras	Flaccid paralysis ³ , local necrosis/blistering, shock	Indian PV or specific
<i>Ophiophagus hannah</i> (E)	King cobra	Flaccid paralysis ³ , local blistering, shock	Indian PV or specific
<i>Echis</i> spp. (Vp)	Saw-scaled vipers	Procoagulant coagulopathy, local necrosis/blistering, renal failure	Indian PV or specific
<i>Daboia russelli</i> (Vp)	Russell's viper	Procoagulant coagulopathy, local necrosis/blistering, myolysis, renal failure, shock, flaccid paralysis ²	Indian PV or specific
<i>Hypnale</i> spp. (Vc)	Hump-nosed vipers	Procoagulant coagulopathy, shock, renal failure	Try Indian PV
<i>Trimeresurus</i> ⁴ spp. (Vc)	Green pit vipers	Procoagulant coagulopathy, local necrosis, shock	Indian PV or specific
<i>Mesobuthus</i> spp. (Sc)	Indian scorpions	Neuroexcitation, cardiotoxicity	Prazosin
East Asia			
<i>Bungarus</i> spp. (E)	Kraits	Flaccid paralysis ^{2,3}	Specific AV from country
<i>Naja</i> spp. (E)	Cobras (some spitters)	Flaccid paralysis ³ , local necrosis, shock	Specific AV from country
<i>Ophiophagus hannah</i> (E)	King cobra	Flaccid paralysis ³ , local necrosis, shock	King cobra AV
<i>Calloselasma rhodostoma</i> (Vc)	Malayan pit viper	Procoagulant coagulopathy, local necrosis/blistering, renal failure, shock	Specific AV from country
<i>Daboia russelli</i> (Vv)	Russell's viper	Procoagulant coagulopathy, local necrosis/blistering, renal failure, shock	Specific AV from country
<i>Gloydius</i> (Vc)	Mamushis, pit vipers	Procoagulant coagulopathy, local necrosis/blistering, shock, renal failure, flaccid paralysis ²	Specific AV from country
<i>Trimeresurus</i> ⁴ (Vc)	Green pit vipers, habus	Procoagulant coagulopathy, local necrosis/blistering, shock	Specific AV from country
<i>Tropidolaemus wagleri</i> (Vc)	Wagler's temple viper	Shock, local necrosis, pain and swelling	None available

¹Family names: A = Atractaspididae; C = Colubridae (mostly non-venomous); E = Elapidae (all venomous); Vv = Viperidae viperinae (Old World vipers); Vc = Viperidae Crotalinae (New World and Asian vipers).
²Pre-synaptic.
³Post-synaptic.
⁴Genus is subject to major taxonomic change.
(AV = antivenom; PV = polyvalent)

Pre-hospital preventable deaths occur when ineffective cardiorespiratory resuscitation is given to patients with respiratory paralysis or cardiac arrest/failure, which can occur due to either primary envenoming or an anaphylactic reaction (p. 89).

Diagnosis

Envenoming is sometimes but not always obvious. Humans may be bitten/stung by an unseen organism, or fail to be aware of a bite/sting at all. If the latter, the patient may present with a variety of symptoms but no linking history to indicate envenoming, so it should be considered in selected cases of unexplained paralysis, myotoxicity, coagulopathy, nephrotoxicity, cardiotoxicity, pulmonary oedema, necrosis, collapse and convulsions.

History, examination and laboratory findings help to confirm or exclude a diagnosis of envenoming, and its extent. Establish whether a bite/sting is a possibility and, if the organism was seen, obtain a description. Multiple bites/stings are more likely to cause major

envenoming. Ask for specific symptoms and search for specific signs that may indicate the type and extent of envenoming (p. 205).

Specific tests for venom are currently only commercially available for Australian snakebite, but are likely to be developed for snakebite in other regions. They are not available for other types of envenoming, where venom concentrations are low. For snakebite, a screen for envenoming includes full blood count, coagulation screen, urea and electrolytes, creatinine, CK and ECG. Lung function tests, peripheral oximetry or arterial blood gases may be indicated in cases with potential or established respiratory failure. In areas without access to routine laboratory tests, the whole blood clotting time (using a glass test tube) is a valuable test for coagulopathy. A derivative of this, the 20-minute whole blood clotting test (are a few millilitres of venous blood clotted at 20 minutes?), is useful.

If patients state that they have been bitten by a particular species, ensure this is accurate. Private keepers of

9.22 Important venomous animals in the Americas and Australia

Scientific name ¹	Common name	Clinical effects	Antivenom/antidote treatment
North America			
<i>Crotalus</i> spp. (Vc)	Rattlesnakes	Procoagulant coagulopathy, local necrosis/blistering (flaccid paralysis ² rare)	CroFab AV
<i>Sistrurus</i> spp. (Vc)	Massasaugas	Procoagulant coagulopathy, local necrosis/blistering, shock	CroFab AV
<i>Agkistrodon</i> spp. (Vc)	Copperheads and moccasins	Procoagulant coagulopathy, local necrosis/blistering, shock	CroFab AV
<i>Micrurus</i> spp. (E)	Coral snakes	Flaccid paralysis ³	Coral snake AV
<i>Latrodectus mactans</i>	Widow spider	Neuroexcitation	Widow spider AV
Central and South America			
<i>Crotalus</i> spp. (Vc)	Rattlesnakes	Flaccid paralysis ² , myolysis, procoagulant coagulopathy, shock, renal failure	Specific AV from country
<i>Bothrops</i> spp. (Vc)	Lancehead vipers	Procoagulant coagulopathy, local necrosis/blistering, shock, renal failure	Specific AV from country
<i>Bothriechis</i> spp. (Vc)	Eyelash pit vipers	Shock, pain and swelling	Specific AV from country
<i>Lachesis</i> spp. (Vc)	Bushmasters	Procoagulant coagulopathy, shock, renal failure, local necrosis/blistering	Specific AV from country
<i>Micrurus</i> spp. (E)	Coral snakes	Flaccid paralysis ^{2,3} , myolysis, renal failure	Specific AV from country
<i>Tityus serrulatus</i>	Brazilian scorpion	Neuroexcitation, shock	Instituto Butantan scorpion AV
<i>Loxosceles</i> spp.	Recluse spiders	Local necrosis	Instituto Butantan spider AV
<i>Phoneutria nigriventer</i>	Banana spider	Neuroexcitation, shock	Instituto Butantan spider AV
<i>Potamotrygon, Dasyatis</i> spp.	Freshwater stingrays	Necrosis of bite area, shock	No available AV; good wound care
Australia			
<i>Pseudonaja</i> spp. (E)	Brown snakes	Procoagulant coagulopathy, renal failure, flaccid paralysis ² (rare)	CSL brown snake AV
<i>Notechis</i> spp. (E)	Tiger snakes	Procoagulant coagulopathy, myolysis, flaccid paralysis ^{2,3} , renal failure	CSL tiger snake AV
<i>Oxyuranus</i> spp. (E)	Taipans	Procoagulant coagulopathy, flaccid paralysis ^{2,3} , myolysis, renal failure	CSL taipan or PV AV
<i>Acanthophis</i> spp. (E)	Death adders	Flaccid paralysis ³	CSL death adder or PV AV
<i>Pseudechis</i> spp.	Black and mulga snakes	Anticoagulant coagulopathy, myolysis, renal failure	CSL black snake AV
<i>Atrax, Hadronyche</i> spp.	Funnel web spiders	Neuroexcitation, shock	CSL funnel web spider AV
<i>Latrodectus hasseltii</i>	Red back spider	Neuroexcitation	CSL red back spider AV
<i>Chironex fleckeri</i>	Box jellyfish	Neuroexcitation, cardiotoxicity, local necrosis	CSL box jellyfish AV

¹For family name, see Box 9.21.

²Pre-synaptic.

³Post-synaptic.

venomous animals may not have accurate knowledge of what they are keeping, and misidentification of a snake, scorpion or spider can have dire consequences if the wrong antivenom is then used.

Treatment

Envenoming is managed on two levels, which must be delivered in tandem:

- treating the effects with specific treatments/antidotes (usually antivenom)
- supportive management of the organ systems affected and of the whole patient.

For a major snakebite such as Russell's viper, the patient might have local effects with oedema, blistering, necrosis, and resultant fluid shifts causing shock, and at the same time have systemic effects such as intrac-table vomiting, coagulopathy, paralysis and secondary renal failure. Specific treatment with antivenom will be required to reverse the coagulopathy, and may prevent worsening of the paralysis and reduce the vomiting, but will not greatly affect the local tissue damage or the renal failure or shock, which will require intravenous fluid therapy, possibly respiratory support, renal dialysis and local wound care, perhaps including antibiotics.

9.23 Important venomous animals in Africa and Europe

Scientific name ¹	Common name	Clinical effects	Antivenom/antidote/treatment
Africa			
<i>Naja</i> spp. (E)	Cobras		
	Non-spitters	Flaccid paralysis ³ ± local necrosis/blistering	South African PV
	Spitters	Local necrosis/blistering (flaccid paralysis ³ uncommon)	South African PV
<i>Dendroaspis</i> spp. (E)	Mambas	Mamba neurotoxin flaccid paralysis and muscle fasciculation, shock	South African PV
<i>Hemachatus haemachatus</i> (E)	Rinkhals	Flaccid paralysis ³ , local necrosis, shock	South African PV
<i>Atheris</i> spp. (Vv)	Bush vipers	Procoagulant coagulopathy, shock, pain and swelling	No available AV (can try South African AV)
<i>Bitis</i> spp. (Vv)	Puff adders etc.	Procoagulant coagulopathy, shock, cardiotoxicity, local necrosis/blistering	South African PV
<i>Causus</i> spp. (Vv)	Night adders	Pain and swelling	No available AV
<i>Echis</i> spp. (Vv)	Carpet vipers	Procoagulant coagulopathy, shock, renal failure, local necrosis/blistering	Specific anti- <i>Echis</i> AV
<i>Cerastes</i> spp. (Vv)	Horned desert vipers	Procoagulant coagulopathy, local necrosis, shock	Specific or polyspecific AV covering <i>Cerastes</i> from country of origin
<i>Dispholidus typus</i> (C)	Boomslang	Procoagulant coagulopathy, shock	Boomslang AV
<i>Androctonus</i> spp.	North African scorpions	Neuroexcitation	Specific scorpion AV (Algeria, Tunisia)
<i>Lelurus quinquestriatus</i>	Yellow scorpion	Neuro excitation, shock	Specific scorpion AV
Europe			
<i>Vipera</i> spp. (Vv)	Vipers and adders	Shock, local necrosis/blistering, procoagulant coagulopathy (flaccid paralysis ² rare)	ViperaTab AV or Zagreb AV

¹For family name, see Box 9.21.

²Pre-synaptic.

³Post-synaptic.

9.24 First aid for envenoming

Method	Situations where indicated
Immobilisation of bitten limb	All snakebites
Pressure bandage and immobilisation of bitten limb	Non-necrotic snakebites (Australian snakes, sea snakes, some cobras, king cobra, kraits, coral snakes, mambas, a few vipers, Australian funnel web spiders, blue-ringed octopus, cone shell)
Local heat (hot water immersion or shower, to 45°C)	Venomous fish stings, stingray injuries, jellyfish stings (except possibly box jellyfish)
Staunching local bleeding	Traumatic injury with significant bleeding (some stingray injuries)
Cardiorespiratory support	Cardiac or respiratory impairment and particularly if respiratory paralysis is developing (some snakes, paralysis ticks, blue-ringed octopus, cone shells)
No specific first aid	Widow and recluse spider bites

Each venomous animal will cause a particular pattern of envenoming, requiring a tailored response. Listing all of these is beyond the scope of this chapter (see Further information below). Pulse, blood pressure, pulse oximetry and urine output should be monitored in all cases.

Antivenom

This is the most important tool in treating envenoming. It is made by hyperimmunising an animal, usually horses, to produce antibodies against venom. Once refined, these bind to venom toxins and render them impotent or allow their rapid clearance. Antivenom is only available for certain venomous animals and cannot reverse all types of envenoming. With a few exceptions it should be given intravenously, with adrenaline (epinephrine) ready in case of an anaphylactoid reaction. It should only be used when clearly indicated, and indications will vary between venomous animals. It is critical that the correct antivenom is used at the appropriate dose. Doses vary widely between antivenoms; those recommended for North American antivenoms are not applicable to those elsewhere.

Antivenom can sometimes reverse post-synaptic neurotoxic paralysis (α -bungarotoxin-like neurotoxins) but will not usually reverse established pre-synaptic

paralysis (β -bungarotoxin-like neurotoxins), so needs to be given before major paralysis has occurred. Coagulopathy is best reversed by antivenom, but even after all venom is neutralised, there may be a delay of hours before normal coagulation is restored. More antivenom should not be given because coagulopathy has failed to normalise fully in the first 1–3 hours (except in very particular circumstances). The role of antivenom in reversing established myolysis and renal failure is uncertain. Antivenom may help reduce local tissue effects/injury in the bitten limb, but this is quite variable and time-dependent. Neuroexcitatory envenoming can respond very well to antivenom (Australian funnel web spider bites, Mexican and South American scorpion stings), but there is controversy about the effectiveness of antivenom for some species (some North African, Middle Eastern and Indian scorpions). The role of antivenom in treating local venom effects, including necrosis, is also controversial; it is most likely to be effective when given early.

All patients receiving antivenom are at risk of both early and late adverse reactions, including anaphylactic/anaphylactoid reactions and serum sickness.

Other treatments

Anticholinesterases are used as an adjunctive treatment for post-synaptic paralysis.

Prazosin (an α -adrenoceptor antagonist) is used in the management of hypertension or pulmonary oedema in scorpion sting cardiotoxicity, particularly for Indian scorpion stings.

Antibiotics are not routinely required for most bites/stings, though a few animals regularly cause significant wound infection/abscess (e.g. some South American pit vipers; stingrays). Tetanus is a risk in some types of bite/sting, such as snakebite, but intramuscular toxoid should not be given until any coagulopathy is reversed.

Mechanical ventilation (p. 196) is vital for established respiratory paralysis that will not reverse with antivenom, and may be required for prolonged periods: up to several months in some cases.

Follow-up

Cases with significant envenoming and those receiving antivenom should be followed up to ensure any complications have resolved and to identify any delayed envenoming.

Psychiatry and the law 252

Psychiatric disorders have traditionally been considered as mental rather than as physical illnesses. This is probably because they manifest with disordered functioning in the areas of emotion, perception, thinking and memory, and/or have had no clearly established biological basis. However, as research identifies abnormalities of the brain in an increasing number of psychiatric disorders and an important role for psychological and behavioural factors in many medical ones, a clear distinction between mental and physical illness has become increasingly questionable.

CLASSIFICATION OF PSYCHIATRIC DISORDERS

There are two main classifications of psychiatric disorders in current use:

- the American Psychiatric Association's Diagnostic and Statistical Manual (4th edition), or DSM-IV
- the World Health Organization's International Classification of Disease (10th edition), known as ICD-10.

The two systems are very similar and here we use the ICD-10 classification (Box 10.1).

EPIDEMIOLOGY OF PSYCHIATRIC DISORDERS

Psychiatric disorders are amongst the most common of human illnesses. The relative frequency of each disorder depends on the setting (Box 10.2). In the general population, depression, anxiety disorders and adjustment disorders are most common (10%) and psychosis is rare (1–2%); in general hospitals, organic disorders such as delirium (10%) are prevalent; in specialist psychiatric services psychoses are amongst the most common disorders.

AETIOLOGY OF PSYCHIATRIC DISORDERS

The aetiology of psychiatric disorders is multifactorial, with a combination of biological, psychological and social causes. Each of these factors may predispose, precipitate or perpetuate the illness (Box 10.3).

Biological factors

Genetic

Genetic factors play a role in many psychiatric disorders, including schizophrenia and bipolar affective disorder.

i

10.1 Classification of psychiatric disorders

Stress-related disorders

- Acute stress disorder
- Adjustment disorder
- Post-traumatic stress disorder

Anxiety disorders

- Generalised anxiety
- Phobic anxiety
- Panic disorder
- Obsessive-compulsive disorder

Affective (mood) disorders

- Depressive disorder
- Mania and bipolar disorder

Schizophrenia and delusional disorders

Substance misuse disorders

- Alcohol
- Drugs

Organic disorders

- Acute, e.g. delirium
- Chronic, e.g. dementia

Disorders of adult personality and behaviour

- Personality disorder
- Factitious disorder

Eating disorders

- Anorexia nervosa
- Bulimia nervosa

Somatoform disorders

- Somatisation disorder
- Dissociative (conversion) disorder
- Pain disorder
- Hypochondriasis
- Body dysmorphic disorder
- Somatoform autonomic dysfunction

Neurasthenia

Puerperal mental disorders

i

10.2 Prevalence of psychiatric disorders by medical setting

	Medical/surgical			
	General practice	Outpatients	Inpatients	Psychiatric services
Adjustment disorders	++	++	+++	++
Depression/anxiety	++	++	+++	+++
Alcohol abuse	++	++	+++	+++
Personality disorders	++	++	++	+++
Somatoform disorders	+	+++	++	+
Delirium	–	–	+++	–
Psychosis	–	–	–	+++
(– rare; + uncommon; ++ common; +++ very common)				

10.3 Classification of aetiological factors in psychiatric disorders

Predisposing

- Increase susceptibility to psychiatric disorder
- Established in utero or in childhood
- Operate throughout patient's lifetime (e.g. genetic factors, congenital defects, chronic physical illness, disturbed family background)

Precipitating

- Trigger an episode of illness
- Determine its time of onset (e.g. stressful life events, acute physical illness)

Perpetuating

- Delay recovery from illness (e.g. lack of social support, chronic physical illness)

Whilst some disorders such as Huntington's disease are due to mutations in a single gene, the genetic contribution to most psychiatric disorders is polygenic in nature and is mediated by the combined effects of several genetic variants, each with modest effects.

Brain structure and function

Brain structure is normal in most psychiatric disorders, although abnormalities may be observed in some conditions such as generalised atrophy in Alzheimer's disease and enlarged ventricles with a slight decrease in brain size in schizophrenia. The function of the brain is commonly altered, however, with, for example, changes in neurotransmitters such as dopamine, noradrenaline (norepinephrine) and 5-hydroxytryptamine (5-HT, serotonin), and differences in activity of specific areas of the brain, as seen on functional brain scans.

Psychological and behavioural factors

Perceived stress and trauma

Early childhood adversity, such as emotional deprivation or abuse, increases the risk of developing psychiatric illnesses such as depression and eating disorders as an adult. Events in adult life that are perceived as stressful may trigger psychiatric illness, as in post-traumatic stress disorder.

Personality

The relationship between personality and psychiatric illness can be difficult to assess because the development of psychiatric illness can change a patient's personality. Some personality types do predispose to illness; for example, a depressive personality increases the risk of clinical depression. Abnormal personality may also perpetuate psychiatric illness once it is established, leading to a poorer prognosis.

Behaviour

A person's behaviour may predispose to the development of a disorder (e.g. excess alcohol intake leading to dependence, and dieting to anorexia) or perpetuate it, as in persistent avoidance of the feared situation in a phobia.

Social and environmental factors

Social isolation

The lack of a close, confiding relationship predisposes to psychiatric illnesses such as depression. The reduced social support resulting from psychiatric illness may also perpetuate it.

Stressors

Social and environmental stressors can precipitate illness in vulnerable people. Their effect is modified by how they are perceived by the individual, although some may be so severe that they precipitate illness in most people. Losses (such as bereavement) commonly precede the onset of depression, and events perceived as threatening (such as potential loss of employment) commonly precipitate anxiety.

DIAGNOSING PSYCHIATRIC DISORDERS

The key differences between a psychiatric and a medical assessment are:

- a greater emphasis on the history
- a systematic examination of the patient's mental state
- routine interviewing of an informant (usually a relative or friend who knows the patient), especially when the illness affects the patient's ability to give an accurate history.

A full psychiatric history and detailed mental state examination (MSE) may take an hour or more, but a much briefer mental state examination should be part of the assessment of *all* patients.

Psychiatric interview

The aims of the interview are to:

- establish a therapeutic relationship with the patient
- elicit the symptoms, history and background information (Box 10.4)
- examine the mental state
- provide information, reassurance and advice.

Some aspects of the patient's mental state may be observed whilst the history is being taken, but specific enquiry must always be made for important features.

Mental state examination

General appearance and behaviour

Any abnormalities of alertness or motor behaviour, such as restlessness or retardation, are noted. The level of consciousness should be examined, especially in the assessment of possible delirium.

Speech

Speed and fluency should be observed, including slow (retarded) speech and word-finding difficulty. 'Pressure of speech' describes rapid speech that is difficult to interrupt.

Mood

This can be judged by facial expression, posture and movements. Patients should also be asked if they feel sad or depressed, or lack ability to experience pleasure

10.4 How to structure a psychiatric interview

Presenting problem

Reason for referral

- Why the patient has been referred and by whom

Presenting complaints

- The patient should be asked to describe the symptoms for which help is requested

History of present illness

- The patient should be asked to describe the course of the illness from the time when symptoms were first noticed
- The interviewer asks direct questions to determine the nature, duration and severity of symptoms and any associated factors

Background

Family history

- Description of parents and siblings, and a record of mental illness in relatives

Personal history

- Birth history, major events in childhood, education, occupational history, relationship, marriage, children, current social circumstances

Previous medical and psychiatric history

- Previous health, accidents and operations
- Use of alcohol, tobacco and other drugs
- Direct questions may be needed concerning previous psychiatric history since this may not be volunteered: 'Have you ever been treated for depression or nerves?' or 'Have you ever suffered a nervous breakdown?'

Previous personality

- The characteristic patterns of behaviour and thinking which determine a person's adjustment to the environment, including relationships with other people and reactions to stress
- The most useful information may be obtained from an informant who has known the patient well for many years

(anhedonia). Are they anxious, worried or tense, or is mood elevated with excess energy and a reduced need for sleep, as in mania?

Thoughts

The content of thought can be elicited by asking 'What are your main concerns?' Is thinking negative, guilty or hopeless, suggesting depression? Are there thoughts of self-harm? If so, enquiry should be made about plans. Does the patient think that he or she is especially powerful, important or gifted (grandiose thoughts), suggesting mania, or is he/she excessively worried about many things, suggesting anxiety?

The form of thinking may also be abnormal. For example, in schizophrenia, patients may display loosened associations between ideas, making it difficult to follow their train of thought. There may also be abnormalities of thought possession, when patients experience the intrusion of alien thoughts or the broadcasting of their own (p. 243).

Abnormal beliefs

A delusion is a false belief, out of keeping with a patient's cultural background, which is held with unshakable conviction despite evidence to the contrary (p. 234).

Abnormal perceptions

Illusions are abnormal perceptions of real stimuli. Hallucinations are sensory perceptions which occur in the absence of external stimuli: for example, hearing voices when no one is present (p. 234).

Cognitive function

The Mini-Mental State Examination (MMSE) is a useful screening questionnaire to detect cognitive impairment (Box 10.5). A score of less than 24 out of 30 indicates cognitive impairment. The degree of cognitive impairment

10.5 How to perform a Mini-Mental State Examination (MMSE)

Patient name _____

Date of birth _____ Date of test _____

Max. points	Patient score	Orientation
5	()	What is the (year) (season) (date) (day) (month)?
5	()	Where are we (country) (county) (town/city) (building) (floor)?
3	()	Registration Name three common objects (e.g. 'apple', 'table', 'penny'). Take 1 second to say each. Then ask the patient to repeat all three after you have said them. Give 1 point for each correct answer. Then repeat them until he/she learns all three. Count trials and record. Trials ()
5	()	Attention Spell 'world' backwards. The score is the number of letters in the correct order. (D _ L _ R _ O _ W _)
3	()	Recall Ask for the three objects repeated above. Give 1 point for each correct answer. (Note: recall cannot be tested if all three objects were not remembered during registration)
2	()	Language Name a 'pencil' and a 'watch'. (2 points)
1	()	Repeat the following: 'No ifs, ands or buts.' (1 point)
3	()	Follow a three-stage command: 'Take this paper in your right hand, fold it in half, and put it on the floor.' (3 points)
1	()	Read and obey the following: (1 point) CLOSE YOUR EYES
1	()	Write a sentence. (1 point)
1	()	Copy the following design. Give 1 point if no construction problem

30 () **Total**

Examiner _____

in delirium typically fluctuates and may be missed by a single assessment.

- **Concentration.** Serial 7s is a test in which the patient is asked to subtract 7 from 100 and then 7 from the answer, down to 0.
- **Orientation.** This is assessed by asking the patient about place—his or her exact location; time—what day, date, month and year it is now; and person—details of personal identity, such as name, date of birth, marital status and address.
- **Intellectual abilities.** These can be gauged from the history of the patient's educational background and attainments but can also be assessed during the interview from the patient's speech and grasp of the interviewer's questions.
- **Memory.** Registration of memories is tested by asking the patient to repeat simple new information, such as a name and address, immediately. Short-term memory is assessed by asking him/her to repeat it after an interval of 1–2 minutes, during which time the patient's attention should be diverted elsewhere. Long-term memory is checked by assessing the recall of previous events.

Patients' understanding of illness ('insight')

Patients should be asked what they think their symptoms are due to, and whether they warrant treatment. Lack of insight is a failure to accept that one is ill and/or in need of treatment, and is characteristic of acute psychosis.

PRESENTING PROBLEMS IN PSYCHIATRIC ILLNESS

Anxiety symptoms

Anxiety may be transient, persistent, episodic or limited to specific situations. The symptoms of anxiety are both psychological and somatic (Box 10.6). The differential diagnosis of anxiety is shown in Box 10.7. Most commonly it is transient, as an adjustment disorder (p. 240), and subsides with time. Other more persistent forms of anxiety are described in detail on pages 241–242. Anxiety may occasionally be a manifestation of a medical condition such as thyrotoxicosis (see Box 10.7).

10.6 Symptoms of anxiety disorder

Psychological

- Apprehension
- Irritability
- Worry
- Fear of impending disaster
- Poor concentration
- Depersonalisation

Somatic

- Palpitations
- Fatigue
- Tremor
- Dizziness
- Sweating
- Diarrhoea
- Frequent desire to pass urine
- Chest pain
- Initial insomnia
- Breathlessness
- Headache

10.7 Differential diagnosis of anxiety

- Normal response to threat
- Adjustment disorder
- Generalised anxiety disorder
- Panic disorder
- Phobic disorder
- Organic (medical) cause
 - Hyperthyroidism
 - Paroxysmal arrhythmias
 - Phaeochromocytoma
 - Alcohol and benzodiazepine withdrawal
 - Hypoglycaemia
 - Temporal lobe epilepsy

Depressed mood

Depressive disorder is common, occurring in a quarter to a half of medical inpatients. The symptoms of depression are both mental and physical (Box 10.8). In the physically ill patient, diagnosis of comorbid depression is based mainly on careful assessment of the core psychological symptoms: namely, persistently lowered mood and anhedonia.

Differential diagnosis

Depressive disorder must be differentiated from an adjustment disorder with depressed mood (p. 240). Adjustment disorders are common, self-limiting reactions to adversity, including physical illness, which are transient and require only general support. On the other hand, depressive disorders (p. 242) are characterised by more severe and persistent mood disturbance and do require specific treatment. In some cases, depression may occur as a result of a direct effect of a medical condition or its treatment on neurotransmitters or neural pathways in the brain, when it is referred to as an 'organic mood disorder' (Box 10.9).

Suicide

Depression is the major risk factor for suicide, especially when it co-occurs with a medical condition or substance misuse. Other risk factors are shown in Box 10.10. When depression is suspected, tactful enquiry should always be made into suicidal thoughts and plans. Asking about suicide does not increase the risk of it occurring, whereas failure to enquire denies the opportunity to prevent it.

10.8 Symptoms of depressive disorders

Psychological

- Depressed mood
- Reduced self-esteem
- Pessimism
- Guilt
- Loss of interest
- Loss of enjoyment (anhedonia)
- Suicidal thinking

Somatic

- Reduced appetite
- Weight change
- Disturbed sleep
- Fatigue
- Loss of libido
- Bowel disturbance
- Motor retardation (slowing of activity)

10.9 Organic affective disorders*

Neurological

- Cerebrovascular disease
- Cerebral tumour
- Multiple sclerosis
- Parkinson's disease
- Huntington's disease
- Alzheimer's disease
- Epilepsy

Endocrine

- Hypothyroidism
- Hyperthyroidism
- Cushing's syndrome
- Addison's disease
- Hyperparathyroidism

Malignant disease

Infections

- Infectious mononucleosis
- Herpes simplex
- Brucellosis
- Typhoid
- Toxoplasmosis

Connective tissue disease

- Systemic lupus erythematosus

Drugs

- Reserpine, methyl dopa
- Phenothiazines
- Phenylbutazone
- Corticosteroids, oral contraceptives
- Interferon

*Diseases that may cause organic affective disorders by direct action on the brain.

i

10.10 Risk factors for suicide

- Psychiatric illness (depressive illness, schizophrenia)
- Older age
- Male sex
- Living alone
- Unemployed
- Recently bereaved, divorced or separated
- Chronic physical ill health
- Drug or alcohol misuse
- Suicide note written
- History of previous attempts (especially if a violent method was used)

Elated mood

Elation, or euphoria, is the converse of depression and is characteristic of mania. It may manifest as infectious joviality, over-activity, lack of sleep and appetite, undue optimism, over-talkativeness, irritability, and recklessness in spending and sexual behaviour. When more severe, psychotic symptoms are often evident, such as delusional degrees of grandiosity. Elevated mood is much less common than depression, and where it arises in medical settings is often secondary to drug or alcohol misuse, an organic disorder or medical treatment. Where none of these applies, the patient may have a bipolar mood disorder (p. 243), a condition which requires specialist treatment.

Delusions and hallucinations

Delusions

Various types of delusion are identified on the basis of their content. They may be:

- persecutory, such as a conviction that others are out to get one
- hypochondriacal, such as an unfounded conviction that one has cancer
- grandiose, such as a belief that one has special powers or status.

The most extreme form of delusion is nihilistic, e.g. 'My head is missing,' 'I have no body,' 'I am dead.' Delusions should be differentiated from overvalued ideas, which are strongly held but not fixed.

Hallucinations

These are perceptions without external stimuli. They can occur in any sensory modality, most commonly visual or auditory. Typical examples are hearing voices when no one else is present, or seeing 'visions'. Hallucinations have the quality of ordinary perceptions and are perceived as originating in the external world, not the patient's own mind (when they are termed pseudo-hallucinations). Those occurring when falling asleep ('hypnagogic') and on waking ('hypnopompic') are not pathological. Hallucinations should be distinguished from illusions, which are misperceptions of real external stimuli (such as mistaking a shrub for a person in poor light).

Differential diagnosis

Agitation, terror or the fear of being thought 'mad' may make patients unable or unwilling to volunteer or describe their abnormal beliefs or experiences. Careful enquiry is therefore required. The nature of hallucinations can be important diagnostically; for example, 'running commentary' voices which discuss the patient in the third person are strongly associated with schizophrenia. In general, auditory hallucinations suggest a 'functional psychosis' such as schizophrenia, while hallucinations in other sensory modalities, especially vision but also taste and smell, suggest an 'organic psychosis' such as delirium or temporal lobe epilepsy.

Hallucinations and delusions often co-occur; if their content is consistent with coexisting emotional symptoms, they are described as 'mood-congruent'. Thus patients with severely depressed mood may believe themselves responsible for all the evils in the world, and hear voices saying 'You're worthless. Go and kill yourself.' In this case, the diagnosis of depressive psychosis is made on the basis of the congruence of different phenomena (mood, delusion and hallucination). Incongruence between hallucinations, delusions and mood suggests schizophrenia.

Where hallucinations and delusions arise within disturbed consciousness and impaired cognition, the diagnosis is usually organic disorder, most commonly delirium and/or dementia (p. 248). This differential diagnosis is made by assessing the nature, extent and time course of any cognitive disturbances, and by investigating for underlying causes.

Disturbed and aggressive behaviour

Disturbed and aggressive behaviour is common in general hospitals, especially in emergency departments. Most behavioural disturbance arises not from medical or psychiatric illness, but from alcohol intoxication and personality. The key principles of management are to establish control of the situation and thereby ensure the safety of the patient and others, and also to assess the cause of the disturbance in order to remedy it. Establishing control requires the presence of an adequate number of trained staff, an appropriate physical environment and sedation, as set out in Figure 10.1. Hospital security staff and sometimes police may be required. In all cases staff behaviour is important; a calm,

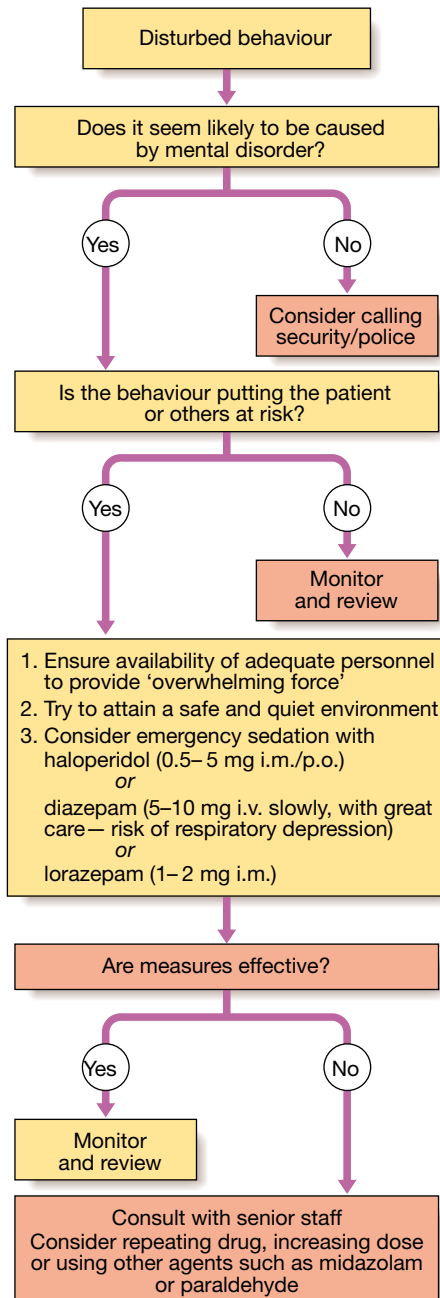

Fig. 10.1 Acute management of disturbed behaviour.

non-threatening approach by someone who can understand and address the patient's fears is often all that is required to defuse potential aggression (Box 10.11).

The most widely used sedating agents are anti-psychotic drugs, such as haloperidol, and benzodiazepines, such as diazepam. The choice of drug, dose, route and rate of administration will depend on the patient's age, sex and physical health, as well as the likely cause of the disturbed behaviour. The benefits of sedation must be balanced against the risks. Haloperidol can cause acute dystonias including oculogyric crises, while the benzodiazepines can precipitate respiratory depression in patients with lung disease, and encephalopathy in those with liver disease. Thus appropriate sedation for a

10.11 Psychiatric emergencies

- Intervene as necessary to reduce the risk of harm to the patient and to others
- Adopt a calm, non-threatening approach
- Arrange availability of other staff and parenteral medication
- Consider diagnostic possibilities of drug intoxication, acute psychosis and delirium
- Involve friends and relatives as appropriate

frail elderly woman with emphysema and delirium may be a low dose (0.5 mg) of oral haloperidol, while a strong young man with an acute psychotic episode may need at least 10 mg of intravenous diazepam and a similar dose of haloperidol. A parenterally administered anticholinergic agent, such as procyclidine, should be available to treat extrapyramidal effects arising from haloperidol. When benzodiazepines are used, flumazenil (p. 215) should be on hand to reverse respiratory depression. When benzodiazepines are used in large doses, oxygen and ventilation should be available.

Differential diagnosis

Many factors may contribute to disturbed behaviour, although little may be learned from an attempted interview with an uncooperative patient. Other sources of information about the patient are therefore crucial and include medical and psychiatric records, and discussion with nursing staff, family members and other informants, including the patient's general practitioner. Important information to obtain includes:

- psychiatric, medical (especially neurological) and criminal history
- current psychiatric and medical treatment
- alcohol and drug misuse
- recent stressors
- the time course and accompaniments of the current episode in terms of mood, belief and behaviour.

Simple observation of the patient's behaviour may also yield useful clues. Do they appear to be responding to hallucinations? Are they alert or variably drowsy and confused? Are there physical features suggestive of drug or alcohol misuse or withdrawal? Are there new injuries or old scars, especially on the head? Do they smell of alcohol or solvents? Do they bear the marks of drug injection? Are they grubby and unkempt, suggesting a gradual development of their condition?

If the person is psychiatrically ill, then admission to a psychiatric facility is indicated. If a medical cause is likely, psychiatric transfer is inappropriate and the patient should be managed in a medical setting, with whatever nursing and security support is required. Where it is clear that there is no medical or psychiatric illness, the person should be removed from the hospital, to police custody if necessary.

Measures such as restraint, sedation, the investigation and treatment of medical problems, and psychiatric transfer all raise legal as well as medical issues (p. 252). In most countries, including the UK, the law confers upon doctors the right and indeed the duty to intervene against a patient's wishes in cases of acute behavioural disturbance, if this is necessary to protect the patient or other people.

Self-harm

Self-harm (SH) is a common reason for presentation to medical services. The term 'attempted suicide' is potentially misleading, as most such patients are not unequivocally trying to kill themselves. Most cases of SH involve overdose, of either prescribed or non-prescribed drugs (Ch. 9). Less common methods include asphyxiation, drowning, hanging, jumping from a height or in front of a moving vehicle, and the use of firearms. Methods which carry a high chance of being fatal are more likely to be associated with serious psychiatric illness. Self-cutting is common and often repetitive, but rarely leads to contact with medical services.

The incidence of SH has changed over time and varies between countries. In the UK, the lifetime prevalence of suicidal ideation is 15% and that of acts of SH 4%. SH is more common in women than in men, and in young adults than in the elderly. In contrast, completed suicide is more common in men and in the elderly (see Box 10.10). There is a higher incidence among lower socioeconomic groups, particularly those living in crowded, socially deprived urban areas. Self-harming patients often have a deprived family background. There is also an association with alcohol misuse, child abuse, unemployment and recently broken relationships.

Differential diagnosis

The main differential diagnosis is from accidental poisoning and from so-called 'recreational' overdose in drug users. It must be remembered that SH is not a diagnosis but a presentation, and may be associated with any psychiatric diagnosis; the most common are adjustment disorders, substance and alcohol misuse, depressive disorders and personality disorders. In many cases there is no psychiatric diagnosis.

Initial management

A thorough psychiatric and social assessment should be carried out in all cases (Fig. 10.2), although some patients will discharge themselves before this can take place. In most UK hospitals, assessment is usually undertaken by psychiatrists, although other doctors, physicians, nurses and social workers can also be trained to do this. Psychiatric assessment should not delay urgent medical or surgical treatment, and may need to be deferred until the patient is well enough for interview, and the sedating or intoxicating effect of the drugs and any alcohol taken have worn off. The purpose of the psychiatric assessment is to:

- establish the short-term risk of suicide
- identify potentially treatable problems, whether medical, psychiatric or social.

Topics to be covered when assessing a patient are listed in Box 10.12. The history should cover events occurring immediately before and after the act and especially any evidence of planning. The nature and severity of any current psychiatric symptoms must be assessed, along with the personal and social supports available to the patient outside hospital.

Most SH patients have depressive and anxiety symptoms on a background of chronic social and personal difficulties and alcohol misuse, and do not require psychotropic medication or specialised psychiatric treatment. They do need emotional support and practical advice from a GP,

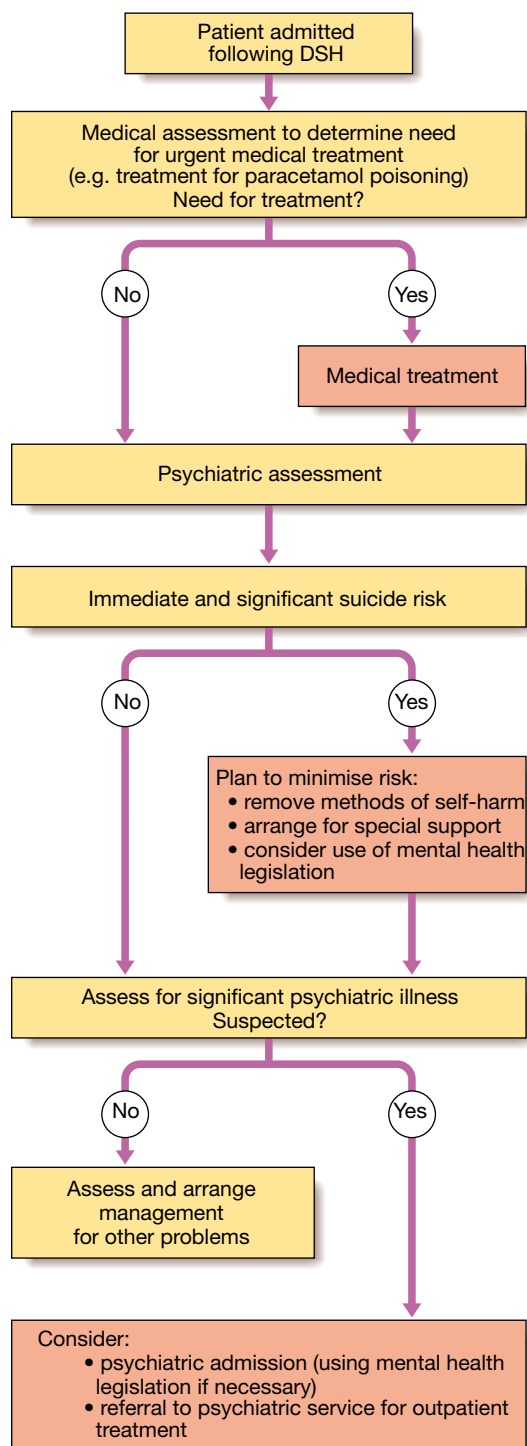

Fig. 10.2 Assessment of patients admitted following self-harm (SH).

social worker or community psychiatric nurse. Admission to a psychiatric ward is necessary only for persons who:

- have major psychiatric illness
- remain intent on suicide
- need temporary respite from intolerable circumstances
- require further assessment of their mental state.

10.12 Assessment of patients after self-harm

Current attempt

- Patient's account
- Degree of intent at the time: preparations, plans, precautions against discovery, note
- Method used, particularly whether violent
- Degree of intent now
- Symptoms of psychiatric illness

Background

- Previous attempts and their outcome
- Family and personal history
- Social support
- Previous response to stress
- Extent of drug and alcohol misuse

Approximately 20% of SH patients make a repeat attempt during the following year and 1–2% kill themselves. Factors associated with suicide after an episode of SH are listed in Box 10.10.

Confusion

This is a vague term used to describe a range of primarily cognitive problems but also includes disturbances in perception, belief and behaviour. 'Confusion' usually presents as a problem when patients cannot comply with medical care; they may repeatedly wander off the ward, pull out essential cannulae and catheters, and hit out at nurses. The apparently confused patient may have deficits in any or all cognitive domains. Cognitive assessments range from simple screening questions to detailed psychometric testing. All doctors should be able to undertake a brief cognitive assessment, as outlined above (p. 232 and Box 10.5).

Differential diagnosis

A history from the patient and informants is essential to establish the time course, variability and functional consequences of any cognitive deficit. Mental state examination is necessary to seek evidence of associated mood disorder, hallucinations, delusions or behavioural abnormalities, and physical examination to identify medical illness. A clinical assessment should distinguish between organic disorders such as delirium, dementia, and focal deficits secondary to brain lesions; psychiatric disorders

10.13 Medical psychiatry in old age

- **Organic psychiatric disorders:** especially common, so cognitive function should always be assessed; if impaired, an associated medical condition or adverse drug effect should be suspected.
- **Disturbed behaviour:** delirium is the most common cause.
- **Depression:** common. Just because a person is old and frail does not mean that depression is 'to be expected' and that it should not be treated.
- **Self-harm:** associated with an increased risk of completed suicide.
- **Medically unexplained symptoms:** common and often associated with depressive disorder.
- **Loneliness, poverty and lack of social support:** must be taken into consideration in management decisions.

such as pseudo-dementia and dissociative disorder; and malingering (p. 252). Further investigation will usually be needed to identify the specific causes of any delirium (Chs 9 and 26).

Alcohol misuse

Misuse of alcohol is a world-wide problem. It presents in a multitude of ways, which are discussed further on page 246 and in Box 10.31 (p. 247). In many cases, the link to alcohol will be all too obvious but in others it may not be. Denial and concealment of alcohol intake is common; consequently, a high index of suspicion is essential. The patient should be asked to describe a typical week's drinking, quantified in terms of units of alcohol (1 unit contains approximately 8g alcohol and is the equivalent of half a pint of beer, a single measure of spirits or a small glass of wine). Drinking becomes hazardous at levels above 21 units weekly for men and 14 units weekly for women. The history from the patient may need corroboration by the GP, earlier medical records and family members. The mean cell volume (MCV) and γ -glutamyl transferase (GGT) may be raised, but are abnormal in only half of problem drinkers, so normal results do not exclude an alcohol problem. When abnormal, these measures may be helpful in challenging denial and monitoring treatment response. The prevention and management of alcohol-related problems is discussed on pages 246–247.

Substance misuse

The misuse of drugs of all kinds is widespread. As well as the general headings listed for alcohol problems in Box 10.31 (p. 247), there are two additional sets of problems associated with drug misuse:

- problems linked with the route of administration rather than the substance taken
- problems arising from pressure applied to doctors by the patient to prescribe the misused substances (Box 10.14).

Assessment and management are described on pages 247–248.

10.14 Substance misuse: additional presenting problems

Complications arising from the route of use

Intravenous

- Local: abscesses, cellulitis, thrombosis
- Systemic: bacterial (endocarditis), viral (hepatitis, human immunodeficiency virus (HIV))

Nasal ingestion

- Erosion of nasal septum, epistaxis

Smoking

- Oral, laryngeal and lung cancer

Inhalation

- Burns, chemical pneumonitis, rashes

Pressure to prescribe misused substance

- Manipulation, deceit and threats
- Factitious description of illness
- Malingering

Psychological factors affecting medical conditions

Psychological factors influence the presentation, management and outcome of most medical conditions. Specific factors are shown in Box 10.15. The most common psychiatric diagnoses in the medically ill are anxiety and depressive disorders. Often these appear understandable as adjustments to illness and treatment; however, if they are severe and persistent, active management is required. Anxiety may present as an increase in somatic symptoms such as breathlessness, tremor or palpitations, or as the avoidance of treatment. It is most common in those facing difficult or painful treatment, deterioration of their illness or death. Depression may manifest as increased symptoms such as pain or fatigue and disability, as well as with depressed mood and loss of interest and pleasure. It is most common in patients who have suffered actual or anticipated loss, such as receiving a terminal diagnosis or undergoing disfiguring surgery.

Treatment is by psychological and/or pharmacological therapies, as described below. Care is required when prescribing psychotropic drugs to the medically ill in order to avoid exacerbating the medical condition or causing interactions with other prescribed drugs.

10.15 Risk factors for psychological problems associated with medical conditions

- Previous history of depression or anxiety
- Lack of social support
- New diagnosis of a serious medical condition
- Deterioration of or failure of treatment for medical condition
- Unpleasant, disabling or disfiguring treatment
- Change in medical care, e.g. discharge from hospital
- Impending death

Medically unexplained somatic symptoms

Patients commonly present to doctors with somatic symptoms. Whilst these are often clearly associated with a medical condition, in other cases they are not. Symptoms may be disproportionate to, or occur in the absence of, a medical condition and are then often referred to as 'medically unexplained symptoms' (MUS). MUS are very common and occur in a quarter to a half of patients attending general medical outpatient clinics. Almost any symptom can be medically unexplained and common examples include:

- pain (including back, chest, abdominal and headache)
- fatigue
- dizziness
- fits, 'funny turns' and feelings of weakness.

Patients with MUS may receive a medical diagnosis of a so-called functional somatic syndrome, such as irritable bowel syndrome (Box 10.16) and may also merit a

psychiatric diagnosis on the basis of the same symptoms. The most frequent psychiatric diagnoses associated with MUS are anxiety or depressive disorders. When these are absent, a diagnosis of somatoform disorder may be applied (Box 10.17).

Differential diagnosis

The main medical differential diagnosis is from symptoms of a medical disease. Diagnostic difficulties are most likely with unusual presentations of common diseases and with rare diseases. A medical and psychiatric assessment should be completed in all cases (Fig. 10.3).

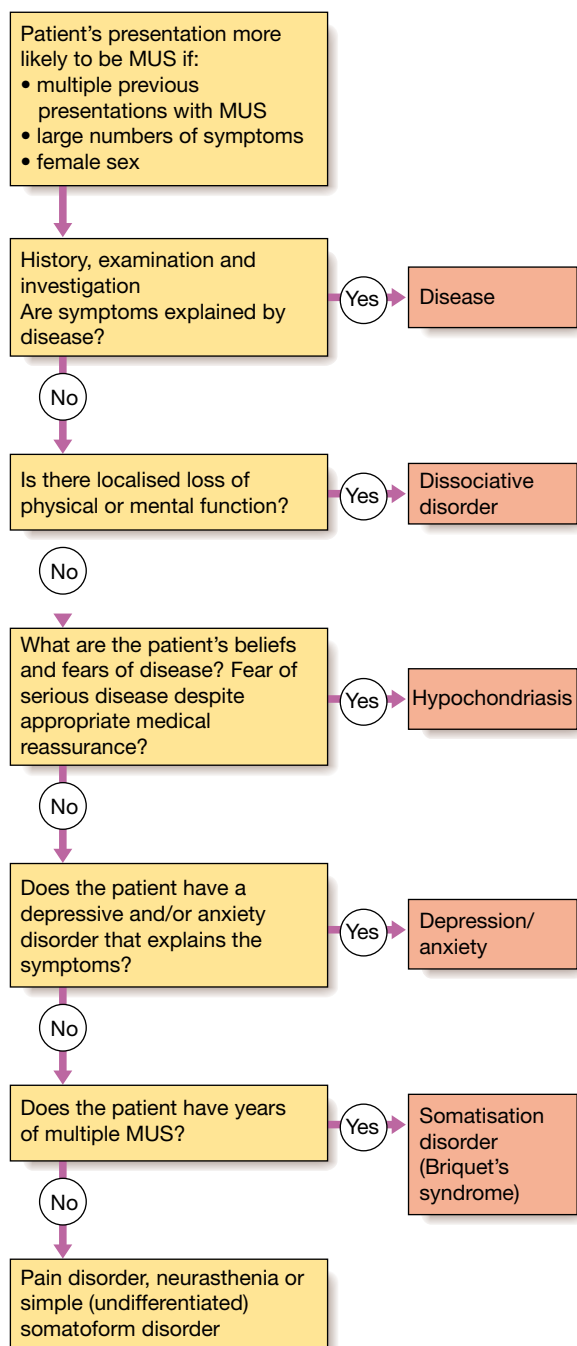

Fig. 10.3 Diagnosis of medically unexplained symptoms (MUS).

10.16 Functional somatic syndromes

- Gastroenterology: irritable bowel syndrome, non-ulcer dyspepsia
- Gynaecology: premenstrual syndrome, chronic pelvic pain
- Rheumatology: fibromyalgia
- Cardiology: atypical or non-cardiac chest pain
- Respiratory medicine: hyperventilation syndrome
- Infectious diseases: chronic (post-viral) fatigue syndrome
- Neurology: tension headache, non-epileptic attacks
- Dentistry: temporomandibular joint dysfunction, atypical facial pain
- Ear, nose and throat: globus syndrome
- Allergy: multiple chemical sensitivity

10.17 Psychiatric diagnoses for medically unexplained somatic symptoms

- Hypochondriasis: predominant concern about disease
- Somatisation: predominant concern about symptoms
- Somatic presentation of depression and anxiety
- Simple somatoform disorders: small number of symptoms
- Somatisation disorder (Briquet's syndrome): chronic multiple symptoms
- Conversion disorder: loss of function
- Body dysmorphic disorder: dislike of body parts

TREATING PSYCHIATRIC DISORDERS

The multifactorial origin of most psychiatric disorders means that there may be multiple potential targets for treatment.

Biological treatments

These aim to relieve psychiatric illness by modifying brain function. Psychotropic drugs are widely used for various purposes; a pragmatic classification is set out

in Box 10.18. It should be noted that some drugs have applications to more than one condition; for example, antidepressants are widely used in the treatment of anxiety *and* chronic pain. The specific subgroups of psychotropic drugs are discussed in the sections on the appropriate disorders.

Electroconvulsive therapy (ECT) entails producing a convulsion by the administration of high-voltage, brief direct current impulses to the head while the patient is anaesthetised and paralysed by muscle relaxants. If properly administered it is remarkably safe, has few side-effects, and is of proven efficacy for severe depressive illness. There may be amnesia for events occurring a few hours before ECT (retrograde) and after it (anterograde). Pronounced amnesia can occur but is infrequent and difficult to distinguish from the effects of severe depression. There is a very limited place for psychosurgery in very severe chronic psychiatric illness.

Psychological treatments

These treatments are useful in many psychiatric disorders and non-psychiatric conditions. They are based on talking with patients, either individually or in groups. Sometimes discussion is supplemented by 'homework' or tasks to complete between sessions. Psychological treatments take a number of forms based on the duration and frequency of contact, the specific techniques applied and their underlying theory.

General or supportive psychotherapy

This should form part of all medical treatment. It involves empathic listening, in which the doctor encourages the patient to describe symptoms, express feelings and reflect on associated problems. The doctor should offer an explanation of the symptoms (and, where possible, a diagnosis), practical advice and such reassurance as is appropriate. For patients with incurable or chronic conditions, supportive psychotherapy may be the best treatment that can be offered.

10.18 Classification of psychotropic drugs

Action	Main groups	Clinical use
Antipsychotic	Phenothiazines Butyrophenones Second-generation antipsychotics	Schizophrenia Bipolar mania Acute confusion
Antidepressant	Tricyclics and related drugs Monoamine oxidase inhibitors Novel noradrenergic or serotonin re-uptake inhibitors	Depression/anxiety Obsessive-compulsive disorder Depression/anxiety Depression/anxiety Obsessive-compulsive disorder
Mood-stabilising	Lithium Carbamazepine (Semi)Sodium valproate Lamotrigine	Treatment and prophylaxis of bipolar disorder Prophylaxis of bipolar disorder Prophylaxis of bipolar disorder Bipolar depression
Anti-anxiety	Benzodiazepines β-adrenoceptor antagonists	Anxiety/insomnia (short term) Alcohol withdrawal (short term) Anxiety (somatic symptoms)

10.19 The negative cognitive triad associated with depression

- Negative view of self, e.g. 'I am no good'
- Negative view of current life experiences, e.g. 'The world is an awful place'
- Negative view of the future, e.g. 'The future is hopeless'

Cognitive therapy

This is based on the observation that some psychiatric disorders are associated with systematic errors in the patient's conscious thinking: for example, a tendency to interpret events in a negative way or see them as unduly threatening. A triad of such cognitive errors has been described in depression (Box 10.19). Cognitive therapy aims to help patients identify recurring negative thoughts and learn how to challenge them. It is widely used for depression, anxiety and bulimia nervosa, and increasingly in the management of somatoform disorders.

Behaviour therapy

This is a practically orientated form of treatment, in which patients are helped to change their behaviour. In conditions such as phobic anxiety, working with the patient through a carefully constructed programme of graded exposure to the feared stimulus is usually remarkably effective.

Cognitive behaviour therapy (CBT)

This combines the methods of behaviour therapy and cognitive therapy. It is the most widely available and most extensively researched psychological treatment.

Problem-solving therapy

This is a simplified brief form of CBT, which helps patients actively tackle problems in a structured way (Box 10.20). It is of benefit in mild to moderate depression, and can be delivered by non-psychiatric doctors and nurses after brief training.

10.20 Stages of problem-solving therapy

- Define and list problems
- Choose one to work on
- List possible solutions
- Evaluate these and choose the best
- Try it out
- Evaluate the result
- Repeat until problems are resolved

Psychodynamic psychotherapy

This treatment, also known as 'interpretive psychotherapy', was pioneered by Freud, Jung and Klein, amongst others. It is based upon the theory that early life experience generates powerful motivating forces, of which the patient is unaware. Psychotherapy aims to help the patient to become aware of these unconscious factors on the assumption that, once identified, their negative effects are reduced. The relationship between therapist and patient is used as a therapeutic tool to identify issues in patients' relationships with others, particularly

parents, which may be replicated or transferred to their relationship with the therapist. Explicit discussion of this transference is the basis for the treatment, which traditionally requires frequent sessions over a period of months or even years.

Interpersonal therapy (IPT) is a specific form of brief psychotherapy which focuses on patients' current interpersonal relationships and is an effective treatment for mild to moderate depression.

Social interventions

Factors such as unemployment may not be readily amenable to intervention but others, such as access to benefits and poor housing, are. Patients can be helped to address these problems themselves by being taught a problem-solving approach. Befrienders and day centres can reduce social isolation, benefits advisers can ensure appropriate financial assistance, and medical recommendations can be made to local housing departments to help patients obtain more appropriate accommodation.

PSYCHIATRIC DISORDERS

Stress-related disorders

Acute stress reaction

Following a stressful event such as a serious medical diagnosis or a major accident, some people develop a characteristic pattern of symptoms. These include a sense of bewilderment, anxiety, anger, depression, altered activity and withdrawal. The symptoms are transient and usually resolve completely within a few days.

Adjustment disorder

A more common psychological response to the onset or deterioration of a medical illness is a less severe but more prolonged emotional reaction. The predominant symptom is usually depression and/or anxiety, which is insufficiently persistent or intense to merit a diagnosis of depressive or anxiety disorder. There may also be anger, aggressive behaviour and excessive alcohol use. Symptoms develop within a month of the onset of the stress, and their duration and severity reflect the course of the underlying physical condition, resolution tending to occur with physical recovery.

Grief reactions following bereavement are a particular type of adjustment disorder. They manifest as a brief period of emotional numbing, followed by a period of distress lasting several weeks, during which sorrow, tearfulness, sleep disturbance, loss of interest and a sense of futility are common. Perceptual distortions may occur, including misinterpreting sounds as the dead person's voice. 'Pathological grief' describes a grief reaction that is abnormally intense or persistent.

Management and prognosis

Ongoing contact with and support from a doctor or other who can listen, reassure, explain and advise are helpful and often all that is needed. Most patients do not require psychotropic medication, although

benzodiazepines reduce arousal in acute stress reactions and can aid sleep in adjustment disorders. Psychotherapy may be helpful for some patients with abnormal grief reactions. These conditions usually resolve with time but can develop into depressive or anxiety disorders.

Post-traumatic stress disorder (PTSD)

This is a protracted response to a stressful event of an exceptionally threatening or catastrophic nature. Examples include natural disasters, terrorist activity, serious accidents and witnessing violent deaths. PTSD may also occur after distressing medical treatments. There is usually a delay ranging from a few days to several months between the traumatic event and the onset of symptoms. Typical symptoms are recurrent intrusive memories (flashbacks) of the trauma, as well as sleep disturbance, especially nightmares (usually of the traumatic event) from which the patient awakes in a state of anxiety, symptoms of autonomic arousal, emotional blunting and avoidance of situations which evoke memories of the trauma. Anxiety and depression are associated and excessive use of alcohol or drugs frequently complicates the clinical picture.

Management and prognosis

Immediate counselling for those who have survived a major trauma is unnecessary and even potentially harmful if forced on people (Box 10.21). It should only be given to those who request it. The main aims are to provide support, direct advice and the opportunity for emotional catharsis. In established PTSD, structured psychological approaches (particularly cognitive therapy) and antidepressant medication are effective. There is some evidence that a novel therapy called eye movement desensitisation and reprocessing (EMDR) is effective. The condition runs a fluctuating course, with most patients recovering within 2 years. In a small proportion the symptoms become chronic.

EBM 10.21 Early debriefing for post-traumatic stress disorder (PTSD)

'At present the routine use of individual debriefing in the aftermath of individual trauma cannot be recommended. Early counselling has been found to be unhelpful and possibly even harmful.'

- Rose S, et al. (Cochrane Review). Cochrane Library, issue 2, 2005. Oxford: Update Software.

For further information:  www.cochrane.org

Anxiety disorders

These are characterised by the emotion of anxiety, worrisome thoughts, avoidance behaviour and the somatic symptoms of autonomic arousal. Anxiety disorders are divided into three main subtypes: phobic, paroxysmal (panic) and generalised (Box 10.22). The nature and prominence of the somatic symptoms often lead the patient to present initially to medical services. Anxiety may be stress-related and phobic anxiety may follow an unpleasant incident. Patients with anxiety often also have depression.

10.22 Classification of anxiety disorders

	Phobic anxiety disorder	Panic disorder	Generalised anxiety disorder
Occurrence	Situational	Paroxysmal	Persistent
Behaviour	Avoidance	Escape	Agitation
Cognitions	Fear of situation	Fear of symptoms	Worry
Symptoms	On exposure	Episodic	Persistent

Phobic anxiety disorder

A phobia is an abnormal or excessive fear of an object or situation, which leads to avoidance of it (such as excessive fear of dying in an air crash leading to avoidance of flying). A generalised phobia of going out alone or being in crowded places is called agoraphobia. Phobic responses can develop to medical interventions such as venepuncture.

Panic disorder

Panic disorder describes repeated attacks of severe anxiety, which are not restricted to any particular situation or circumstances. Somatic symptoms such as chest pain, palpitations and paraesthesiae in lips and fingers are common. The symptoms are in part due to involuntary over-breathing (hyperventilation). Patients often fear they are suffering from a serious illness such as a heart attack or stroke, and may therefore seek emergency medical attention. Panic disorder is often associated with agoraphobia.

Generalised anxiety disorder

This is chronic anxiety associated with uncontrollable worry. Somatic symptoms of muscle tension and bowel disturbance often lead to a medical presentation.

Management of anxiety disorders

Psychological treatment

Explanation and reassurance are essential, especially when patients fear they have a serious medical condition. Specific treatment may be needed. Treatments include relaxation, graded exposure (desensitisation) to feared situations for phobic disorders, and CBT.

Drug treatment

Antidepressants are the drugs of choice. Benzodiazepines are useful in the short term but long-term use can lead to dependence. A β -blocker such as propranolol can help when somatic symptoms are prominent.

Obsessive-compulsive disorder

Obsessive-compulsive disorder (OCD) is characterised by obsessive thoughts, which are recurrent, unwanted and usually anxiety-provoking, and by compulsions, which are repeated acts performed to relieve feelings of tension. An example is repeated hand-washing because of thoughts of contamination. The differential diagnosis is from normal checking behaviour and from delusional beliefs about thought possession. OCD is equally common in men and women.

Management and prognosis

OCD usually responds to antidepressant drugs such as clomipramine, and to CBT which helps patients expose themselves to the feared thought or situation without performing the anxiety-relieving compulsions. Relapses are common and the condition often becomes chronic.

Mood disorders

Mood or affective disorders include:

- *unipolar depression*: one or more episodes of low mood and associated symptoms
- *bipolar disorder*: episodes of elevated mood interspersed with episodes of depression
- *dysthymia*: chronic low-grade depressed mood without sufficient other symptoms to count as 'clinically significant' or 'major' depression.

Depression

Major depressive disorder has a prevalence of 5% in the general population and approximately 10% in chronically ill medical outpatients. It is a major cause of disability and of suicide. If comorbid with a medical condition, depression magnifies disability, diminishes adherence to medical treatment and rehabilitation, and may even shorten life expectancy. Such comorbid depression may incrementally worsen health more than any combination of chronic diseases without depression.

Aetiology

There is a genetic predisposition to depression, especially when of early onset. The number and identity of the genes are largely unknown but the serotonin transporter gene is a candidate. Adversity and emotional deprivation early in life also predispose to depression. Depressive episodes are often triggered by stressful life events (especially those that involve loss), including medical illnesses. Associated biological factors include hypofunction of monoamine neurotransmitter systems (5-HT and noradrenaline (norepinephrine)) and abnormal hypothalamo-pituitary-adrenal axis (HPA) regulation, which results in elevated cortisol levels that do not suppress with dexamethasone. Exclusion of Cushing's syndrome is described on pages 771–772.

Dagnosis

The symptoms are listed in Box 10.8 (p. 233). Depression may be mild, moderate or severe, and episodic, recurrent or chronic. It can be both a complication of a medical condition and a cause of MUS (see below), so physical examination is essential; and an associated medical condition should always be considered (Box 10.23).

10.23 Pointers to an organic cause for psychiatric disorder

- Late age of onset of psychiatric illness
- No previous history of psychiatric illness
- No family history of psychiatric illness
- No apparent psychological precipitant

Management and prognosis

There is evidence that both drug and psychological treatments work in depression. In practice, the choice is determined by patient preference and local availability. Severe depression complicated by psychosis, dehydration or suicide risk may require ECT.

Drug treatment

Antidepressant drugs are effective in patients whose depression is secondary to medical illness, as well as those in whom it is the primary problem (Box 10.24). These agents are all effective in moderate and severe depression. Commonly used antidepressants are shown in Box 10.25.

- *Tricyclic antidepressants (TCAs)*. These agents inhibit the re-uptake of the amines noradrenaline (norepinephrine) and 5-HT at synaptic clefts. The therapeutic effect is noticeable within 1–2 weeks. Side-effects, such as sedation, anticholinergic effects, postural hypotension, lowering of the seizure threshold and cardiotoxicity can be troublesome during this period. TCAs may be dangerous in overdose and in people who have coexisting heart disease, glaucoma and prostatism.
- *Selective serotonin re-uptake inhibitors (SSRIs)*. These are less cardiotoxic and less sedative, and have fewer

EBM 10.24 Antidepressants in the medically ill

'There is evidence to support the use of antidepressants in depressed patients who are also physically ill.'

- Evan DL, et al. *Biol Psychiatry* 2005; 58(3):175–189.

10.25 Antidepressant drugs

Group	Drug	Usual dose*
Tricyclics	Amitriptyline	75–150 mg daily
	Imipramine	75–150 mg daily
	Dosulepin	75–150 mg daily
	Clomipramine	75–150 mg daily
SSRIs	Citalopram	20–40 mg daily
	Escitalopram	10–20 mg daily
	Fluoxetine	20–60 mg daily
	Fluvoxamine	100–300 mg daily
	Sertraline	50–100 mg daily
	Paroxetine	20–50 mg daily
Monoamine oxidase inhibitors (MAOIs)	Phenelzine	45–90 mg daily
	Tranylcypromine	20–40 mg daily
	Moclobemide	300–600 mg daily
Noradrenergic re-uptake inhibitors and SSRIs	Venlafaxine	75–375 mg daily
Selective noradrenaline (norepinephrine) re-uptake inhibitor	Reboxetine	8–12 mg daily
Noradrenergic and specific serotonergic inhibitor	Mirtazapine	15–45 mg daily

*Higher doses may be required: see guidelines.

anticholinergic effects than tricyclics. They are safer in overdose, but can still cause headache, nausea, anorexia and sexual dysfunction.

- **Newer antidepressants.** A variety is available, including venlafaxine, mirtazapine, reboxetine and duloxetine. They have different modes of action and adverse effects but none has been shown to be more effective than the agents listed above.
- **Monoamine oxidase inhibitors (MAOIs).** These drugs increase the availability of neurotransmitters at synaptic clefts by inhibiting metabolism of noradrenaline (norepinephrine) and 5-HT. They are now rarely prescribed in the UK, since they can cause potentially dangerous interactions with drugs such as amphetamines, and foods rich in tyramine such as cheese and red wine. This is due to accumulation of amines in the systemic circulation, causing a potentially fatal hypertensive crisis.
- **Moclobemide.** This is a reversible and selective inhibitor of monoamine oxidase subtype A, which causes minimal potentiation of the pressor response to dietary tyramine.

The different classes of antidepressants have similar efficacy and about three-quarters of patients respond to treatment. Successful treatment requires the patient to take an appropriate dose of an effective drug for an adequate period. In case of non-response it is worth trying a different agent. The patient's progress must be monitored and, after recovery, treatment should be continued for at least 6–12 months to reduce the high risk of relapse; the dose should then be tapered off over several weeks to avoid discontinuation symptoms. In England and Wales, NICE guidelines help with the choice of an antidepressant regimen (www.nice.org.uk).

Psychological treatments

Both CBT and interpersonal psychotherapy are as effective as antidepressants for mild to moderate depression. Antidepressant drugs are, however, preferred for severe depression. Drug and psychological treatments can be used in combination.

Over 50% of people who have had one depressive episode and over 90% of people who have had three or more episodes will have another. The risk of suicide in an individual who has had a depressive disorder is ten times greater than in the general population.

Bipolar disorder

Bipolar disorder is an episodic disturbance with interspersed periods of depressed and elevated mood; the latter is known as hypomania, or mania when severe. The lifetime risk of developing bipolar disorder is approximately 1%. Onset is usually in the teens, and men and women are equally affected. Bipolar disorder has been divided into two types:

- **Bipolar I disorder** has a clinical course characterised by one or more manic episodes or mixed episodes. Often individuals have also had one or more major depressive episodes.
- **Bipolar II disorder** features depressive episodes which are more frequent and more intense than manic episodes, but there is a history of at least one hypomanic episode.

Aetiology

Bipolar disorder is strongly heritable (80%). Relatives of patients have an increased incidence of both bipolar and unipolar affective disorder but life events, such as physical illness and medication, may play a role in triggering episodes.

Diagnosis

Isolated episodes of hypomania or mania do occur but they are usually preceded or followed by an episode of depression. Psychosis may occur in both the depressive and the manic phases, with delusions and hallucinations that are usually in keeping with the mood disturbance. This is described as an affective psychosis. Patients who present with symptoms of both bipolar disorder and schizophrenia may be given a diagnosis of schizoaffective disorder.

Management and prognosis

Depression should be treated, as described above. Manic episodes usually respond well to antipsychotic drugs (see Box 10.28 below). Prophylaxis to prevent recurrent episodes is important. The main drugs used are lithium, carbamazepine and sodium valproate. Lamotrigine and quetiapine are increasingly being used. Caution must be exercised when stopping these, as a relapse may follow.

- **Lithium carbonate** is the drug of choice. It is also used for acute mania, and in combination with a tricyclic as an adjuvant treatment for resistant depression. It has a narrow therapeutic range, so regular blood monitoring is required to maintain a serum level of 0.5–1.0 mmol/L. Toxic effects include nausea, vomiting, tremor and convulsions. With long-term treatment, weight gain, hypothyroidism, nephrogenic diabetes insipidus (p. 792) and renal failure can occur. Thyroid and renal function should be checked before treatment is started and every 6–12 months thereafter. Lithium is teratogenic, as are anti-epileptics, and should never be prescribed during the first trimester of pregnancy.
- **Carbamazepine** and **sodium valproate** are established anticonvulsant drugs that have been used successfully as prophylaxis in bipolar disorder, usually as second-line alternatives to lithium. Both can cause the adverse effects of ataxia, nausea and tremor.

The relapse rate is high, although patients may be perfectly well between episodes. After one episode the annual average risk of relapse is about 10–15%, which doubles after more than three episodes. There is a substantially increased lifetime risk of suicide of 5–10%.

Schizophrenia

Schizophrenia is a psychosis characterised by delusions, hallucinations and lack of insight. Acute schizophrenia may present with disturbed behaviour, marked delusions, hallucinations and disordered thinking, or with insidious social withdrawal and less obvious delusions and hallucinations. The prevalence is similar world-wide at about 1% and the disorder is more common in men. The children of one affected parent have approximately a 10% risk of developing the illness, but this rises to 50%

if an identical twin is affected. The usual age of onset is the mid-twenties.

Aetiology

There is a strong genetic contribution, probably involving many susceptibility genes, each of small effect. The best candidates, such as *disrupted in schizophrenia-1* (*DISC1*) and *neuregulin1* (*NRG1*), have supportive linkage, association, animal model and basic neurobiological evidence. Environmental risk factors include obstetric complications and urban birth. Brain imaging techniques have identified subtle structural abnormalities, including an enlargement of the lateral ventricles and an overall decrease in brain size (by about 3% on average), with relatively greater reduction in temporal lobe volume (5–10%). Episodes of acute schizophrenia may be precipitated by social stress and cannabis, which increase dopamine turnover and sensitivity. Consequently, schizophrenia is now viewed as a neurodevelopmental disorder, caused by abnormalities of brain development associated with genetic predisposition and early environmental influences, but precipitated by later triggers.

Diagnosis

Schizophrenia usually presents with an acute episode and may progress to a chronic state. Acute schizophrenia should be suspected in any individual with bizarre behaviour accompanied by delusions and hallucinations that are not due to organic brain disease or substance misuse. The diagnosis is made on clinical grounds, with investigations used principally to rule out organic brain disease. The characteristic clinical features are listed in Box 10.26. Hallucinations are typically auditory, although they can occur in any sensory modality. They commonly involve voices from outside the head that talk to or about the person. Sometimes the voices repeat the person's thoughts. Patients may also describe 'passivity of thought', experienced as disturbances in the normal privacy of thinking; this is expressed in the belief that their thoughts are being 'withdrawn' from them, perhaps 'broadcast' to others, with alien thoughts being 'inserted' into their mind. Other characteristic symptoms are delusions of control: believing that one's emotions, impulses or acts are controlled by others. Another first-rank phenomenon is delusional perception, a delusion

which arises suddenly alongside a perception (e.g. 'I saw the moon and I immediately knew he was evil'). Many other less specific symptoms may occur, including thought disorder, as manifest by incomprehensible speech, and abnormalities of movement, such as those in which the patient can become immobile or adopt awkward postures for prolonged periods (catatonia).

The main differential diagnosis of schizophrenia is from:

- *Other functional psychoses*, particularly psychotic depression and mania, in which delusions and hallucinations are congruent with a marked mood disturbance (negative in depression and grandiose in mania). If features of schizophrenia and affective disorder coexist in equal measure, a diagnosis of schizoaffective disorder is made. Schizophrenia must also be differentiated from specific delusional disorders that are not associated with the other typical features of schizophrenia (Box 10.27).
- *Organic psychoses*, including delirium, in which there is impairment of consciousness and loss of orientation (not found in the functional psychoses), with typically visual hallucinations and drug misuse, the latter particularly in young people. Schizophrenia must also be differentiated from other organic psychoses such as temporal lobe epilepsy, in which olfactory and gustatory hallucinations may occur (see Box 10.27).

Some of those who experience acute schizophrenia go on to develop a chronic state. The acute, so-called positive symptoms resolve, or at least do not dominate the clinical picture, leaving so-called negative symptoms which include blunt affect, apathy, social isolation, poverty of speech and poor self-care. Patients with chronic schizophrenia may also manifest positive symptoms, particularly when under stress, and it can be difficult for those who do not know the patient to judge whether or not these are signs of an acute relapse.

10.26 Symptoms of schizophrenia

First-rank symptoms of acute schizophrenia

- A = Auditory hallucinations—second or third person/écho de la pensée
- B = Broadcasting, insertion/withdrawal of thoughts
- C = Controlled feelings, impulses or acts ('passivity' experiences/phenomena)
- D = Delusional perception (a particular experience is bizarrely interpreted)

Symptoms of chronic schizophrenia (negative symptoms)

- Flattened (blunted) affect
- Apathy and loss of drive (avolition)
- Social isolation
- Poverty of speech
- Poor self-care

10.27 Differential diagnosis of schizophrenia

Alternative diagnosis	Distinguishing features
Other functional psychoses	
Delusional disorders	Absence of specific features of schizophrenia
Psychotic depression	Prominent depressive symptoms
Manic episode	Prominent manic symptoms
Schizoaffective disorder	Mood and schizophrenia symptoms both prominent
Puerperal psychosis	Acute onset after childbirth
Organic disorders	
Drug-induced psychosis	Evidence of drug or alcohol misuse
Side-effects of prescribed drugs	Levodopa, methylidopa, corticosteroids, antimalarial drugs
Temporal lobe epilepsy	Other evidence of seizures
Delirium	Visual hallucinations; impaired consciousness
Dementia	Age; established cognitive impairment
Huntington's disease	Family history; choreiform movements; dementia

Management

First-episode schizophrenia usually requires admission to hospital because patients lack insight that they are ill and are unwilling to accept treatment. In some cases, they may be at risk of harming themselves or others. Subsequent acute relapses and chronic schizophrenia are now usually managed in the community.

Drug treatment

Antipsychotic agents are effective against the positive symptoms of schizophrenia in the majority of cases. They take 2–4 weeks to be maximally effective, but have some beneficial effects shortly after administration. Treatment is then ideally continued to prevent relapse. In a patient with a first episode of schizophrenia, this will usually be for 1–2 years, but in patients with multiple episodes, treatment may be required for many years. The benefits of prolonged treatment must be weighed against the adverse effects, which include tardive dyskinesia (abnormal movements, commonly of the face, over which the patient has no voluntary control). For long-term use, antipsychotic agents are often given in slow-release (depot) injected form to improve patient adherence.

A number of antipsychotic agents are available (Box 10.28). These may be divided into conventional (typical, first-generation) drugs such as chlorpromazine and haloperidol, and newer or atypical (also so-called novel or second-generation) drugs such as clozapine. All are believed to work by blocking D₂ dopamine receptors in the brain. Patients who have not responded to conventional drugs may respond to newer agents, which are also less likely to produce unwanted extrapyramidal side-effects but do tend to cause greater weight gain. Clozapine can also cause an agranulocytosis and consequently requires regular monitoring of the white blood cell count, initially on a weekly basis. Details of the side-effects of antipsychotic drugs are listed in Box 10.29.

10.28 Antipsychotic drugs		
Group	Drug	Usual dose
Phenothiazines	Chlorpromazine	100–1500 mg daily
	Trifluoperazine	5–30 mg daily
	Fluphenazine	20–100 mg fortnightly
Butyrophenones	Haloperidol	5–30 mg daily
Thioxanthenes	Flupentixol decanoate	20–200 mg fortnightly (depot injection)
Diphenylbutylpiperidines	Pimozide	4–30 mg daily
Substituted benzamides	Sulpiride	200–1800 mg daily
Dibenzodiazepines*	Clozapine	25–900 mg daily
Benzisoxazole*	Risperidone	2–16 mg daily
Thienobenzodiazepines*	Olanzapine	5–20 mg daily
Dibenzothiazepines	Quetiapine	200–800 mg daily

*Second-generation antipsychotics.

10.29 Side-effects of antipsychotic drugs

Weight gain due to increased appetite

Effects due to dopamine blockade*

- Parkinsonism
- Akathisia (motor restlessness)
- Acute dystonia
- Tardive dyskinesia
- Gynaecomastia
- Galactorrhoea

Effects due to cholinergic blockade

- Dry mouth
- Blurred vision
- Constipation
- Urinary retention
- Impotence

Hypersensitivity reactions

- Cholestatic jaundice
- Photosensitive dermatitis
- Blood dyscrasias (neutropenia with clozapine)

Ocular complications (long-term use)

- Corneal and lens opacities

*Less severe with clozapine, quetiapine and olanzapine because of strong 5-HT-blocking effect and relatively weak dopamine blockade.

Serious adverse effects of antipsychotic drugs include:

- *Neuroleptic malignant syndrome*, which is rare but serious. It is characterised by fever, tremor and rigidity, autonomic instability and confusion. Characteristic laboratory findings are an elevated creatinine phosphokinase and leucocytosis. Antipsychotic medication must be stopped immediately and supportive therapy provided, often in an intensive care unit. Treatment includes ensuring hydration and reducing hyperthermia. Dantrolene sodium and bromocriptine may be helpful. Mortality is 20% untreated and 5% with treatment.
- *Prolongation of the QT_c interval*, which may be associated with ventricular tachycardia, torsades de pointes and sudden death. Treatment is by stopping the drug, monitoring the ECG and treating serious arrhythmias (p. 559).

Psychological treatment

Psychological treatment, including general support for the patient and his or her family, is now seen as an essential component of the therapeutic plan. CBT may help patients to cope with treatment-resistant symptoms. There is evidence that personal and/or family education reduces the rate of relapse.

Social treatment

After an acute episode of schizophrenia has been controlled by drug therapy, social rehabilitation may be required. Recurrent illness is likely to cause disruption to patients' relationships and their ability to manage their accommodation and occupation; consequently, they may need help to obtain housing and employment. A graded return to employment and sometimes a period of supported accommodation are required.

Patients with chronic schizophrenia have particular difficulties and may need long-term supervised accommodation. This was previously provided in mental hospitals but now tends to be in sheltered or hostel accommodation in the community. Patients may also benefit from sheltered employment if they are unable to participate effectively in the labour market. Ongoing contact with a health worker allows monitoring for signs of relapse so that treatment can be administered early. This is sometimes called 'assertive outreach', with multidisciplinary teams working to agreed plans (a 'care programme approach'). Partly because of a tendency to inactivity, smoking and a poor diet, patients with chronic schizophrenia are at increased risk of cardiovascular disease, diabetes and tuberculosis, and require medical as well as psychiatric care.

Prognosis

About one-quarter of those who develop an acute schizophrenic episode have a good outcome. One-third develop chronic schizophrenia, and the remainder recover after each episode but suffer relapses. Most will not work or live independently. Prophylactic treatment with antipsychotic drugs reduces the rate of relapse in the first 2 years after an episode of schizophrenia from 70% to 40%. Schizophrenia is associated with suicide, 1 in 10 patients taking their own lives.

Alcohol misuse and dependence

Alcohol consumption associated with social, psychological and physical problems constitutes harmful use. The criteria for alcohol dependence, a more restricted term, are shown in Box 10.30. Approximately one-quarter of male patients in general hospital medical wards in the UK have a current or previous alcohol problem.

Aetiology

Availability of alcohol and social patterns of use appear to be the most important factors. Genetic factors may play some part in predisposition to dependence. The majority of alcoholics do not have an associated psychiatric illness, but a few drink heavily in an attempt to relieve anxiety or depression.

Diagnosis

Alcohol misuse may emerge during the patient's history, although patients may minimise their intake. It may also present via its effects on one or more aspects of the patient's life, listed below. Alcohol dependence commonly presents with withdrawal in those admitted to hospital, as they can no longer maintain their high alcohol intake in this setting.

10.30 Criteria for alcohol dependence

- Narrowing of the drinking repertoire
- Priority of drinking over other activities (salience)
- Tolerance of effects of alcohol
- Repeated withdrawal symptoms
- Relief of withdrawal symptoms by further drinking
- Subjective compulsion to drink
- Reinstatement of drinking behaviour after abstinence

Complications of chronic alcohol misuse

Social problems include absenteeism from work, unemployment, marital tensions, child abuse, financial difficulties and problems with the law, such as violence and traffic offences.

Psychological problems

- *Depression* is common. Alcohol has a direct depressant effect and heavy drinking creates numerous social problems. Attempted suicide and completed suicide are often associated with alcohol misuse.
- *Anxiety* is relieved by alcohol. People who are socially anxious may consequently use alcohol in this way and may develop dependence. Conversely, alcohol withdrawal increases anxiety.
- *Alcoholic hallucinosis* is a rare condition in which alcoholic individuals experience auditory hallucination in clear consciousness.
- *Alcohol withdrawal* is described in Box 10.30. Symptoms usually become maximal about 2 days after the last drink and can include seizures ('rum fits').
- *Delirium tremens* is a form of delirium associated with severe alcohol withdrawal. It has a significant mortality and morbidity (see Box 10.31).

Effects on the brain

The familiar features of drunkenness are ataxia, slurred speech, emotional incontinence and aggression. Very heavy drinkers may experience periods of amnesia for events which occurred during bouts of intoxication, termed 'alcoholic blackouts'. Established alcoholism may lead to alcoholic dementia, a global cognitive impairment resembling Alzheimer's disease, but which does not progress and may even improve if the patient becomes abstinent. Indirect effects on behaviour can result from head injury, hypoglycaemia and encephalopathy (p. 938).

A rare but important effect of chronic alcohol misuse is the Wernicke-Korsakoff syndrome. This organic brain disorder results from damage to the mamillary bodies, dorsomedial nuclei of the thalamus and adjacent areas of periventricular grey matter. It is caused by a deficiency of thiamin (vitamin B₁), which is most commonly caused by long-standing heavy drinking and an inadequate diet. Without prompt treatment (see below), the acute presentation of Wernicke's encephalopathy (nystagmus, ophthalmoplegia, ataxia and confusion) can progress to the irreversible deficits of Korsakoff's syndrome (severe short-term memory deficits and confabulation). In those who die in the acute stage, microscopic examination of the brain shows hyperaemia, petechial haemorrhages and astrocytic proliferation.

Effects on other organs

These are protean and virtually any organ can be involved (see Box 10.31); alcohol has replaced syphilis as the great mimic of disease. These effects are discussed in detail in the relevant chapters.

Management and prognosis

The provision of clear information from a doctor about the harmful effects of alcohol and safe levels of consumption is often all that is needed. In more serious cases, patients may have to be advised to alter leisure activities or change jobs if these are contributing to the problem. Psychological treatment is used for patients who have

10.31 Consequences of chronic alcohol misuse

Acute intoxication

- Emotional and behavioural disturbance
- Medical problems: hypoglycaemia, aspiration of vomit, respiratory depression
- Complicating other medical problems
- Accidents, and injuries sustained in fights

Withdrawal phenomena

- Psychological symptoms: restlessness, anxiety, panic attacks
- Autonomic symptoms: tachycardia, sweating, pupil dilatation, nausea, vomiting
- Delirium tremens: agitation, hallucinations, illusions, delusions
- Seizures

Harmful use

Medical consequences

- Neurological: peripheral neuropathy, cerebellar degeneration, cerebral haemorrhage, dementia
- Hepatic: fatty change and cirrhosis, liver cancer
- Gastrointestinal: oesophagitis, gastritis, pancreatitis, oesophageal cancer, Mallory–Weiss syndrome, malabsorption, oesophageal varices
- Respiratory: pulmonary TB, pneumonia
- Skin: spider naevi, palmar erythema, Dupuytren's contractures, telangiectasiae
- Cardiac: cardiomyopathy, hypertension
- Musculoskeletal: myopathy, fractures
- Endocrine and metabolic: pseudo-Cushing's syndrome, hypoglycaemia, gout
- Reproductive: hypogonadism, fetal alcohol syndrome, infertility

Psychiatric and cerebral consequences

- Depression
- Alcoholic hallucinosis
- Alcoholic 'blackouts'
- Wernicke's encephalopathy: nystagmus, ophthalmoplegia, ataxia, confusion
- Korsakoff's syndrome: short-term memory deficits, confabulation

recurrent relapses and is usually available at specialised centres. Support is also provided by voluntary organisations, such as Alcoholics Anonymous (AA) in the UK.

If alcohol dependence is suspected, withdrawal syndromes can be prevented, or treated once established, with benzodiazepines. Large doses may be required (e.g. diazepam 20 mg 6-hourly), tailed off over a period of 5–7 days as symptoms subside. Prevention of the Wernicke–Korsakoff complex requires the immediate use of high doses of thiamin, which is given parenterally in the form of Pabrinex (p. 1199). There is no treatment for Korsakoff's syndrome once it has arisen. The risk of side-effects, such as respiratory depression with benzodiazepines and anaphylaxis with Pabrinex, is small when weighed against the risks of no treatment.

Disulfiram (200–400 mg daily) can be given as a deterrent to patients who have difficulty resisting the impulse to drink after becoming abstinent. It blocks the metabolism of alcohol, causing acetaldehyde to accumulate.

When alcohol is consumed, an unpleasant reaction follows with headache, flushing and nausea. Disulfiram is always an adjunct to other treatments, especially supportive psychotherapy. Acamprosate (666 mg 8-hourly) has recently been introduced to maintain abstinence by reducing the craving for alcohol. Only rarely are antidepressants required; depressive symptoms, if present, usually resolve with abstinence. Antipsychotics (e.g. chlorpromazine 100 mg 8-hourly) are required for alcoholic hallucinosis.

Many but not all who become dependent on alcohol relapse after treatment. Chronic alcohol misuse greatly increases the risk of death from accidents, disease and suicide.

Substance misuse disorder

Dependence on and misuse of both illegal and prescribed drugs is a major problem world-wide. Drugs of misuse are described in detail in Chapter 9. They can be grouped as follows.

Sedatives

These commonly give rise to physical dependence, the manifestations being tolerance and a withdrawal syndrome. They include benzodiazepines, opiates (including morphine, heroin, methadone and dihydrocodeine) and barbiturates (now rarely prescribed). Overdose can be dangerous with the opiates and benzodiazepines, primarily as a result of respiratory depression (Ch. 9). Withdrawal from opiates is notoriously unpleasant, and withdrawal from benzodiazepines (Box 10.32) and barbiturates may be dangerous because of seizures.

Intravenous opiate users are prone to bacterial infections, hepatitis B, hepatitis C (pp. 948–954) and HIV infection (Ch. 14) through needle contamination. Accidental overdose is common, mainly because of the varied and uncertain potency of illicit supplies of the drug. The withdrawal syndrome, which can start within 12 hours of the drug's last use, presents with intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

Stimulants

These include amphetamines and cocaine. They are less dangerous than the sedatives in overdose, although they can cause cardiac and cerebrovascular problems through their pressor effects. With prolonged heavy use, psychiatric disturbance can be prominent. Physical dependence syndromes do not arise, but withdrawal causes a rebound lowering in mood and can give rise to an intense craving for further use, especially in any form of

10.32 Benzodiazepine withdrawal symptoms

- Anxiety
- Heightened sensory perception
- Hallucinations
- Epileptic seizures
- Ataxia
- Paranoid delusions

drug with a rapid onset and offset of effect such as crack cocaine. Chronic ingestion can cause a syndrome similar to schizophrenia. A toxic psychosis can occur with high levels of consumption, and tactile hallucinations (formication) may be prominent.

Hallucinogens

The hallucinogens are a disparate group of drugs that cause prominent sensory disturbances. They include cannabis, ecstasy, lysergic acid diethylamide (LSD) and *Psilocybin* (magic mushrooms).

A toxic confusional state can occur after heavy cannabis consumption. Acute psychotic episodes are well recognised, especially in those with a family or personal history of psychotic illness, and there is evidence that prolonged heavy use increases the risk of developing schizophrenia. Paranoid psychoses have been reported in association with ecstasy. A chronic psychotic illness has also been reported after regular LSD use.

Organic solvents

Solvent inhalation (glue sniffing) is popular in some adolescent groups. Solvents produce acute intoxication characterised by euphoria, excitement, dizziness and a floating sensation. Further inhalation leads to loss of consciousness; death can occur from the direct toxic effect of the solvent, or from asphyxiation if the substance is inhaled from a plastic bag.

Aetiology

Many of the aetiological factors for alcohol misuse also apply to drug dependence. The main factors are cultural pressures, particularly within a peer group, and availability of a drug. In the case of some drugs, medical overprescribing has increased their availability, but there has also been a relative decline in the price of illegal drugs. Most drug users take a range of drugs – so-called polydrug misuse.

Diagnosis

As with alcohol, the diagnosis either may be apparent from the history, or may only be made once the patient presents with a complication. Drug screening of samples of urine or blood can be very valuable in confirming the diagnosis, especially if the patient persists in denial.

Management and prognosis

The first step is to determine whether patients wish to stop using the drug. If they do not, they can still benefit from advice about how to minimise harm from their habit: for example, advice to use clean needles for those who inject. For those who are physically dependent on sedative drugs, substitute prescribing (using methadone, for example, in opiate dependence) may help stabilise their lifestyles sufficiently to allow a gradual reduction in dosage until they reach abstinence. Some specialist units offer inpatient detoxification. For details of the medical management of overdose, see Chapter 9.

The drug lofexidine, a centrally acting α -agonist, can be useful in treating the autonomic symptoms of opiate withdrawal, as can clonidine, although this carries a risk of hypotension and is best used by specialists. Long-

acting opiate antagonists, such as naltrexone, may also have a place, again in specialist hands, in blocking the euphoriant effects of the opiate, which may aid in breaking patterns of addiction.

In some cases, complete opiate withdrawal is not successful and the patient functions better if maintained on regular doses of oral methadone as an outpatient. This decision should only be taken by a specialist, and long-term supervision requires the patient to attend a specialist drug treatment centre.

Substitute prescribing is neither necessary nor possible for the hallucinogens and stimulants, so the principles of management are the same as those that should accompany prescribing for the sedatives. These include identifying problems associated with the drug misuse which may serve to maintain it, and intervening where possible. Intervention may be directed at physical ill health, psychiatric comorbidity, social problems or family disharmony.

Relapsing patients and those with complications should be referred to specialist drug misuse services. Support can also be provided by self-help groups and voluntary bodies such as Narcotics Anonymous in the UK.

Delirium, dementia and organic disorders

Delirium, dementia and other organic disorders can be thought of as medical conditions rather than psychiatric disorders, but are included in psychiatric classifications and sometimes misdiagnosed because they manifest with disturbed behaviour.

Delirium

Delirium is common in acute medical settings, affecting more than half of patients in high-dependency and intensive care units. Aetiology, assessment and management are described in Chapters 26 and 7.

Dementia

Dementia affects 5% of those over 65 and 20% of those over 85. It is defined as a global impairment of cognitive function, and although memory is most affected in the early stages, deficits in visuo-spatial function, language ability, concentration and attention gradually become apparent. Aetiology and investigation are described in Chapter 26. Management is essentially symptomatic and supportive. The anticholinesterase inhibitors, such as donepezil, may arrest progression for a time in Alzheimer-type dementia, while addressing the underlying vascular risk factors may slow deterioration in vascular dementia, but neither can be reversed. Psychotropic drugs may help where there is associated disturbance of sleep, perception or mood, but should only be used with care, especially since evidence shows increased mortality in patients treated long term with these agents. Sedation is not a substitute for good community support for patients and carers or, in the later stages, attentive residential nursing care. In the UK, incapacity and mental health legislation may be required to manage patients' financial and domestic affairs, as well as to determine safe placement. Most dementias have a progressive

course, which may be gradual (as in Alzheimer's disease) or step-wise (as in vascular dementia).

Personality disorders

Personality is the set of characteristics and behavioural traits which best describes an individual's patterns of interaction with the world. The intensity of particular traits varies from person to person, although many, such as shyness or irritability, are displayed to some degree by most people.

A personality disorder is diagnosed when an individual's personality causes persistent and severe problems for the person himself or herself or for others. For example, shyness may be so pronounced that the individual never ventures into any situation where he/she fears scrutiny, so that that person's life becomes narrow and empty. Antisocial traits, such as disregard for the well-being of others and a lack of guilt concerning the adverse effects of one's actions on others, may lead to damage to others and to criminal acts.

Personality disorder is classified into 8–10 types (such as emotionally unstable, antisocial or schizotypal), depending on the particular behavioural traits in question. There are differences between ICD-10 and DSM-IV classifications. A patient who meets diagnostic criteria for one subtype commonly meets criteria for two or three others. As allocation to one particular subtype gives little guidance to management or prognosis, classification is of limited value. Personality disorder commonly accompanies other psychiatric conditions, making treatment of those conditions more difficult and therefore affecting their prognosis.

Aetiology

Some personality disorders appear to have an inherited aspect but most are more clearly related to an unsatisfactory upbringing and childhood abuse.

Management and prognosis

Personality disorder is largely untreatable. There is little evidence of benefit from psychotropics, and limited evidence for the value of psychotherapy. Furthermore, any such treatment has to be intensive and/or long-term if it is to effect any substantial change. By definition, personality disorders tend to persist throughout life, although they may become less extreme with age.

Eating disorders

There are two well-defined eating disorders, anorexia nervosa (AN) and bulimia nervosa (BN), which share some overlapping features. Ninety per cent of cases are female. There is a much higher prevalence of abnormal eating behaviour in the population which does not meet diagnostic criteria for AN or BN. In developed societies, obesity is arguably a much greater problem but is usually considered to be more a disorder of lifestyle or physiology than a psychiatric illness.

Anorexia nervosa

There is marked weight loss, arising from food avoidance, often in combination with bingeing, purging,

excessive exercise, or the use of diuretics and laxatives. Body image is profoundly disturbed so that, despite emaciation, patients still feel overweight and are terrified of weight gain. These preoccupations are intense and pervasive, and the false beliefs may be held with a conviction approaching the delusional. Anxiety and depressive symptoms are common accompaniments. Downy hair (lanugo) may develop on the back, forearms and cheeks. Extreme starvation is associated with a wide range of physiological and pathological bodily changes. All organ systems may be affected, although the most serious problems are cardiac and skeletal (Box 10.33).

Aetiology

This is unknown but probably includes genetic and environmental factors, including the social pressure on women to be thin.

Diagnosis

The condition usually emerges in adolescence, with a marked female preponderance. Diagnostic criteria are shown in Box 10.34. Differential diagnosis covers other causes of weight loss, including psychiatric disorders such as depression, and medical conditions such as inflammatory bowel disease, malabsorption, hypopituitarism and cancer. The diagnosis is made on the presence of a pronounced fear of fatness despite being thin, and on the absence of alternative causes of weight loss.

Management and prognosis

The aims of management are to ensure the patient's physical well-being, whilst helping her to increase her weight to the normal range by addressing abnormal beliefs and behaviour. Treatment is usually given on an outpatient basis, inpatient treatment being indicated only if weight loss is intractable and severe (for example, less than 65% of normal), or if there is a risk of death from medical complications or from suicide. There is a limited evidence base for treatment, although individual

10.33 Physical consequences of eating disorders

Cardiac

- ECG abnormalities: T wave inversion, ST depression and prolonged QT_c interval
- Arrhythmias, including profound sinus bradycardia and ventricular tachycardia

Haematological

- Anaemia, thrombocytopenia and leucopenia

Endocrine

- Pubertal delay or arrest
- Growth retardation and short stature
- Amenorrhoea
- Sick euthyroid state

Metabolic

- Uraemia
- Renal calculi
- Osteoporosis

Gastrointestinal

- Constipation
- Abnormal liver function tests

10.34 Diagnostic criteria for eating disorders

Anorexia nervosa

- Weight loss of at least 15% of total body weight (or body mass index ≤ 17.5)
- Avoidance of high-calorie foods
- Distortion of body image so that patients regard themselves as fat even when grossly underweight
- Amenorrhoea for at least 3 months

Bulimia nervosa

- Recurrent bouts of binge eating
- Lack of self-control over eating during binges
- Self-induced vomiting, purgation or dieting after binges
- Weight maintained within normal limits

psychological treatments, particularly CBT and family therapy, are commonly used. Psychotropic drugs are of little benefit except in those with clear-cut comorbid depressive disorder.

Weight gain is best managed in a collaborative fashion. Compulsory admission and refeeding (including tube feeding) are very occasionally resorted to when patients are at risk of death and other measures have failed. Whilst this may produce a short-term improvement in weight, it probably does not change long-term prognosis. About 20% of patients with anorexia nervosa have a good outcome, a further 20% develop a chronic intractable disorder and the rest have an intermediate outcome. There is a long-term mortality rate of 10–20%, either due to the complications of starvation or from suicide.

Bulimia nervosa

In BN, patients are usually at or near normal weight (unlike in AN), but display a morbid fear of fatness associated with disordered eating behaviour. They recurrently embark on eating binges, often followed by corrective measures such as self-induced vomiting. The prevalence is similar to or slightly greater than that of AN, but only a small proportion of sufferers reach treatment services.

Diagnosis

BN usually begins later in adolescence than AN, and is even more predominantly a female malady. Diagnostic criteria are shown in Box 10.33. Physical signs of repeated self-induced vomiting include pitted teeth (from gastric acid), calluses on knuckles ('Russell's sign') and parotid gland enlargement. There are many associated physical complications, including the dental and oesophageal consequences of repeated vomiting, as well as electrolyte abnormalities, cardiac arrhythmias and renal problems (see Box 10.32).

Management and prognosis

CBT achieves short- and long-term improvements. Guided self-help and interpersonal psychotherapy may also be of value. There is also evidence for benefit from the SSRI, fluoxetine, although high doses (60 mg daily) and long courses (1 year) may be required; this appears to be independent of the antidepressant effect.

Bulimia does not carry the mortality associated with AN, and few sufferers develop anorexia. At 10 years, approximately 10% are still unwell, 20% have a subclinical degree of BN, and the remainder have recovered.

Somatoform disorders

The essential feature of these disorders is somatic symptoms which are not explained by a medical condition (MUS) and not better diagnosed as part of a depressive or anxiety disorder. Several syndromes are described within this category; there is considerable overlap between them in both aetiology and clinical presentation.

Aetiology

The cause of somatoform disorders is incompletely understood but contributory factors include depression or anxiety, the erroneous interpretation of somatic symptoms as evidence of disease, and excessive concern with physical illness. A family history or previous history of a particular condition may have shaped the patient's beliefs about illness. Doctors may exacerbate the problem, either by dismissing the complaints as non-existent or by over-emphasising the possibility of disease.

Somatisation disorder

Somatisation disorder (Briquet's syndrome) is characterised by the occurrence of chronic multiple somatic symptoms for which there is no physical cause. Symptoms start in early adult life and may be referred to any part of the body. It is much more common in women. Common complaints include pain, vomiting, nausea, headache, dizziness, menstrual irregularities and sexual dysfunction. Patients may undergo a multitude of negative investigations and unhelpful operations, particularly hysterectomy and cholecystectomy. There is no proven treatment but minimisation of iatrogenic harm from investigation and attempts at medical treatment is important.

Hypochondriacal disorder

Patients with hypochondriasis have a strong fear or belief that they have a serious, often fatal, disease that persists despite appropriate medical reassurance. They are typically anxious and seek many medical opinions and investigations in futile but repeated attempts to relieve their fears. CBT may be helpful. The condition may become chronic.

In a small proportion of cases, the conviction that disease is present reaches delusional intensity, the best-known example being that of parasitic infestation ('delusional parasitosis'), which leads patients to consult dermatologists. Antipsychotic medication may be effective.

Body dysmorphic disorder

This describes a preoccupation with bodily shape or appearance, with the belief that one is disfigured in some way (previously known as dysmorphophobia). People with this condition may make inappropriate requests for cosmetic surgery. CBT may be helpful. The belief in disfigurement may sometimes be delusional, in which case antipsychotic drugs may help.

Somatoform autonomic dysfunction

This describes somatic symptoms referable to bodily organs which are largely under the control of the autonomic nervous system. The most common examples involve the cardiovascular system (cardiac neurosis), respiratory system (psychogenic hyperventilation) and gut (psychogenic vomiting and irritable bowel syndrome). Antidepressant drugs and CBT may be helpful.

Somatoform pain disorder

This describes severe, persistent pain which cannot be explained by a medical condition. Antidepressant drugs (especially tricyclics and dual action drugs such as duloxetine and mirtazapine) are helpful, as are some of the anticonvulsant drugs, particularly carbamazepine and gabapentin. CBT and multidisciplinary pain management teams are also useful.

Chronic fatigue syndrome

Neurasthenia is characterised by excessive fatigue after minimal physical or mental exertion, poor concentration, dizziness, muscular aches and sleep disturbance. This pattern of symptoms may follow a viral infection such as infectious mononucleosis, influenza or hepatitis. Symptoms overlap considerably with those of depression and anxiety. There is evidence that many patients improve with carefully graded exercise and with CBT.

Dissociative (conversion) disorder

This has replaced the term 'hysteria' in the ICD-10 classification. It is characterised by a loss or distortion of neurological function not fully explained by organic disease. The most common symptoms mimic lesions in the motor or sensory nervous system (Box 10.35). Dissociative disorder can also involve psychological functions, especially memory and general intelligence. The aetiology of dissociation is unknown. It has been considered to be the result of unconscious psychological processes and there is an association with adverse childhood experiences, including physical and sexual abuse. Organic disease may facilitate dissociative mechanisms and provide a model for symptoms; thus, for example, non-epileptic seizures may occur in those with epilepsy. Coexisting depression should be treated with CBT or antidepressant drugs.

10.35 Common presentations of dissociative (conversion) disorder

- Gait disturbance
- Loss of function in limbs
- Aphonia
- Non-epileptic seizures
- Sensory loss
- Blindness

General management of patients with medically unexplained symptoms

Management of the various syndromes of medically unexplained complaints described above is based on general principles (Box 10.36) and specific measures for individual syndromes.

Reassurance

Patients should be asked what they are most worried about. Clearly, it may be unwise to state categorically

10.36 General management principles for medically unexplained symptoms

- Take a full, sympathetic history
- Exclude disease but avoid unnecessary investigation or referral
- Seek specific treatable psychiatric syndromes
- Demonstrate to patients that you believe their complaints
- Establish a collaborative relationship
- Give the patient a positive explanation including but not over-emphasising psychological factors
- Encourage a return to normal functioning

that the patient has no disease but it can be emphasised that the probability of having disease is low. If patients repeatedly ask for reassurance about the same issue, they may have hypochondriasis.

Explanation

Patients need a positive explanation for their symptoms. It is unhelpful to say that symptoms are psychological or 'all in the mind', but useful to describe a plausible physiological mechanism for the symptom that emphasises the link with psychological factors such as stress and which demonstrates that the symptoms are reversible. For example, in irritable bowel syndrome, psychological stress results in increased activation of the autonomic nervous system which leads to constriction of smooth muscle in the gut wall, which in turn causes pain.

Advice

This should focus on how to overcome probable perpetuating factors: for example, by resolving stressful social problems or by practising relaxation. The doctor can offer to review progress, to prescribe (for example) an antidepressant drug and, if appropriate, to refer for physiotherapy or psychological treatments. The attitudes of relatives may need to be addressed if they have adopted an over-protective role, unwittingly reinforcing the patient's disability.

Drug treatment

Antidepressant drugs are often helpful, even if the patient is not depressed (Box 10.37).

Psychological treatment

There is moderate evidence for the effectiveness of CBT (Box 10.38). Other psychological treatments may also have a role.

10.38 CBT for medically unexplained somatic symptoms

'CBT is the best established treatment for a variety of somatoform disorders.'

- Kroenke K. Psychosom Med 2007; 69:881–888.

Rehabilitation

Where there is chronic disability, particularly in dissociative disorder, conventional physical rehabilitation may be the best approach.

Shared care with the GP

Ongoing planned care is required for patients with chronic intractable symptoms, especially somatisation disorder. Review by the same specialist, interspersed with visits to the GP, is probably the best way to avoid unnecessary re-referral for investigation, to ensure that treatable aspects of the patient's problems such as depression are actively managed, and also to prevent the GP from becoming demoralised by feelings of helplessness.

Factitious disorders and malingering

It is important to distinguish somatoform disorders from factitious disorder and malingering.

Factitious disorder

This describes the repeated and deliberate production of the signs or symptoms of disease, apparently to obtain medical care. It is uncommon and typically presents in young women who work in paramedical professions. Examples include the dipping of thermometers into hot drinks to fake a fever, or patients with diabetes who deliberately induce hypo- and hyperglycaemic episodes. The factitious disorder is usually medical but may relate to a psychiatric illness, with reports of hallucinations or depressive illness.

Münchhausen's syndrome

This refers to a severe chronic form of factitious disorder. Patients are usually older and male, with a solitary, peripatetic lifestyle in which they travel widely, sometimes visiting several hospitals in one day. Although the condition is rare, such patients are memorable because they present so frequently and so dramatically. The history can be convincing enough to persuade doctors to undertake investigations or initiate treatment, including exploratory surgery. It may be possible to trace the patient's history and show that he has presented similarly elsewhere, often changing name several times. Some emergency departments hold lists of such patients.

Management is by gentle but firm confrontation with clear evidence of the fabrication of illness, together with an offer of psychological support. Treatment is usually declined but recognition of the condition may help to avoid further iatrogenic harm.

Malingering

Malingering is a description of a behaviour, not a psychiatric diagnosis. It refers to the conscious simulation of signs of disease and disability. Patients have motives which are clear to them but which they conceal from doctors. Examples include the avoidance of burdensome responsibilities (such as work or court appearances) or the pursuit of financial gain (fraudulent claims for benefits or compensation). Malingering can be hard to detect at clinical assessment, but is suggested by evasion or inconsistency in the history.

Puerperal disorders

There are three common psychiatric complications of childbirth. When managing these conditions, it is important always to consider both the mother and the baby, and their relationship (Box 10.39).

Post-partum blues

These are characterised by irritability, labile mood and tearfulness. Most women are affected to some degree. Symptoms begin soon after childbirth, peak on about the fourth day and then resolve. They may be related to hormonal or psychological changes associated with childbirth. No treatment is required, other than to reassure the mother.

Post-partum depression

This occurs in 10–15% of women and within a month of delivery. Women with a previous history of depression are at risk. Explanation and reassurance are important. The usual psychological and drug treatments for depression should be considered, as well as practical help with childcare. If hospital admission is required, it should ideally be to a mother and baby unit. Further episodes of depression, both after childbirth and in response to other stressors, are likely.

Puerperal psychosis

This has its onset in the first 2 weeks after childbirth. It is a rare but serious complication affecting about 1 in 500 women and usually takes the form of a manic or depressive psychosis, although a schizophrenic psychosis can also occur. Delirium is rare with modern obstetric management but should still be considered in the differential diagnosis. Management depends on the type of psychosis that presents. In addition, it is important to consider the baby, and especially so to establish whether the mother has ideas of harming it. If so, the risk to the baby must be assessed and, if necessary, the baby temporarily removed. Most women recover but are at an increased (25%) risk of puerperal psychosis with the next pregnancy, and a 50% lifetime risk. Admission to a psychiatric mother and baby unit may be required.

10.39 Psychiatric illness and pregnancy

- Always consider the effects of psychiatric disorder and treatment on mother, fetus and neonate
- Lithium, carbamazepine and valproate are significant teratogens, so minimise their use
- Most cases of post-partum low mood ('blues') are transient
- However, persistent low mood may indicate depressive illness
- Puerperal psychosis usually requires psychiatric admission

PSYCHIATRY AND THE LAW

Medicine takes place in a legal framework, made up of legislation (statute law) drafted by parliament or other governing bodies, and common law (case law) built up from court judgements over time. Psychiatry differs from other branches of medicine in that patients can be subject to legislative requirements to remain in hospital or to

undergo treatments they refuse, such as the administration of antipsychotic drugs to a patient with acute schizophrenia who lacks insight, and whose symptoms and/or behaviour pose a risk to himself/herself or to others.

The UK has three different Mental Health Acts, covering England and Wales, Scotland, and Northern Ireland, and all of these have recently been revised. Other countries may have very different provisions. It is important for practitioners to be familiar with the relevant provisions that apply in their jurisdictions, and are likely to arise in the clinical settings in which they work.

Scotland has an Incapacity Act, with detailed provisions covering medical treatments for patients incapable of consenting, whether this incapacity arises from physical or mental illness. Similar legislation is being introduced elsewhere in the UK. In general, the guiding principle in British law is that people should be free to make their own decisions about medical treatment, except where their ability to decide is impaired by mental illness or physical incapacity, and where there are clear risks to the health and safety of themselves or others. Any restrictions or compulsions applied should be the minimum necessary, and they should only be applied for as long as is necessary; there should also be provisions for appeals and oversight.

Examination of the skin

Important features of skin lesions that should alert suspicion include:

- Asymmetry: irregular shape
- Bleeding
- Border: not a smooth edge
- Colour: uneven, variegated or changing colour
- Diameter: > 6 mm in diameter or growing
- Itching or pain in a pre-existing mole

7 Abdominal examination

- Are there scars from previous surgery?
- Is the umbilicus everted, suggesting ascites?
- Is there a firm nodule at the umbilicus due to ovarian cancer metastasis, causing a Sister Mary Joseph's nodule?
- Is there smooth hepatomegaly—possibly primary liver cancer or heart failure?
- Is the liver firm or knobby, suggesting metastasis?
- Is the ascites too tense to demonstrate hepatomegaly?
- Are other masses palpable in the abdomen?
- Are there signs of obstruction or paralytic ileus with absence of bowel sounds?
- Palpate for inguinal nodes (occasionally involved in ovarian cancer)
- Percuss for flank dullness and shifting dullness
- Perform vaginal and rectal examinations to detect adnexal or rectal masses

3 Examination of the lymph nodes

6 Malignant pleural effusions

Large right pleural effusion

Inspection
Tachypnoea
Palpation
↓Expansion on R
Trachea and apex may be moved to L
Percussion
Stony dull
R mid- and lower zones
Auscultation
Absent breath sounds and diminished or absent vocal resonance R base
Crackles above effusion

5 SVC obstruction

- Venous distension of neck
- Elevated but non-pulsatile JVP
- Venous distension of chest wall
- Facial oedema
- Cyanosis
- Plethora of face
- Oedema of arms

5 Pericardial effusion

- Tachycardia
- Falling BP
- Rising JVP
- Muffled heart sounds
- Kussmaul's sign

Cancer is a significant global health-care problem, with an estimated world-wide incidence of 10 million new cases per year, 46% of which are in developed countries. Mortality is high, with more than 7 million deaths per year. The global costs and socioeconomic impact are considerable. The most common solid organ malignancies arise in the lung, breast and gastrointestinal tract (Fig. 11.1), but the most common form world-wide is skin cancer. Tobacco is a major factor in the aetiology of 30% of cancers, including those of the lung, nasopharynx, bladder and kidney, and these could be prevented by smoking cessation. Diet and alcohol contribute to a further 30% of cancers, including those of the stomach, colon, oesophagus, breast and liver. Lifestyle modification could reduce these if steps were taken to avoid animal fat and red meat, reduce alcohol, increase fibre, fresh fruit and vegetable intake, and avoid obesity. Infections account for a further 15% of cancers, including those of the cervix, stomach, liver, nasopharynx and bladder, and some of these could be prevented by infection control and vaccination.

FUNCTIONAL ANATOMY AND PATHOPHYSIOLOGY

Cancer cells possess unique characteristics, in that their proliferation is unregulated and in that they have the capacity to invade surrounding tissues and penetrate the walls of blood vessels and lymphatics to spread to other sites. Oncogenesis is a multistage process which often begins with a somatic mutation in a single cell, resulting in a growth advantage (Fig. 11.2).

Subsequently, further mutations occur, selecting a subset of cells for more rapid growth which is mediated by increased growth factor production, constitutive activation of signalling pathways that stimulate cell division, and failure of apoptosis. Angiogenic factors are then produced which provide the growing tumour with a blood supply, and other factors are expressed that break down connective tissues and disturb cell adhesion, resulting in distant spread and the development of metastases. Important factors in the pathophysiology of cancer are discussed in detail below.

The cell cycle

Proliferation of both normal cells and cancer cells is dependent on progression of the cell cycle, which consists of four phases (Fig. 11.3). Briefly, there are two functional (S phase and M phase) and two preparatory phases (G_1 phase and G_2 phase). In the S phase, DNA replication occurs, doubling the number of chromosomes and producing sister chromatids. In the M phase, the nucleus divides and the chromosomes separate into two daughter cells during the process of mitosis. The G_1 phase precedes the S phase, while the G_2 phase precedes the M phase; their function is primarily synthesis of the materials needed for the subsequent phase. Following division, some cells enter a phase called G_0 , in which differentiated functions are carried out.

The cell cycle is regulated by two families of molecules known as cyclins and cyclin-dependant kinases (CDKs). Cyclins bind to CDKs, which regulate target proteins required for entry into the next phase of the cell cycle. Multiple checkpoints monitor and regulate the progress of the cell cycle. These checkpoints prevent the cell cycle

Fig. 11.1 The 20 most commonly diagnosed cancers in the UK.

Fig. 11.2 Oncogenesis. The multistep origin of cancer, showing events implicated in cancer initiation, progression, invasion and metastasis.

Fig. 11.3 The cell cycle and sites of action of chemotherapeutic agents. (Rb = retinoblastoma gene; CDK = cyclin-dependent kinase)

from progressing if certain requirements have not been met, allowing verification of the necessary phase processes and repair of defective DNA products. Two main checkpoints exist: namely, the G_1/S checkpoint and the G_2/M checkpoint. The cell cycle is also regulated by genes which prevent its progression, such as *p53*, *p21* and *p16*. These play an important part in tumour prevention, and are known as tumour suppressor genes. They halt the cell cycle by binding to and deactivating cyclin-CDK complexes. Dysregulation of any part of the cell cycle may be associated with increased susceptibility to cancer.

An understanding of the cell cycle has been used to develop chemotherapeutic agents. Actively replicating cells are targeted in cancer therapy, as the DNA during cell division is susceptible to damage or radiation. Examples of chemotherapeutic agents include anti-metabolites such as azathioprine and methotrexate, which prevent purines and pyrimidines from becoming incorporated into DNA during the S phase of the cell cycle, thereby arresting cell division. The mitotic spindle poisons vinblastine and vincristine inhibit assembly of tubulin into microtubules, hence disrupting the M phase of the cell cycle. Other anticancer drugs, such as antibiotics and alkylating agents, affect cell division by a variety of mechanisms. The effects of cytotoxic drugs on the cell cycle are depicted in Figure 11.3.

Regulation of cancer cell growth

Abnormal regulation of cell growth in cancer can occur as the result of several mechanisms.

Activation of cell growth

Many cancer cells produce growth factors which drive their own proliferation by a positive feedback loop, a process known as autocrine stimulation. Examples include tumour growth factor- α (TGF- α) and platelet-derived growth factor (PDGF) production by hepatocellular cancer and non-small cell lung cancer respectively. Other cancer cells express growth factor receptors at increased levels due to gene amplification, or express abnormal receptors that are permanently activated. This results in abnormal cell growth in response to physiological growth factor stimulation or even in the absence of growth factor stimulation (ligand independent signalling). The epidermal growth factor receptor (EGFR) is often over-expressed in lung and gastrointestinal tumours and the Her2/neu receptor is frequently over-expressed in breast cancer. Both receptors activate the Ras-Raf-MAP kinase pathway which stimulates cell growth. Understanding these effects has been important in the development of novel therapies targeted to these receptors (p. 274). An example of ligand independent signalling occurs in the case of Ras mutations, which are present in about 30% of all cancers and cause constitutive activation of MAP kinase signalling, leading to abnormal cell growth.

Inhibition of tumour suppressor genes

In the normal cell, several proteins inhibit cell growth; these may be inactivated by loss of function mutations or their levels reduced by diverse mechanisms. The retinoblastoma protein (Rb) is an example. This protein sequesters transcription factors essential for cell cycle progression and inhibits cell growth. One mechanism

via which Rb function is disrupted in cancer is inactivating mutations in Rb protein, as occur in retinoblastoma. Another is abnormal regulation of the Rb pathway by growth factors. For example, transforming growth factor- β (TGF- β) normally regulates Rb function by producing proteins that block its phosphorylation, causing growth inhibition. Loss of TGF- β responsiveness, down-regulation of TGF- β receptors and dysfunctional receptors occur in some types of cancer, leading to disruption of the Rb signalling circuit and rendering cancer cells insensitive to growth inhibition.

Avoidance of apoptosis

Evasion of apoptosis is a common finding in cancer; it can occur through altered activity or loss of function of molecules that take part in the apoptotic process. The molecules involved are numerous and have complex interactions, but the Bcl-2 family plays a critical role. Some members of the Bcl-2 family (Bcl-2, Bcl- X_L) are anti-apoptotic, while others (Bax, Bak) are pro-apoptotic. In some cancer cells, reduced levels of apoptosis are associated with increased levels of Bcl-2/Bcl- X_L or decreased levels of Bax/Bak. Another molecule that plays a key role in apoptosis is PTEN. The PTEN molecule is a phosphatase which dephosphorylates Akt (pAkt), a molecule which stimulates cell growth. PTEN also affects the function of the tumour suppressor gene *p53*, by sequestering an inhibitory molecule called Mdm-2, allowing *p53* to promote apoptosis of cells with damaged DNA. Inactivating mutations of PTEN have been found in a number of different tumours. They cause activation of pAkt and inhibition of the *p53* pathway, which stimulates cell growth and inhibits apoptosis.

Maintenance of telomeres

When normal cells replicate, there is progressive shortening of the telomeres; eventually, this prevents the cell from dividing further. Cancer cells can replicate an infinite number of times and this is associated with maintenance of telomere length. There are several mechanisms by which this occurs, the best established being up-regulation of the telomerase enzyme, which adds nucleotides to the telomeres and allows cell division to continue.

Angiogenesis

Malignant tumours need to acquire a network of blood vessels for continued growth. This process is known as angiogenesis and is dependent on the production of angiogenic growth factors by the tumour. There are more than 15 angiogenic molecules, the best characterised being vascular endothelial growth factor (VEGF) and PDGF. Both play a central role in producing neovascularisation for the tumour cells and metastasis. The requirement for tumours to promote angiogenesis has been exploited therapeutically in the development of agents that target angiogenic molecules or their receptors. Examples include bevacizumab (an antibody against VEGF) and sunitinib (a small-molecule inhibitor of the PDGF and VEGF receptors). Bevacizumab has been shown to improve survival in metastatic colon, breast and lung cancer, while sunitinib has been shown to be useful in the treatment of renal cell cancer and second-line treatment of gastrointestinal stromal tumour (GIST).

Immune surveillance

The immune system is thought to protect against cancer via a continuous surveillance programme which eliminates cells that have undergone malignant transformation. One of the hallmarks of cancer development is escape from immune surveillance. Tumour cells constantly shed surface antigens into the circulation. Although this would normally evoke a response from the immune system, including the recruitment of cytotoxic T cells, natural killer cells and macrophages, it is thought that tumours escape from immune control for one of three reasons:

- failure of antigen recognition by immune cells
- tumour escape from the activity of cytotoxic lymphocytes
- tumour-induced immune dysfunction.

It has been speculated that the increased risk of some cancers in patients receiving anti-TNF therapy for inflammatory diseases (p. 1092) may be due to impairment of immune surveillance.

Invasion and metastasis

The ability of cancer cells to transgress normal tissue boundaries and to spread to other sites is an important process in cancer progression. Cells are attached to one another and to the extracellular matrix (ECM) by cell adhesion molecules (CAM) such as cadherins and integrins. Cell-cell and cell-matrix interactions are critical for the survival of normal cells. In cancer cells, CAMs are absent or dysfunctional, allowing the cell to detach from the primary site and to replicate, despite not being anchored to another cell or to the ECM (anchorage-independent growth). Cancer cells are also able to penetrate the basement membrane by producing enzymes called matrix metalloproteinases (MMP). The MMP degrade the basement membrane, allowing cancer cells to penetrate blood vessels at the primary site and to develop in new sites.

Anatomical spread of tumours

Tumours can spread both by local invasion and by migration to distant sites. The process of staging determines the extent of the tumour; it entails clinical examination and imaging to establish possible sites or extent of disease involvement. The outcome is recorded using a standard staging system which allows comparisons to be made between different groups of patients. Therapeutic decisions and prognostic predictions can then be made using the evidence base for the disease. One of the most commonly used systems is the T (tumour), N (regional lymph nodes), M (metastatic sites) approach of the International Union against Cancer (UICC, Box 11.1). For some tumours, such as colon cancer, the Dukes system (p. 912) is used rather than the UICC classification.

ENVIRONMENTAL AND GENETIC DETERMINANTS OF CANCER

The majority of cancers do not have a single cause but rather are the result of a complex interaction between genetic factors and exposure to environmental carcinogens. These are often tumour type-specific but some general principles do apply.

11.1 TNM classification

Extent of primary tumour*

TX	Not assessed
T0	Excised tumour
T1	Increases in primary tumour size or depth of invasion
T2	
T3	

Increased involvement of nodes*

NX	Not assessed
N0	No nodal involvement
N1	Increases in involvement
N2/3	

Presence of metastases

MX	Not assessed
M0	Not present
M1	Present

*Exact criteria for size and region of nodal involvement have been defined for each anatomical site.

Environmental factors

Environmental triggers for cancer have mainly been identified through epidemiological studies which examine patterns of distribution of cancers in patients in whom age, sex, presence of other illnesses, social class, geography and so on differ. Sometimes these give strong pointers to the molecular or cellular causes of the disease, such as the association between aflatoxin production within contaminated food supplies and hepatocellular carcinomas. However, for many solid cancers such as breast and colorectal, there is evidence of a multifactorial pathogenesis, even when there is a principal environmental cause (Box 11.2).

Smoking is now established beyond all doubt as a major cause of lung cancer, but there are obviously additional predisposing factors since not all smokers develop cancer. Similarly, most carcinomas of the cervix are related to infection with human papillomavirus (HPV subtype 16 and 18). For carcinomas of the bowel and breast, there is strong evidence of an environmental component. For example, the risk of breast cancer in women of Far Eastern origin remains relatively low when they first migrate to a country with a Western lifestyle, but rises in subsequent generations approach that of the resident population of the host country. The precise environmental factor that causes this change is unclear, but may include diet (higher intake of saturated fat and/or dairy products), reproductive patterns (later onset of first pregnancy) and lifestyle (increased use of artificial light and shift in diurnal rhythm).

Genetic factors

A number of inherited cancer syndromes are recognised which account for 5–10% of all cancers (Box 11.3). The molecular basis of these is discussed in Chapter 3, but in general they occur as the result of inherited mutations in genes which regulate cell growth, cell death and apoptosis. Examples include the *BRCA1*, *BRCA2* and *AT* (ataxia telangiectasia) genes which cause breast cancer and some other cancers, the *FAP* gene which causes bowel cancer,

11.2 Environmental factors that predispose to cancer

Environmental aetiology	Processes	Diseases
Occupational exposure (see also ultraviolet and radiation)	Dye and rubber manufacturing (aromatic amines) Asbestos mining, construction work, shipbuilding (asbestos) Vinyl chloride (PVC) manufacturing Petroleum industry (benzene)	Bladder cancer Lung cancer and mesothelioma Liver angiosarcoma Acute leukaemia
Chemicals	Chemotherapy (e.g. melphalan, cyclophosphamide)	Acute myeloid leukaemia
Cigarette smoking	Exposure to carcinogens from inhaled smoke	Lung and bladder cancer
Viral infection	Epstein–Barr virus Human papillomavirus	Burkitt's lymphoma and nasopharyngeal cancer Cervical cancer
Bacterial infection	<i>Helicobacter pylori</i>	Gastric mucosa-associated lymphoid tissue (MALT) lymphomas, gastric cancer
Parasitic infection	Liver fluke (<i>Opisthorchis sinensis</i>) <i>Schistosoma haematobium</i>	Cholangiocarcinoma Squamous cell bladder cancer
Dietary factors	Low-roughage/high-fat content diet High nitrosamine intake Aflatoxin from contamination of <i>Aspergillus flavus</i>	Colonic cancer Gastric cancer Hepatocellular cancer
Radiation	Ultraviolet (UV) exposure Nuclear fallout following explosion (e.g. Hiroshima) Diagnostic exposure (e.g. computed tomography (CT)) Occupational exposure (e.g. beryllium and strontium mining) Therapeutic radiotherapy	Basal cell carcinoma Melanoma Non-melanocytic skin cancer Leukaemia Solid tumours Cholangiocarcinoma following thorotrast usage Lung cancer Medullary thyroid cancer Sarcoma
Inflammatory diseases	Ulcerative colitis	Colon cancer
Hormonal	Use of diethylstilboestrol Oestrogens	Vaginal cancer Endometrial cancer Breast cancer

and the *Rb* gene which causes retinoblastoma. Although carriers of these gene mutations have a greatly elevated risk of cancer, none has 100% penetrance and additional modulating factors, both genetic and environmental, are likely to be operative. Exploration of a possible genetic contribution is a key part of cancer management, especially with regard to ascertaining the risk for an affected patient's offspring.

INVESTIGATIONS

When a patient is suspected of having cancer, a full history should be taken; specific questions should be included as to potential risk factors such as smoking and occupational exposures. A thorough clinical examination is also essential to identify sites of metastases, and to discover any other conditions that may have a bearing on the management plan. In order to make a diagnosis and to plan the most appropriate management, information is needed on:

- the type of tumour
- the extent of disease, as assessed by staging investigations
- the patient's general condition and any comorbidity.

The overall fitness of a patient is often assessed by the Eastern Cooperative Oncology Group (ECOG) performance scale (Box 11.4). The outcome for patients with a performance status of 3 or 4 is worse in almost all malignancies than for those with a status of 0–2, and this has a strong influence on the approach to treatment in the individual patient.

Histology

Histological analysis of a biopsy or resected specimen is pivotal in clinching the diagnosis and in deciding on the best form of management. The results of histological analysis are most informative when combined with knowledge of the clinical picture, and so biopsy results should ideally be reviewed within the context of a multidisciplinary meeting involving oncologists and pathologists.

Light microscopy

Examination of tumour samples by light microscopy remains the core method of cancer diagnosis and, in cases where the primary site is unclear, may also give clues to the origin of the tumour:

- Signet-ring cells favour a gastric primary.
- Presence of melanin favours melanoma.

11.3 Inherited cancer predisposition syndromes

Syndrome	Malignancies	Inheritance	Gene
Ataxia telangiectasia	Leukaemia, lymphoma, ovarian, gastric, brain, colon	AR	<i>AT</i>
Breast/ovarian	Breast, ovarian, colonic, prostatic, pancreatic	AD	<i>BRCA1, BRCA2</i>
Bloom syndrome	Leukaemia, tongue, oesophageal, colonic, Wilms' tumour	AR	<i>BLM</i>
Cowden syndrome	Breast, thyroid, gastrointestinal tract, pancreatic	AD	<i>PTEN</i>
Familial polyposis coli	Colonic, upper gastrointestinal tract	AD	<i>APC</i>
Fanconi anaemia	Leukaemia, oesophageal, skin, hepatoma	AR	<i>FACA, FACC, FADC</i>
Gorlin syndrome	Basal cell skin, brain	AD	<i>PTCH</i>
Hereditary non-polyposis colon cancer (HNPCC)	Colonic, endometrial, ovarian, pancreatic, gastric	AD	<i>MSH2, MLH1, PMS1, PMS2</i>
Li–Fraumeni syndrome	Sarcoma, breast, osteosarcoma, leukaemia, glioma, adrenocortical	AD	<i>p53</i>
Melanoma	Melanoma	AD	<i>CDK2 (p16)</i>
Multiple endocrine neoplasia (MEN)-1	Pancreatic islet cell, pituitary adenoma, parathyroid adenoma and hyperplasia	AD	<i>MEN1</i>
MEN-2	Medullary thyroid, pheochromocytoma, parathyroid hyperplasia	AD	<i>RET</i>
Neurofibromatosis 1	Neurofibrosarcoma, pheochromocytoma, optic glioma	AD	<i>NF1</i>
Neurofibromatosis 2	Vestibular schwannoma	AD	<i>NF2</i>
Papillary renal cell cancer syndrome	Renal cell cancer	AD	<i>MET</i>
Peutz–Jeghers syndrome	Colonic, ileal, breast, ovarian	AD	<i>STK11</i>
Prostate cancer	Prostate	AD	<i>HPC1</i>
Retinoblastoma	Retinoblastoma, osteosarcoma	AD	<i>RB1</i>
von Hippel–Lindau syndrome	Haemangioblastoma of retina and CNS, renal cell, pheochromocytoma	AD	<i>VHL</i>
Wilms' tumour	Nephroblastoma, neuroblastoma, hepatoblastoma, rhabdomyosarcoma	AD	<i>WT1</i>
Xeroderma pigmentosa	Skin, leukaemia, melanoma	AR	<i>XPA, XPC, XPD (ERCC2), XPF</i>

(AD = autosomal dominant; AR = autosomal recessive)

11.4 Eastern Cooperative Oncology Group (ECOG) performance status scale

0	Fully active, able to carry on all usual activities without restriction and without the aid of analgesics
1	Restricted in strenuous activity but ambulatory and able to carry out light work or pursue a sedentary occupation. This group also contains patients who are fully active, as in grade 0, but only with the aid of analgesics
2	Ambulatory and capable of all self-care but unable to work. Up and about more than 50% of waking hours
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
4	Completely disabled, unable to carry out any self-care and confined totally to bed or chair

- Mucin is common in gut/lung/breast/endometrial cancers, but particularly common in ovarian cancer and rare in renal cell or thyroid cancers.
- Psammoma bodies are a feature of ovarian cancer (mucin +) and thyroid cancer (mucin –).

Immunohistochemistry

Immunohistochemical (IHC) staining for tumour markers can provide useful diagnostic information and can help with treatment decisions. Commonly used examples of IHC in clinical practice include:

- *Oestrogen (ER) and progesterone (PR) receptors*. Positive results indicate that the tumour may be sensitive to hormonal manipulation.
- *Alpha fetoprotein (AFP) and human chorionic gonadotrophin (HC) ± placental alkaline phosphatase (PLAP)*. These favour germ-cell tumours.

- *Prostate-specific antigen (PSA)* and *prostatic acid phosphatase (PAP)*. These favour prostate cancer.
- *Carcinoembryonic antigen (CEA)*, *cytokeratin* and *epithelial membrane antigen (EMA)*. These favour carcinomas.
- *HER2 receptor*. Breast cancers which have high levels of expression of HER2 indicate that the tumour may respond to trastuzumab (herceptin), an antibody directed against the HER2 receptor.

The pattern of immunoglobulin, T-cell receptor and cluster designation (CD) antigen expression on the surface is also helpful in the diagnosis and classification of lymphomas. This can be achieved by immunohistochemical staining of biopsy samples or flow cytometry.

Electron microscopy

Electron microscopy (EM) can sometimes be of diagnostic value. Examples include the visualisation of melanosomes in amelanotic melanoma and dense core granules in neuroendocrine tumours. EM may also help to distinguish adenocarcinoma from mesothelioma, as the ultrastructural properties of these two diseases are different (mesothelioma appears to have long, narrow, branching microvilli while adenocarcinomas appear to have short, stubby microvilli). EM is also useful for differentiating spindle-cell tumours (sarcomas, melanomas, squamous cell cancers) from small round-cell tumours, again due to their ultrastructural differences.

Cytogenetic analysis

Some tumours demonstrate typical chromosomal changes that help in diagnosis. The utilisation of fluorescent in-situ hybridisation (FISH) techniques can be useful in Ewing's sarcoma and peripheral neuroectodermal tumours where there is a translocation between chromosome 11 and 22 – t(11; 22)(q24; q12). In some cases, gene amplification can also be detected via FISH (e.g. determining over-expression of Her2/neu).

Imaging

Imaging plays a critical role in oncology, not only in locating the primary tumour, but also in staging the disease. The imaging modality employed depends primarily on the site of the disease and the likely patterns of spread, but usually more than one modality is required.

Radiography

Plain radiographs remain part of the initial workup, but have a limited role in defining disease extent and have been superseded by more sophisticated techniques.

Ultrasound

Ultrasound is useful in characterising lesions within the liver, kidney, pancreas and reproductive organs. It is also used for guiding the placement of needles during biopsies of tumours in the breast and the liver. Endoscopic ultrasound is useful in staging upper gastrointestinal cancers; it involves using a special endoscope with an ultrasound probe attached.

Computerised tomography

Computerised tomography (CT) is a key investigation in cancer patients and is particularly useful in imaging the thorax and abdomen. With some modern CT scanners it is also possible to visualise the bowel, and in some instances, diagnosis of intestinal cancer is possible.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) has a high resolution and because of this is the preferred technique for brain imaging. It is also used to image structures within the pelvis and is widely employed for staging of rectal, cervical and prostate cancers.

Positron emission tomography

Positron emission tomography (PET) visualises metabolic activity of tumour cells and is widely used, often in combination with CT (PET-CT), to evaluate patients with various cancers, including lung cancer and lymphoma (Fig. 11.4). It can accurately assess the severity and spread of cancer by detecting tumour metabolic activity following injection of small amounts of radioactive tracers such as fluorodeoxyglucose (FDG). In addition to having a role in diagnosis, PET can also be used in some patients to assess treatment response.

Biochemical markers

Many tumours produce substances called tumour markers which can be used in diagnosis and surveillance.

Fig. 11.4 PET-CT images. **A** There is a neoplastic lesion in the left axilla, evidenced by the increased uptake of FDG traces. **B** Imaging after chemotherapy, demonstrating that the abnormal uptake has disappeared and indicating a response to treatment.

11.5 Commonly used serum tumour markers

Name	Natural occurrence	Tumours
Alphafetoprotein (AFP)	Glycoprotein found in yolk sac and fetal liver tissue. Transient elevation in liver diseases. Has a role in screening during pregnancy for the detection of neural tube defects and Down's syndrome	Ovarian non-seminomatous germ cell tumours (80%), hepatocellular cancer (50%)
Calcitonin	32 amino acid peptide from C-cells of thyroid. Used to screen for MEN-2	Medullary cell carcinoma of thyroid
Cancer antigen 125 (CA-125)	Differentiation antigen of coelomic epithelium (Muller's duct). Raised in any cause of ascites, pleural effusion or heart failure. Can be raised in inflammatory conditions	Ovarian epithelial cancer (75%), gastrointestinal cancer (10%), lung cancer (5%) and breast cancer (5%)
Carcinoembryonic antigen (CEA)	Glycoprotein found in intestinal mucosa during embryonic and fetal life. Elevated in smokers, cirrhosis, chronic hepatitis, ulcerative colitis, pneumonia	Colorectal cancer, particularly with liver metastasis, gastric cancer, breast cancer, lung cancer, mucinous cancer of the ovary
Human chorionic gonadotrophin (HCG)	Glycoprotein hormone, 14KD α subunit and 24KD β subunit from placental syncytiotrophoblasts. Used for disease monitoring in hydatidiform mole and as the basis of a pregnancy test	Choriocarcinoma (100%), hydatidiform moles (97%), ovarian non-seminomatous germ cell tumours (50–80%), seminoma (15%)
Placental alkaline phosphatase (PLAP)	Isoenzyme of alkaline phosphatase	Seminoma (40%), ovarian dysgerminoma (50%)
Prostate-specific antigen (PSA)	Glycoprotein member of human kallikrein gene family. PSA is a serine protease that liquefies semen in excretory ducts of prostate. Can be elevated in benign prostatic hypertrophy and prostatitis	Prostate cancer (95%)
Thyroglobulin	Matrix protein for thyroid hormone synthesis in normal thyroid follicles	Papillary and follicular thyroid cancer
β-2-microglobulin	A human leucocyte antigen (HLA) common fragment present on surface of lymphocytes, macrophages and some epithelial cells. Can be elevated in autoimmune disease and renal glomerular disease	Non-Hodgkin's lymphoma, myeloma

Some of these are useful in population screening, diagnosis, prognostication, treatment monitoring, detection of relapse and imaging of metastasis. Unfortunately, most tumour markers are not sufficiently sensitive or specific to be used in isolation and need to be interpreted in the context of the other clinical features. However, some tumour markers can be used for antibody-directed therapy or imaging, where they have a greater role in diagnosis. Tumour markers in routine use are outlined in Box 11.5.

PRESENTING PROBLEMS IN ONCOLOGY

In the early stages of cancer development, the number of malignant cells is small and the patient is usually asymptomatic. With tumour progression, localised signs or symptoms develop due to mass effects and/or invasion of local tissues. With further progression, symptoms may occur at distant sites as a result of metastatic disease or from non-metastatic manifestations due to production of biologically active hormones by the tumour or as the result of an immune response to the tumour. The possible presentations of patients with cancer are summarised in Boxes 11.6 and 11.7, and common presenting features are discussed below. Although the incidence of cancer

11.6 Local features of malignant disease

Symptom	Typical site or possible tumour
Haemorrhage	Stomach, colon, bronchus, endometrium, bladder, kidney
Lump	Breast, lymph node (any site), testicle
Bone pain or fracture	Bone (primary sarcoma, secondary metastasis from breast, prostate, bronchus, thyroid, kidney)
Skin abnormality	Melanoma, basal cell carcinoma (rodent ulcer)
Ulcer	Oesophagus, stomach, anus, skin
Dysphagia	Oesophagus, bronchus, gastric
Increasing constipation, abdominal discomfort or pain	Colon, rectum, ovary
Airway obstruction, stridor, cough, recurrent infection	Bronchus, thyroid
Odynophagia, early satiety, vomiting	Bronchus, stomach, oesophagus, colon, rectum
Abdominal swelling (ascites)	Ovary, stomach, pancreas

11.7 Non-metastatic manifestations of malignant disease

Feature	Common cancer site associations
Weight loss and anorexia	Lung, gastrointestinal tract
Fatigue	Any
Hypercalcaemia	Myeloma, breast, kidney
Prothrombotic tendency	Ovary, pancreas, gastrointestinal tract
Syndrome of inappropriate antidiuretic hormone secretion (SIADH) Ectopic adrenocorticotrophin hormone (ACTH)	Small cell lung cancer
Lambert–Eaton myasthenia-like syndrome	Small cell lung cancer
Subacute cerebellar degeneration	Small cell lung cancer, ovarian cancer
Acanthosis nigricans	Stomach, oesophagus
Dermatomyositis/polymyositis	Stomach, lung

11.8 Cancer in old age

- **Incidence:** around 50% of cancers occur in the 15% of the population aged over 65 years.
- **Screening:** women aged over 65 in the UK are not invited to breast cancer screening but can request it. Uptake is low despite increasing incidence with age.
- **Presentation:** may be later for some cancers. When symptoms are non-specific, patients (and their doctors) may initially attribute them to age alone.
- **Life expectancy:** an 80-year-old woman can expect to live 8 years, so cancer may still shorten life and an active approach remains appropriate.
- **Prognosis:** histology, stage at presentation and observation for a brief period are better guides to outcome than age alone.
- **Rate of progression:** malignancy may have a more indolent course. This is poorly understood but may be due to reduced effectiveness of angiogenesis with age, inhibiting the development of metastases.
- **Response to treatment:** equivalent to that in younger people. This is well documented for a range of cancers and for surgery, radiotherapy, chemotherapy and hormonal therapy.
- **Treatment selection:** chronological age is of minor importance compared to comorbid illness and patient choice. Although older patients can be treated effectively and safely, aggressive intervention is not appropriate for all individuals. Symptom control may be all that is possible or desired by the patient.

increases with patient age, the approach to investigation and management is similar at all ages (Box 11.8).

Palpable mass

A palpable mass detected by the patient or physician may be the first sign of cancer. Primary tumours of

the thyroid, breast, testis and skin are often detected in this way, whereas palpable lymph nodes in the neck, groin or axilla may indicate secondary spread of tumour. Hepatomegaly may be the first sign of primary liver cancer or tumour metastasis, whereas skin cancer may present as an enlarging or changing pigmented lesion.

Weight loss and fever

Unintentional weight loss is a characteristic feature of advanced cancer, but can be due to other causes such as thyrotoxicosis, chronic inflammatory disease and chronic infective disorders. Fever can occur in any cancer secondary to infection, but may be a primary feature in Hodgkin's disease, lymphoma, leukaemia, renal cancer and liver cancer. The presence of unexplained weight loss or fever warrants investigation to exclude the presence of occult malignancy.

Finger clubbing

Finger clubbing is a characteristic feature of lung cancer, and especially non-small cell lung cancer, although benign causes are also recognised. It is often part of the wider process of hypertrophic osteoarthropathy in which there is periosteal new bone formation and arthritis. Recent evidence suggests that this may be due to increased levels of prostaglandin E. The diagnosis is primarily clinical, but X-rays show periosteal reaction and an isotope bone scan shows increased tracer uptake in the affected digits. The condition responds to antitumour therapy, but if this is not possible, non-steroidal anti-inflammatory drugs (NSAIDs) and corticosteroids should be given.

Ectopic hormone production

In some cases, the first presentation of cancer is with a metabolic abnormality due to ectopic production of hormones by tumour cells, including insulin, ACTH, ADH, FGF23, erythropoietin and parathyroid hormone-related protein (PTHrP). This can result in a wide variety of presentations, as summarised in Box 11.9. Further details on presentation and management of ACTH and ADH-producing tumours are given on page 774, and of FGF23-producing tumours on page 1123. The management of hypercalcaemia associated with malignancy is discussed on page 268.

Neurological paraneoplastic syndromes

These form a group of conditions associated with cancer which are thought to be due to an immunological response to the tumour that results in damage to the nervous system or muscle. The cancers most commonly implicated are those of the lung (small cell and non-small cell), pancreas, breast, prostate, ovary and lymphoma.

11.9 Ectopic hormone production by tumours

Hormone	Consequence	Tumours
ADH	Hyponatraemia	SCLC
ACTH	Cushing's syndrome	SCLC
FGF-23	Hypophosphataemic osteomalacia	Mesenchymal tumours
Insulin	Hypoglycaemia	Insulinoma
Erythropoietin	Polycythaemia	Kidney, hepatoma, cerebellar haemangioblastoma, uterine fibroids
PTHrP	Hypercalcaemia	NSCLC (squamous cell), breast, kidney

(SCLC = small cell lung cancer)

- *Peripheral neuropathy* results from axonal degeneration or demyelination.
- *Encephalomyelitis* can present with diverse symptoms, depending on which region of the brain is involved. Lumbar puncture shows raised protein in the cerebrospinal fluid (CSF) and a pleocytosis, predominantly that of lymphocytes. In some centres, flow cytometry of the CSF is also used to detect carcinomatous cells. MRI shows meningeal enhancement, particularly at the level of the brain stem, and anti-Hu antibodies may be detectable in serum. Encephalomyelitis is due to perivascular inflammation and selective neuronal degeneration. Most cases are caused by small cell lung cancer (75%).
- *Cerebellar degeneration* may be the presenting feature of an underlying malignancy and presents with rapid onset of cerebellar ataxia. Diagnosis is by MRI or CT, which may show cerebellar atrophy. Patients with these neurological paraneoplastic syndromes may be found to have circulating anti-Yo, Tr and Hu antibodies, but these are not completely specific and negative results do not exclude the diagnosis.
- *Retinopathy* is a rare complication of cancer and presents with blurred vision, episodic visual loss and impaired colour vision. If left untreated, it may lead to blindness. The diagnosis should be suspected if the electroretinogram is abnormal and anti-retinal antibodies are detected.
- *Lambert-Eaton syndrome (LEMS)* is due to underlying cancer in about 60% of cases. It presents with proximal muscle weakness which improves on exercise and is caused by the development of antibodies to presynaptic calcium channels (p. 1232). The diagnosis is made by electromyogram (EMG), which shows a low-amplitude compound muscle action potential that enhances to near normal following exercise.
- *Dermatomyositis or polymyositis* may be the first presentation of some cancers. Clinical features and management of these conditions are discussed on page 1111.

Cutaneous manifestations of cancer

Many cancers can present with skin manifestations which are not due to metastases.

- *Pruritus* may be a presenting feature of lymphoma, leukaemia and central nervous system tumours.
- *Acanthosis nigricans* may precede cancers by many years and is particularly associated with gastric cancer.
- *Vitiligo* may be associated with malignant melanoma, and is possibly due to an immune response to melanocytes.
- *Pemphigus* may occur in lymphoma, Kaposi's sarcoma and thymic tumours.
- *Dermatitis herpetiformis* associated with coeliac disease may precede tumour development by many years, and is associated with gastrointestinal lymphoma.

The clinical features and management of these skin conditions is discussed in Chapter 27.

EMERGENCY COMPLICATIONS OF CANCER

Spinal cord compression

Spinal cord compression complicates 5% of cancers and is most common in myeloma, prostate, breast and lung cancers which involve bone. Cord compression often results from posterior extension of a vertebral body mass but intrathecal spinal cord metastases can cause similar signs and symptoms.

Clinical features

The earliest sign is back pain, particularly on coughing and lying flat. Subsequently, sensory changes develop in dermatomes below the level of compression and motor weakness distal to the block occurs. Finally, sphincter disturbance, causing urinary retention and bowel incontinence, is observed. Involvement of the lumbar spine may cause conus medullaris or cauda equina compression (Box 11.10). Physical examination reveals findings consistent with an upper motor neuron lesion, but lower motor neuron findings may predominate early on or in cases of nerve root compression.

Management

Spinal cord compression is a medical emergency which should be treated with analgesia and high-dose steroid therapy (dexamethasone 10 mg i.v. stat and 4 mg 6-hourly orally; Box 11.11). Neurosurgical treatment produces superior outcome and survival compared to radiotherapy alone, and should be considered first for all patients. Radiotherapy is used for the remaining patients and selected tumour types when the cancer is likely to be radiosensitive. The prognosis varies considerably, depending on tumour type, but the degree of neurological dysfunction at presentation is the strongest predictor of outcome irrespective of the underlying diagnosis. Ambulation can be preserved in more than 80% of patients who are ambulatory at presentation, but neurological function is seldom regained in patients with established deficits such as paraplegia.

11.10 Comparison of features of neurological deficit

Clinical feature	Spinal cord	Conus medullaris	Cauda equina
Weakness	Symmetrical and profound	Symmetrical and variable	Asymmetrical, may be mild
Reflexes	Increased (or absent) knee and ankle reflexes with extensor plantar reflex	Increased knee reflex, decreased ankle reflex, extensor plantar reflex	Decreased knee and ankle reflexes with flexor plantar reflex
Sensory loss	Symmetrical, sensory level	Symmetrical, saddle distribution	Asymmetrical, radicular pattern
Sphincters	Late loss	Early loss	Spared often
Progression	Rapid	Variable	Variable

11.11 Management of suspected spinal cord compression

- Confirm diagnosis with urgent MRI scan
- Administer high-dose steroids
- Dexamethasone 10 mg i.v. stat
- Dexamethasone 4 mg 6-hourly orally
- Ensure adequate analgesia
- Refer for surgical decompression or urgent radiotherapy

Superior vena cava obstruction

Superior vena cava obstruction (SVCO) is a common complication of cancer which can occur through extrinsic compression or intravascular blockage. The most common causes of extrinsic compression are lung cancer, lymphoma and metastatic tumours. Patients with cancer can also develop SVCO due to intravascular blockage in association with a central catheter or thrombophilia secondary to the tumour.

Clinical features

The typical presentation is with oedema of the arms and face, distended neck and arm veins and dusky skin coloration over the chest, arms and face. Collaterals may develop over a period of weeks and the flow of blood in the collaterals helps to confirm the diagnosis. Headache secondary to cerebral oedema arising from the backflow pressure may also occur and tends to be aggravated by bending forward, stooping or lying down. The severity of symptoms is related to the rate of obstruction and the development of a venous collateral circulation. Accordingly, symptoms may develop rapidly or gradually. Clinical features are summarised in Box 11.12.

Diagnosis and management

The investigation of choice is CT of the thorax since it can clinch the diagnosis and distinguish between extra- and intravascular causes. A biopsy should be obtained when the tumour type is unknown because tumour type has a major influence on treatment. CT of the brain may be indicated if cerebral oedema is suspected. Patients with suspected cerebral oedema, usually manifesting as a headache, should be started on high-dose steroid therapy (dexamethasone 16–24 mg/24 hours), and mannitol should be considered if the response is inadequate. Tumours that are exquisitely sensitive to chemotherapy, such as germ cell tumours and lymphoma, can be treated with chemotherapy alone, but for most other

11.12 Common symptoms and physical findings in SVC obstruction (% patients affected)

Symptoms

- Dyspnoea (63%)
- Facial swelling and head fullness (50%)
- Cough (24%)
- Arm swelling (18%)
- Chest pain (15%)
- Dysphagia (9%)

Physical findings

- Venous distension of neck (66%)
- Venous distension of chest wall (54%)
- Facial oedema (46%)
- Cyanosis (20%)
- Plethora of face (19%)
- Oedema of arms (14%)

tumours mediastinal radiotherapy is required. This relieves symptoms within 2 weeks in 50–90% of patients. In most centres, stenting is now increasingly favoured over radiotherapy, as it produces rapid results and can be repeated with reasonable effectiveness. This technique is particularly useful when dealing with tumours that are relatively chemo- or radio-resistant, such as non-small cell lung cancer.

Where possible, these measures should be followed by treatment of the primary tumour, as long-term outcome strongly is dependent on the prognosis of the underlying cancer.

Hypercalcaemia

Hypercalcaemia is the most common metabolic disorder in patients with cancer and has a prevalence of 15–20 cases per 100 000 persons. The incidence is highest in myeloma and breast cancer (approximately 40%), intermediate in non-small cell lung cancer, and uncommon in colon, prostate and small cell lung carcinomas. It is most commonly due to over-production of PTHrP, which binds to the PTH receptor and elevates serum calcium by stimulating osteoclastic bone resorption and increasing renal tubular reabsorption of calcium.

Clinical features

The symptoms of hypercalcaemia are often non-specific and may mimic those of the underlying malignancy. They include drowsiness, confusion, nausea and vomiting, constipation, polyuria, polydipsia and dehydration.

11.13 Medical management of severe hypercalcaemia

- I.v. 0.9% saline 2–4 L/day
- I.v. bisphosphonate
- Zoledronic acid 4 mg i.v.

or

- Pamidronate 60–90 mg i.v.

or

- Clodronate 300 mg i.v. daily over 5 days
- I.m./s.c. calcitonin 100 U 8-hourly for first 24–48 hours in life-threatening hypercalcaemia

Diagnosis and management

The diagnosis is made by measuring serum total calcium and adjusting for albumin. It is especially important to correct for albumin in cancer because hypoalbuminaemia is common and total calcium values underestimate the level of ionised calcium. The principles of management are outlined in Box 11.13.

Patients should initially be treated with intravenous 0.9% saline (2–4 L/day) to improve renal function and increase urinary calcium excretion. This alone often results in clinical improvement. Concurrently, intravenous bisphosphonates should be given to inhibit bone resorption. Intravenous pamidronate (60–90 mg i.v.), zoledronic acid (4 mg i.v.) or clodronate (1500 mg i.v. in divided doses) are all effective. Calcitonin (100 U s.c. or i.m. 8-hourly) acts rapidly to increase calcium excretion and to reduce bone resorption and can be combined with fluid and bisphosphonate therapy for the first 24–48 hours in patients with life-threatening hypercalcaemia. Bisphosphonates will usually reduce the serum calcium levels to normal within 5 days, but if not, treatment can be repeated. The duration of action is up to 4 weeks and repeated therapy can be given at 3–4-weekly intervals as an outpatient. Hypercalcaemia is frequently a sign of tumour progression and the patient requires further investigation to establish disease status and review of the anticancer therapy.

Neutropenic sepsis

Neutropenia is a common complication of malignancy. It is usually secondary to chemotherapy but may occur with radiotherapy if large amounts of marrow are irradiated; alternatively, it may be a component of pancytopenia due to malignant infiltration of the marrow. Neutropenic sepsis is defined as a pyrexia of 38°C for over 1 hour in a patient with a neutrophil count $< 1.0 \times 10^9/L$. The risk of sepsis is related to the severity and duration of neutropenia and the presence of other risk factors such as intravenous or bladder catheters.

Clinical features

The typical presentation is with high fever and affected patients are often non-specifically unwell. Examination is usually unhelpful in defining a primary source of the infection. Hypotension is an adverse prognostic feature and may progress to systemic circulatory shutdown and organ failure.

Investigations and management

An infection screen should be performed to include blood cultures (both peripheral and from central lines if present), urine culture, chest X-ray, and swabs for culture (throat, central line, wound). High-dose intravenous antibiotics should then be commenced, pending the results of cultures. Typical first line empirical therapy consists of an antipseudomonal β -lactam (cef-tazidime, cefotaxime or meropenem), or a combination of an aminoglycoside and a broad-spectrum penicillin with antipseudomonal activity (gentamicin and piperacillin), but this may need adjusting on the basis of local hospital policy and antibiotic resistance patterns. Metronidazole should be added if anaerobic infection is suspected, and flucloxacillin or vancomycin or teicoplanin where Gram-positive infection is suspected (for example, in patients with central lines). If there is no response after 36–48 hours, treatment with amphotericin-B or voriconazole should be considered to cover fungal infection. Antibiotics should be adjusted according to culture results, though these are often negative. Other supportive therapy, including intravenous fluids, inotropes, ventilation or haemofiltration, may be required.

METASTATIC DISEASE

Metastatic disease is the major cause of death in cancer patients and the principal cause of morbidity. For the majority of patients, the aim of treatment is palliative, but treatment of a solitary metastasis can occasionally be curative.

Brain metastases

Brain metastases occur in 10–30% of adults and 6–10% of children with cancer, and are an increasingly important cause of morbidity. Tumours which typically metastasise to the brain are shown in Box 11.14. Most involve the brain parenchyma but can also affect the cranial nerves, the blood vessels and other intracranial structures. The median survival without treatment is 1 month. Steroids can increase survival to 2–3 months and whole-brain radiotherapy improves survival to 3–6 months. Patients with brain metastases as the only manifestation of an undetected primary tumour have a more favourable prognosis, with an overall median survival of 13.4 months. Tumour type also influences prognosis; breast cancer patients have a better prognosis than those with other types of tumour, and

11.14 Primary tumour sites that metastasise to brain

Primary tumour	Patients (%)
Lung	48
Breast	15
Melanoma	9
Colon	5
Other known primary	13
Unknown primary	11

those with colorectal carcinoma tend to have a poorer prognosis.

Clinical features

The presentation is with headaches (40–50% of patients), focal neurological dysfunction (20–40%), cognitive dysfunction (35%), seizures (10–20%) and papilloedema (< 10% of cases).

Diagnosis and management

The diagnosis can be confirmed by CT or contrast-enhanced MRI. Treatment options include high-dose steroids (dexamethasone 4 mg 6-hourly) for tumour-associated oedema, anticonvulsants for seizures, whole-brain radiotherapy, and chemotherapy. Surgery may be considered for single sites of disease and can be curative; stereotactic radiotherapy may also be considered for patients with solitary site involvement where surgery is not possible.

Lung metastases

These are common in breast cancer, colon cancer, and tumours of the head and neck. The presentation is usually with a lesion on chest X-ray or CT. Solitary lesions require investigation, as single metastases can be difficult to distinguish from a primary lung tumour. Patients with two or more pulmonary nodules can be assumed to have metastases. The approach to treatment depends on the extent of disease in the lung and elsewhere. For solitary lesions, surgery should be considered with a generous wedge resection. Radiotherapy, chemotherapy or endocrine therapy can be used as systemic treatment and is dependent on the underlying primary cancer diagnosis.

Liver metastases

Metastatic cancer in the liver can represent the sole or life-limiting component of disease for many patients with colorectal cancer, ocular melanoma, neuroendocrine tumours and, less commonly, other tumour types. The most common clinical presentations are with right upper quadrant pain due to stretching of the liver capsule, jaundice, deranged liver function tests or an abnormality detected on imaging. In selected cases, resection of the metastasis can be contemplated. In colorectal cancer, successful resection of a metastasis improves 5-year survival from 3% to 30–40%. Other techniques, such as chemoembolisation or radio-frequency ablation, can also be used, provided the number and size of metastases remain small. If these approaches are not feasible, symptoms may respond to systemic chemotherapy.

Bone metastases

Bone is the third most common organ involved by metastasis, after lung and liver. Bone metastases are a major clinical problem in patients with myeloma and breast or prostate cancers, but other tumours that commonly metastasise to bone include those of the kidney and thyroid. Bone metastases are an increasing management problem in other tumour types which do not classically target bone, due to the prolonged survival of patients generally. Accordingly, effective management of bony metastases has become a focus in the treatment of patients with many incurable cancers.

Clinical features

The main presentations are with pain, pathological fractures and spinal cord compression (p. 267). The pain tends to be worst at night and may be partially relieved by activity, but subsequently becomes more constant in nature and is exacerbated by movement. The majority of pathological fractures occur in patients with metastatic breast cancer (53%); other tumour types associated with fracture include the kidney (11%), lung (8%), thyroid (5%), lymphoma (5%) and prostate (3%).

Diagnosis and management

The most sensitive way of detecting bone metastases is by isotope bone scan, but this may give false negative results in multiple myeloma due to suppression of osteoblast activity so in this situation X-rays are preferred. In patients with a single lesion, it is especially important to perform a biopsy to obtain a tissue diagnosis, since primary bone tumours may look very similar to metastases on X-ray. The main goals of management are as follows:

- pain relief
- preservation and restoration of function
- skeletal stabilisation
- local tumour control (e.g. relief of tumour impingement on normal structure).

Surgical intervention may be warranted where there is evidence of skeletal instability (e.g. anterior or posterior spinal column fracture) or an impending fracture (e.g. large lytic lesion on a weight-bearing bone). Intravenous bisphosphonates (pamidronate, zoledronic acid or ibandronate) are widely used in the treatment of patients with bone metastases and are effective at improving pain and in reducing further skeletal related events, such as fractures and hypercalcaemia (Box 11.15). In certain types of cancer, such as breast and prostate, hormonal therapy may be effective. Radiotherapy, in the form of external beam therapy or systemic radionuclides (strontium treatment) can also be useful for these patients. In some settings (e.g. breast carcinoma) chemotherapy may also be used in the management of bony metastases.

EBM 11.15 Use of bisphosphonates in bony metastases

'The use of bisphosphonates in cancer patients with bony metastases results in decreased pain and a decrease in skeletal-related events.'

Malignant pleural effusion

This is a common complication of cancer and 40% of all pleural effusions are due to malignancy. The most common causes are lung and breast cancers, and the presence of an effusion indicates advanced and incurable disease. The presentation may be with dyspnoea, cough or chest discomfort, which can be dull or pleuritic in nature.

Diagnosis and management

Pleural aspirate is the key investigation and may show the presence of malignant cells. Malignant effusions are

11.16 How to aspirate a malignant pleural effusion

- Ask the patient to sit up and lean forward slightly.
- Identify a suitable site for aspiration. Typically this should be in the midscapular line, below the top of the fluid level and above the diaphragm.
- Confirm that the site is below the fluid level by reviewing the chest X-ray and percussing the chest.
- Infiltrate the skin and the intercostal space immediately above the rib below with 1% lidocaine.
- As you advance the needle, aspirate at each step prior to injecting the local anaesthetic.
- On reaching the pleural cavity, you should be able to aspirate pleural fluid; when you do, note the depth of the needle.
- Insert a thoracentesis needle into the pleural space by advancing it along the same track as was used for the local anaesthetic and connect it to a three-way tap and container to collect the fluid.
- Drain the pleural effusion, to a maximum of 1.5 L. If the effusion is larger than this, repeat the procedure on further occasions as necessary.
- Consider using ultrasound-guided placement of a drainage catheter if the effusion proves difficult to drain.

commonly blood-stained and are exudates with a raised fluid:serum lactate dehydrogenase (LDH) ratio (> 0.6) and a raised fluid:serum protein ratio (> 0.5). Treatment should focus on palliation of symptoms and be tailored to the patient's physical condition and prognosis. Aspiration alone may be an appropriate treatment in frail patients with a limited life expectancy (Box 11.16). Those who present with malignant pleural effusion as the initial manifestation of breast cancer, small cell lung cancer, germ cell tumours or lymphoma should have the fluid aspirated and should be given systemic chemotherapy to try to treat disease in the pleural space. Treatment options for patients with recurrent pleural effusion include pleurodesis, pleurectomy and pleuroperitoneal shunt. Ideally, pleurodesis should be attempted once recurrence of effusion after initial drainage occurs.

THERAPEUTICS IN ONCOLOGY

Anticancer therapy may be either curative or palliative, and this distinction influences the approach to management of individual patients.

- **Palliation.** The majority of patients who receive chemotherapy for metastatic disease do so for the palliation of symptoms. The aim of palliative chemotherapy is to produce an improvement in quality of life with a minimised impact of toxicity on the patient; there may be a small increase in survival.
- **Adjuvant treatment.** This is administered after surgery and the main aim is to increase the disease-free and overall survival. As impact on survival is the main focus, a greater toxicity is acceptable, sometimes with a significant impact on quality of life. As patients have often had their cancers surgically removed, it is not possible to assess the response to treatment, other than by improvement in survival.

11.17 Goals of non-surgical treatment

Curative

- Choriocarcinoma
- Teratoma
- Seminoma
- High-grade lymphoma
- Cervical cancer
- Head and neck cancer

Radical, occasionally curative

- Small cell lung cancer
- Stage III ovarian cancer

Adjuvant (following surgery)

- Breast cancer
- Stage I–II ovarian cancer
- Colorectal cancer
- Osteosarcoma

Palliative

- Metastatic breast cancer
- Stage IV ovarian cancer
- Advanced gastrointestinal cancer
- Metastatic sarcoma
- Metastatic prostate cancer
- Advanced lung cancer

- **Neoadjuvant treatment.** This also has the long-term aim of improved survival but in this case patients receive chemotherapy, radiotherapy or hormonal treatment before surgery. The response of the cancer to the treatment can be assessed and a reduction in the extent of surgery required may be produced. Examples of approach are outlined in Box 11.17.

Surgical treatment

Surgery has a pivotal role in the management of cancer. There are three main situations in which it is necessary.

Biopsy

In the vast majority of cases, a histological or cytological diagnosis of cancer is necessary, and tissue will also provide important information such as tumour type and differentiation, to assist subsequent management. Cytology can be obtained with fine needle aspiration, but a biopsy is usually preferred. This can be a core biopsy, an image-guided biopsy or an excision biopsy.

Excision

The main curative management of most solid cancers is surgical excision. In early localised cases of colorectal, breast and lung cancer, cure rates are high with surgery. There is increasing evidence that outcome is related to surgical expertise, and most multidisciplinary teams include surgeons experienced in the management of a particular cancer. There are some cancers for which surgery is one of two or more options for primary management, and the role of the multidisciplinary team is to recommend appropriate treatment for a specific patient. Examples include prostate and transitional cell carcinoma of the bladder, in which radiotherapy and surgery may be equally effective.

Palliation

Surgical procedures are often the quickest and most effective way of palliating symptoms. Examples include the treatment of faecal incontinence with a defunctioning colostomy; fixation of pathological fractures and decompression of spinal cord compression; and the treatment

of fungating skin lesions by 'toilet' surgery. A more specialist role for surgery is in resection of residual masses after chemotherapy and, in very selected cases, resection of metastases.

Systemic chemotherapy

Chemotherapeutic drugs are classified by their mode of action. They have the greatest activity in proliferating cells and this provides the rationale for their use in the treatment of cancer. Chemotherapeutic agents are not specific for cancer cells, however, and the side-effects of treatment are a result of their antiproliferative actions in normal tissues such as the bone marrow, skin and gut.

Combination therapy

In order to overcome drug resistance and to limit the side-effects of different drugs, chemotherapy is most commonly given as a combination of agents. Combinations usually include drugs from different classes, with the aim of targeting several pathways and gaining maximum therapeutic effect. Drugs are conventionally given by intravenous injection every 3–4 weeks, allowing enough time for the patient to recover from short-term toxic effects before the next dose. Between four and eight such cycles of treatment are usually given in total. More recently, other strategies have been developed. For example, 5-fluorouracil (5-FU), which has a very short half-life, has increased efficacy when given by continuous intravenous infusion, using a semi-permanent indwelling intravenous catheter. However, the use of such catheters is not without risk and the potential of oral 5-FU is now being explored, using precursors such as capecitabine. Schedules of administration at weekly or 2-weekly intervals have also found their place in the management of both solid and haematological malignancies. Each tumour type has specific regimens that are used at various stages of the disease.

Mode of administration

Most drugs have to be given intravenously, and many are vesicant or locally irritant if there is an extravasation. Chemotherapy should be administered into a vein in which the infusion is free-flowing to minimise the risk of extravasation. A few patients require central venous catheters due to the nature of their treatment or poor vascular access. Patients who receive chemotherapy through a peripheral line must be carefully observed, and the chemotherapy stopped at the first sign of any extravasation. Chemotherapy is potentially dangerous to the person giving the therapy, because cytotoxics are carcinogenic and teratogenic. In view of this, policies must be in place for the use of gloves and aprons and for the safe disposal of syringes containing cytotoxics. Other oral chemotherapeutic agents have been developed over the past 30 years, although not many have replaced their intravenous counterparts.

Adverse effects

Most cytotoxics have a narrow therapeutic window or index and can have significant adverse effects, as shown in Figure 11.5. Considerable supportive therapy is often required to enable patients to tolerate therapy and achieve benefit. Nausea and vomiting are common,

but with modern antiemetics, regimens such as the combination of dexamethasone and highly selective 5-hydroxytryptamine (5-HT) receptor antagonists such as ondansetron, most patients now receive chemotherapy without any significant problems. Myelosuppression is common to almost all cytotoxics. This not only limits the dose of drug, but also can cause life-threatening complications. The risk of neutropenia can be reduced with the use of specific growth factors that accelerate the repopulation of myeloid precursor cells. The most commonly employed is granulocyte colony-stimulating factor (G-CSF), which is widely used in conjunction with chemotherapy regimens that induce a high rate of neutropenia. More recently, it has also been used to 'accelerate' the administration of chemotherapy, enabling standard doses to be given at shorter intervals where the rate-limiting factor has been the time taken for the peripheral neutrophil count to recover. Accelerated chemotherapy regimens have now been demonstrated to offer therapeutic advantages in small cell lung cancer, lymphoma and possibly breast cancer.

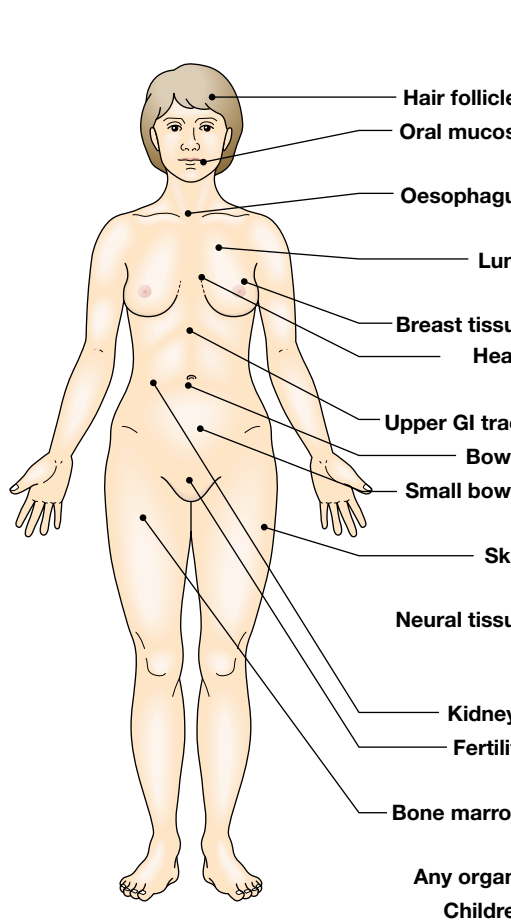

Radiation therapy

Radiation therapy (radiotherapy) involves treating the cancer with ionising radiation; for certain localised cancers it may be curative. Ionising radiation can be delivered by radiation emitted from the decay of radioactive isotopes or by high-energy radiation beams, usually X-rays. Three methods are usually employed:

- *Teletherapy*: application from a distance by a linear accelerator.
- *Brachytherapy*: direct application of a radioactive source on to or into a tumour. This allows the delivery of a very high, localised dose of radiation and is integral to the management of localised cancers of the head and neck and cancer of the cervix and endometrium.
- *Intravenous injection of a radioisotope*: such as ^{131}I iodine for cancer of the thyroid and ^{89}Sr strontium for the treatment of bone metastases from prostate cancer.

The majority of treatments are now delivered by linear accelerators which produce electron or X-ray beams of high energy that are used to target tumour tissue. Whatever the method of delivery, the biological effect of ionising radiation is to cause lethal and sublethal damage to DNA. Since normal tissues are also radiosensitive, treatment has to be designed to maximise exposure of the tumour and minimise exposure of normal tissues. This is now possible with modern imaging techniques such as CT and MRI, which allow better visualisation of normal and tumour tissue. In addition, techniques such as conformal radiotherapy, where shaped rather than conventional square or rectangular beams are used, allow much more precise targeting of therapy to the tumour, and reduce the volume of normal tissue irradiated by up to 40% compared to non-conformal techniques.

Biological differences between normal and tumour tissues are also used to obtain therapeutic gain. Fundamental to this is fractionation, which entails delivering the radiation as a number of small doses on a daily basis. This allows normal cells to recover from irradiation damage, but recovery occurs to a lesser degree in malignant cells. Fractionation regimens vary from centre to centre but radical treatments given with curative intent are often

	Chemotherapy (often drug-specific)	Radiotherapy
Hair follicles	Alopecia	Alopecia
Oral mucosa	Mucositis	Mucositis
		Xerostomia
Oesophagus	Mucositis	Mucositis
		Strictures
Lung	Fibrosis	Cough
		Fibrosis
Breast tissue		↑ Risk breast cancer
Heart	Arrhythmias	↑ Risk ischaemic heart disease
	Heart failure	
Upper GI tract	Nausea and vomiting	
Bowel	Mucositis, diarrhoea	
Small bowel		Nausea, diarrhoea
		Fibrosis and perforation
Skin	Erythema	Erythema and desquamation
		Telangiectasia, thinning of the skin
Neural tissue	Sensory neuropathy	
	Motor neuropathy	
	Nerve deafness	
Kidneys	Renal impairment	
Fertility	Premature gonadal failure	Premature gonadal failure
	Amenorrhoea	
Bone marrow	Neutropenia, anaemia	Neutropenia
	Thrombocytopenia	↓ Haemoglobin, platelet count
Any organs		Increased risk of malignancy
Children		Reduced growth

Fig. 11.5 Adverse effects of chemotherapy and radiotherapy. Acute effects are shown in red and late effects in blue.

delivered in 20–30 fractions given daily, 5 days a week over 4–6 weeks. Radiotherapy can also be extremely useful for the alleviation of symptoms, and for palliative treatments such as this a smaller number of fractions (1–5) is usually adequate.

Both normal and malignant tissues vary widely in their sensitivity to radiotherapy. Germ cell tumours and lymphomas are extremely radiosensitive and relatively low doses are adequate for cure, but most cancers require doses close to or beyond that which can be tolerated by adjacent normal structures. Normal tissue also varies in its radiosensitivity, the central nervous system, small bowel and lung being amongst the most sensitive. The side-effects of radiotherapy (see Fig. 11.5) depend on the normal tissues treated, their radiosensitivity and the dose delivered.

Adverse effects

An acute inflammatory reaction commonly occurs towards the end of most radical treatments and is localised to the area treated. For example, skin reactions are common with breast or chest wall radiotherapy, and proctitis and cystitis with treatment to the bladder or prostate. These acute reactions settle over a period of a few weeks after treatment, assuming normal tissue tolerance has not been exceeded. Late effects of radiotherapy develop 6 weeks or more after treatment and occur in 5–10% of patients. Examples include brachial nerve

damage and subcutaneous fibrosis after breast cancer treatment, and shrinkage and fibrosis of the bladder after treatment for bladder cancer. There is a risk of inducing cancer after radiotherapy, which varies depending on the site treated and whether the patient has had other treatment such as chemotherapy.

Hormone therapy

Hormone therapy is most commonly used in the treatment of breast cancer and prostate cancer. Breast tumours which are positive for expression of the oestrogen receptor (ER) respond well to anti-oestrogen therapy, and assessment of ER status is now standard in the diagnosis of breast cancer. Several drugs are now available which reduce oestrogen levels or block the effects of oestrogen on the receptor. When targeted appropriately, adjuvant hormone therapy reduces the risk of relapse and death at least as much as chemotherapy, and in advanced cases can induce stable disease and remissions that may last months to years, with acceptable toxicity. Hormonal manipulation may be effective in other cancers. In prostate cancer, hormonal therapy (e.g. luteinising hormone releasing hormone (LHRH) analogues such as goserelin and/or anti-androgens such as bicalutamide) aimed at reducing androgen levels can provide good long-term control of advanced disease, but there

is no convincing evidence that it is an effective therapy following potentially curative surgery. Progestogens are active in the treatment of endometrial and breast cancer. In the metastatic setting, progestogen use (e.g. megestrol acetate) is associated with response rates of 20–40% in endometrial cancer. In breast cancer, progestogens are used in patients whose disease has progressed with conventional anti-oestrogen therapy. Their exact mechanism in this setting is not fully understood.

Immunotherapy

A profound stimulus to the patient's immune system can sometimes alter the natural history of a malignancy, and the discovery of interferons stimulated much research. Although solid tumours show little benefit, interferons are active in melanoma and lymphoma, and there is evidence that they are beneficial as adjuvants (after surgery and chemotherapy respectively) to delay recurrence. Whether interferon-induced stimulation of the immune system is capable of eradicating microscopic disease remains unproven. More powerful immune responses can be achieved with potent agents like interleukin-2 (IL-2), but the accompanying systemic toxicity is a problem still to be overcome. The most striking example of successful immunotherapy is with rituximab, an antibody against the common B-cell antigen CD20. It increases complete response rates and improves survival in diffuse large cell non-Hodgkin's lymphoma when combined with chemotherapy, and is also effective in palliating advanced follicular non-Hodgkin's lymphoma (p. 1040).

Biological therapies

Advances in knowledge about the molecular basis of cancer have resulted in the development of a new generation of treatments to block the signalling pathways responsible for the growth of specific tumours. This has created the potential to target cancer cells more selectively, with reduced toxicity to normal tissues. Some examples are discussed below, but in the years to come many more such agents will come into clinical use, with the potential to revolutionise our approach to some cancers.

Gefitinib/erlotinib

These agents inhibit the activity of the epidermal growth factor receptor, which is over-expressed in many solid tumours. However, the drugs' activity does not depend on the amount of receptor over-expression but on factors such as gene copy number and mutation status.

Imatinib

Imatinib was developed to inhibit the *BCR-ABL* gene product tyrosine kinase that is responsible for chronic myeloid leukaemia (p. 1034), which it does extremely effectively. It is also active in gastrointestinal stromal tumour (GIST), a type of sarcoma which has over-expression of another cell surface tyrosine kinase, *c-kit*. This agent has good tolerability and is particularly useful in GIST, where conventional chemotherapy is less effective.

Trastuzumab

Trastuzumab (herceptin) targets the *Her-2* receptor, which is an oncogene that is over-expressed in around

one-third of breast cancers and in a number of other solid tumours. It is effective as a single-agent therapy, but also improves survival in patients with advanced breast cancer when used in conjunction with chemotherapy. Unfortunately, trastuzumab can induce cardiac failure by an unknown biological mechanism, especially in combination with doxorubicin.

SPECIFIC CANCERS

The diagnosis and management of cancers is discussed in more detail elsewhere in the book. Here we discuss the clinical features, pathogenesis and management of common tumours that are not covered elsewhere.

Breast cancer

Globally, the incidence of breast cancer is only second to that of lung cancer and it represents the leading cause of cancer-related deaths among women. Invasive ductal carcinoma with or without ductal carcinoma in situ (DCIS) is the most common histology, accounting for 70%, whilst invasive lobular carcinoma accounts for most of the remaining cases. DCIS constitutes 20% of breast cancers detected by mammography screening. It is multifocal in one-third of women and has a high risk of becoming invasive (10% at 5 years following excision only). Pure DCIS does not cause lymph node metastases, although these are found in 2% of cases where nodes are examined, owing to undetected invasive cancer. Lobular carcinoma in situ (LCIS) is a predisposing risk factor for developing cancer in either breast (7% at 10 years). The survival for breast cancer by stage is outlined in Box 11.18.

Pathogenesis

Both genetic and hormonal factors play a role; about 5–10% of breast cancers are hereditary and occur in patients with mutations of *BRCA1*, *BRCA2*, *AT* or *p53* genes. Prolonged oestrogen exposure associated with early menarche, late menopause and HRT use has been associated with an increased risk. Other risk factors include obesity, alcohol intake, nulliparity and late first pregnancy. There is no definite evidence linking use of the contraceptive pill to breast cancer.

Clinical features

The presentation is usually with a painless mass in the breast that persists throughout the menstrual cycle.

11.18 Five-year survival rates for breast cancer by stage

Tumour stage	Stage definition	5-year survival (%)
Stage I	Tumour < 2 cm, no lymph nodes	96
Stage II	Tumour 2–5 cm, and/or mobile axillary lymph nodes	81
Stage III	Chest wall or skin fixation, and/or fixed axillary lymph nodes	52
Stage IV	Metastasis	18

Increasingly, however, patients are diagnosed through mammography screening programmes. Nipple discharge or pain is present in less than 10% of cases. Approximately 40% of patients have axillary lymph nodes at diagnosis and the risk is proportionate to the size of the primary tumour. Distant metastases are uncommon at presentation but the most common sites in those with advanced disease are bone, lung, liver, pleura and the adrenal glands. These patients may present with bone pain, breathlessness, hepatomegaly or jaundice.

Investigations

Following clinical examination, patients should have an imaging procedure in the form of mammography or ultrasound evaluation and a biopsy. Histological assessment should be carried out to assess tumour type and to determine oestrogen and progesterone receptor (ER/PR) status and Her-2 status. If distant spread is suspected, CT of the thorax and abdomen, and a bone scan may be indicated.

Management

Surgery is the mainstay of treatment for most patients, and this can range from a lumpectomy, where only the tumour is removed, to mastectomy, where the whole breast is removed. Lymph node sampling is performed at the time of surgery to obtain prognostic information that may influence the subsequent decision on adjuvant treatment. Radiotherapy is offered to patients who have breast-sparing surgery in which multifocal disease has been demonstrated and those with lymph node involvement. Systemic therapy is offered as adjuvant treatment to patients with adverse prognostic features such as a large primary tumour (≥ 20 mm) and positive axillary lymph nodes (Box 11.19). Patients whose tumours are found to be positive for ER or PR should have anti-oestrogen treatment with either tamoxifen or aromatase inhibitors (e.g. anastrozole, exemestane), or sequential use of the two. It is important to remember that the use of an aromatase inhibitor should be limited to postmenopausal women. In some cases, where Her-2/neu is over-expressed, trastuzumab may be used.

For patients with metastatic disease, the choice of initial systemic therapy would depend on receptor status (ER, PR and Her-2), rapidity of tumour growth and patient symptomatology. ER/PR-positive patients who are relatively asymptomatic or who have slow tumour growth should be given anti-oestrogen treatment, while patients with rapid tumour growth or negative ER/PR status are best treated with chemotherapy with or

without trastuzumab (in Her-2/neu over-expressing tumours). Pamidronate or zoledronic acid should be given to patients with bone metastases. Radiotherapy may be indicated for treating specific problems such as brain metastases, painful bone metastasis or spinal cord compression. Surgery has a role in the treatment of certain complications, such as decompression and fixation of the spine in cord compression.

Ovarian cancer

Ovarian cancer is the most common gynaecological tumour in Western countries. Most ovarian cancers are epithelial in origin (90%) and up to 7% of women with ovarian cancer have a positive family history. Patients often present late in ovarian cancer with vague abdominal discomfort, low back pain, bloating, altered bowel habit and weight loss. Occasionally, peritoneal deposits are palpable as an omental 'cake' and nodules in the umbilicus (Sister Mary Joseph nodules).

The 5-year survival for ovarian and other gynaecological cancers is outlined in Box 11.20.

11.20 Five-year survival rates for gynaecological cancers

Tumour type	5-year survival (%)
Ovarian cancer	36
Endometrial cancer	73
Cervical cancer	61

Pathogenesis

Genetic and environmental factors play a role. The risk of ovarian cancer is increased in patients with *BRCA1* or 2 mutations, and Lynch type II families (a subtype of hereditary non-polyposis colon cancer (HNPCC)) have ovarian, endometrial, colorectal and gastric tumours due to mutations of mismatch repair enzymes. Advanced age, nulliparity, ovarian stimulation and Caucasian descent all increase the risk of ovarian cancer whilst suppressed ovulation appears to protect, so pregnancy, prolonged breastfeeding and the contraceptive pill have all been shown to reduce the risk of ovarian cancer.

Investigations

Initial workup for patients with suspected ovarian malignancy includes imaging in the form of ultrasound and CT. Serum levels of the tumour marker CA-125 are often measured. Surgery plays a key role in the diagnosis, staging and treatment of ovarian cancer, and in early cases palpation of viscera, intraoperative washing and biopsies are generally performed to define disease extent.

Management

In early disease surgery followed by adjuvant chemotherapy with carboplatin, or carboplatin plus paclitaxel, is the treatment of choice. Surgery should include removal of the tumour along with total hysterectomy, bilateral salpingo-oophorectomy, and omentectomy. Even in advanced tumours, surgery is undertaken to debulk the tumour and is followed by adjuvant chemotherapy, typically using carboplatin and paclitaxel. Monitoring for relapse is achieved through a combination of serum

EBM 11.19 Use of adjuvant chemotherapy and endocrine therapy in early breast cancer

'The use of anthracycline-based chemotherapy reduces the annual breast cancer rate from 38% to 20%, while the adjuvant use of tamoxifen for 5 years in early breast cancer for patients with ER-positive disease reduces the annual breast cancer death rate by 31%.'

- Early Breast Cancer Trialists Collaborative Group (EBCTCG). *Lancet* 2005; 366:2087–2106.

For further information:  www.oncoconferences.ch/2007/home/home.htm

CA-125 and CT. If the patient relapses, second-line chemotherapy may be tried with either a further platinum/paclitaxel combination or liposomal doxorubicin or topotecan. These regimens are associated with a response rate of 10–40%. The best responses are observed in patients with a treatment-free interval of more than 12 months.

Endometrial cancer

Endometrial cancer accounts for 4% of all female malignancies, producing a 1 in 73 lifetime risk. The majority of patients are post-menopausal, with a peak incidence at 50–60 years of age. Mortality from endometrial cancer is currently falling. The most common presentation is with post-menopausal bleeding, which often results in detection of the disease before distant spread has occurred.

Pathogenesis

Oestrogen plays an important role in the pathogenesis of endometrial cancer, and factors that increase the duration of oestrogen exposure, such as nulliparity, early menarche, late menopause and unopposed hormone replacement therapy (HRT), increase the risk. Endometrial cancer is 10 times more common in obese women, and this is thought to be due to elevated levels of oestrogens.

Investigations

The diagnosis is confirmed by endometrial biopsy.

Management

Surgery is the treatment of choice and is also used for staging. A hysterectomy and bilateral salpingo-oophorectomy are performed with peritoneal cytology, and in some cases, lymph node dissection. Where the tumour extends beyond the inner 50% of the myometrium, adjuvant pelvic radiotherapy is recommended. Chemotherapy and hormonal therapies have not demonstrated a sufficient survival advantage to be recommended for routine use.

Cervical cancer

This is the second most common gynaecological tumour world-wide. The incidence is decreasing in developed countries but continues to rise in developing nations. Cervical cancer is the leading cause of death from gynaecological cancer. The most common presentation is with an abnormal smear test, but with locally advanced disease the presentation is with vaginal bleeding, discomfort, discharge or symptoms attributable to involvement of adjacent structures, such as bladder, or rectal or pelvic wall. Occasionally, patients present with distant metastases to bone and lung.

Pathogenesis

There is a strong association between cervical cancer and sexual activity that includes sex at a young age and multiple sexual partners. Infection with HPV has an important causal role, and this has underpinned the introduction of programmes to immunise teenagers against HPV in an effort to prevent the later development of cervical cancer (p. 423).

Investigations

Diagnosis is made by smear or cone biopsy. Dilatation and curettage is also used diagnostically, with cystoscopy and rectosigmoidoscopy if there are symptoms referable to the bladder, colon or rectum. In contrast to

other gynaecological malignancies, cervical cancer is a clinically staged disease. MRI is often used to characterise the primary tumour. A routine chest X-ray should be obtained to help rule out pulmonary metastasis. CT of the abdomen and pelvis is performed to look for metastasis in the liver and lymph nodes and to exclude hydronephrosis and hydroureter.

Management

This depends on the stage of disease. Pre-malignant disease can be treated with laser ablation or diathermy, whereas in microinvasive disease cone biopsy or a simple hysterectomy is employed. Invasive but localised disease requires radical surgery, while chemotherapy and radiotherapy may be given as primary treatment, especially in patients with adverse prognostic features such as bulky or locally advanced disease, or lymph node or parametrium invasion. In metastatic disease, cisplatin-based chemotherapy may be beneficial in improving symptoms but does not improve survival significantly.

Head and neck tumours

Head and neck cancers are typically squamous tumours which arise in the nasopharynx, hypopharynx and larynx. They are most common in elderly males, but now occur with increasing frequency in a younger cohort, as well as in women. Presentation depends on the location of the primary tumour and the extent of disease. For example, early laryngeal cancers may present with hoarseness, while more extensive local disease may present with pain due to invasion of local structures or with a lump in the neck. Patients who present late often have pulmonary symptoms, as this is the most common site of distant metastases (Box 11.21).

Pathogenesis

The tumours are strongly associated with a history of smoking and excess alcohol intake, but other recognised risk factors include Epstein-Barr virus and HPV infection.

11.21 Common presenting features by location in head and neck cancer

Hypopharynx	
• Dysphagia	• Referred otalgia
• Odynophagia	• Enlarged lymph nodes
Mouth	
• Non-healing ulcers	• Ipsilateral otalgia
Nasal cavity and sinuses	
• Discharge (bloody) or obstruction	
Nasopharynx	
• Nasal discharge or obstruction	• Diplopia
• Conduction deafness	• Hoarse voice
• Atypical facial pain	• Horner's syndrome
Oropharynx	
• Dysphagia	• Otalgia
• Pain	
Salivary gland	
• Painless swelling	• Facial nerve palsy

Investigations

Careful inspection of the primary site is required as part of the staging process, and most patients will require endoscopic evaluation and examination under anaesthesia. Tissue biopsies should be taken from the most accessible site. CT of the primary site and the thorax is the investigation of choice for visualising the tumour, while MRI may be useful in certain cases.

Management

In localised disease where there is no involvement of the lymph nodes, long-term remission can be achieved in 60–70% of patients with surgery or radiotherapy. The choice of surgery versus radiotherapy often depends on patient preference, as surgical treatment can be mutilating with an adverse cosmetic outcome. Patients with lymph node involvement or metastasis are treated with a combination of surgery and radiotherapy (often with chemotherapy as a radiosensitising agent), and this produces long-term remission in approximately 30% of patients. Recurrent or metastatic tumour may be palliated with further surgery or radiotherapy to aid local control, and systemic chemotherapy has a response rate of around 30%. Second malignancies are common (3% per year) following successful treatment for primary disease, and all patients should be encouraged to give up smoking and drinking alcohol to lower their risk.

Carcinoma of unknown origin

Some patients are found to have evidence of metastatic disease at their initial presentation prior to diagnosis of a primary site. In many cases, a subsequent biopsy reveals adenocarcinoma but the primary site is not always clear.

Investigations

In this situation, there is a temptation to investigate the patient endlessly in order to determine the original primary site. However, there is a compromise between exhaustive investigation and obtaining sufficient information to plan appropriate management. For all patients, histological examination of an accessible site of metastasis is required. The architecture of the tissue can assist the pathologist in determining the likely primary site, and therefore it is better to perform a biopsy rather than fine needle aspiration. The greater volume of tissue also permits the use of immunohistochemistry. Extensive imaging to search for the primary is rarely indicated; a careful history to identify symptoms and risk factors (including familial) will often permit a judicious choice of imaging.

Management

Management of the patient will depend on that person's circumstances, as well as on the site(s) involved and the likely primary sites. The overriding principle is to

ensure that a curable diagnosis has not been overlooked. For example, lung metastases from a testicular teratoma do not preclude cure; nor do one or two liver metastases from a colorectal cancer. Early discussion with an oncologist within a multidisciplinary team is essential and avoids unnecessary investigation; for example, a single hCG-based pregnancy test in a young man with lung metastases might confirm the presence of a teratoma and allow rapid administration of potentially curative chemotherapy. Treatment should not necessarily wait for a definitive diagnosis; appropriate analgesia, radiotherapy and surgical palliation can all be helpful. Some patients remain free of cancer for some years after resection of a single metastasis of an adenocarcinoma of unknown primary, justifying this approach in selected patients.

In those with no obvious primary, systemic chemotherapy may achieve some reduction in tumour burden and alleviation of symptoms, but long-term survival is rare.

Palliative care is the active total care of patients with far advanced, rapidly progressive and ultimately fatal disease. Its focus is quality of life rather than cure, and it encompasses a distinct body of knowledge and skills that all good physicians must possess to allow them to care effectively for patients at the end of life. In palliative care, there is a fundamental change of emphasis in decision-making, with investigations and treatments kept appropriate to the stage of the patient's disease and the prognosis. The principles of palliative care may be applied not only to cancer but to any chronic disease state. In this chapter, the management of cancer and non-malignant pain control are described, along with other issues in palliative care.

PAIN

The International Association for the Study of Pain (IASP) has defined pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage'. It follows that severity of pain does not correlate with the degree of tissue damage, and that each patient's experience and expression of pain are different. Effective pain treatment facilitates recovery from injury or surgery, aids rapid recovery of function, and may minimise chronic pain and disability. Unfortunately, obstacles to the delivery of good pain relief may include poor assessment and concerns about the use of opioid analgesia.

Pain classification and mechanisms

Pain can be classified into two types:

- *nociceptive*: due to direct stimulation of peripheral nerve endings (e.g. wounds, fractures, burns, angina)
- *neuropathic*: due to dysfunction of the pain perception system within the peripheral or central nervous system as a result of injury, disease or surgical damage (e.g. continuing pain experienced from a limb which has been amputated – 'phantom limb pain'). This should be identified early (Box 12.1) because it is more difficult to treat once established.

The pain perception system is described on page 1140. There is considerable plasticity (changeability) in all the peripheral and central components of the pain pathway. It is not therefore a simple hard-wired circuit of nerves connecting tissue pain receptors to the brain, but a dynamic system in which a continuing pain stimulus can cause central changes that lead to an increase in pain

perception. Early and appropriate treatment of pain reduces the potential for these changes to develop.

Assessment and measurement of pain

Accurate assessment of the patient is the first step in providing good analgesia.

History and measurement of pain

A full pain history should be taken, to establish its causes and the underlying diagnoses. Patients may have more than one pain; for example, bone and neuropathic pain may arise from skeletal metastases (Box 12.2).

A diagram of the body on which the patient can mark the pain site can be helpful. When patients are asked to score pain, they consistently rate it higher than their physicians and nurses, so if they are able, they should always be asked to rate it. Methods include:

- *Verbal rating scale*. Different verbal descriptions are used to rate pain – 'no pain', 'mild pain', 'moderate pain' and 'severe pain'.
- *11-point scale*. A question is used, such as 'Over the past 24 hours, how would you rate your pain, if 0 is no pain and 10 is the worst pain you could imagine?'
- *Behavioural rating scale*. It can be particularly difficult to decide whether a patient with cognitive impairment is suffering pain. A variety of measures are available which assess how a patient is behaving to estimate whether he or she has pain, e.g. agitation, withdrawn posture. Changes in behavioural rating pain scores can indicate whether drug measures have been successful.

Regular recording of formal pain assessment and patient-rated pain scores improves pain management and reduces the time taken to achieve pain control.

Psychological aspects of chronic pain

Perception of pain is influenced by many factors other than the painful stimulus, and pain cannot therefore be easily classified as wholly physical or psychogenic in any individual (Fig. 12.1). Patients who suffer chronic pain will be affected emotionally and, conversely, emotional distress can exacerbate physical pain (p. 238). Full assessment for symptoms of anxiety and depression is fundamental to effective pain management.

Examination

This should include careful assessment of the painful area, looking for signs of neuropathic pain (see Box 12.1) or bony tenderness suggestive of bone metastases. In patients with cancer, it should not be assumed that all pains are due to the cancer or its metastases.

Appropriate investigations

Investigations should be directed towards diagnosis of an underlying cause, remembering that reversible causes are possible even in patients with terminal cancer. Imaging may be indicated, such as plain X-ray for fracture or magnetic resonance imaging (MRI) for spinal cord compression.

12.1 Features of neuropathic pain

- Burning, stabbing or pulsing pain
- Spontaneous pain, without ongoing tissue damage
- Pain in an area of sensory loss
- The presence of a major neurological deficit (e.g. spinal cord trauma)
- Pain in response to non-painful stimuli: 'allodynia'
- Increased pain in response to painful stimuli: 'hyperalgesia'
- Unpleasant abnormal sensations: 'dysaesthesias'
- Poor relief from opioids alone

12.2 Types of pain		
Type of pain	Features	Management options
Bone pain	Tender area over bone Possible pain on movement	Non-steroidal anti-inflammatory drugs (NSAIDs) Bisphosphonates Radiotherapy
Increased intracranial pressure	Headache, worse in the morning, associated with vomiting and occasionally confusion	Corticosteroids Radiotherapy Codeine
Abdominal colic	Intermittent severe spasmodic, associated with nausea or vomiting	Antispasmodics, e.g. hyoscine butylbromide
Liver capsule pain	Right upper quadrant abdominal pain, often associated with tender enlarged liver	Corticosteroids (Poor relief with opioids)
Neuropathic pain	See Box 12.1	Anticonvulsants, e.g. gabapentin, valproate Antidepressants, e.g. amitriptyline Ketamine
Ischaemic pain	Diffuse severe aching pain associated with evidence of poor perfusion	Poorly responsive to opioids NSAIDs Ketamine
Incident pain	Episodic pain usually related to movement or bowel spasm	Intermittent short-acting opioids Nerve block

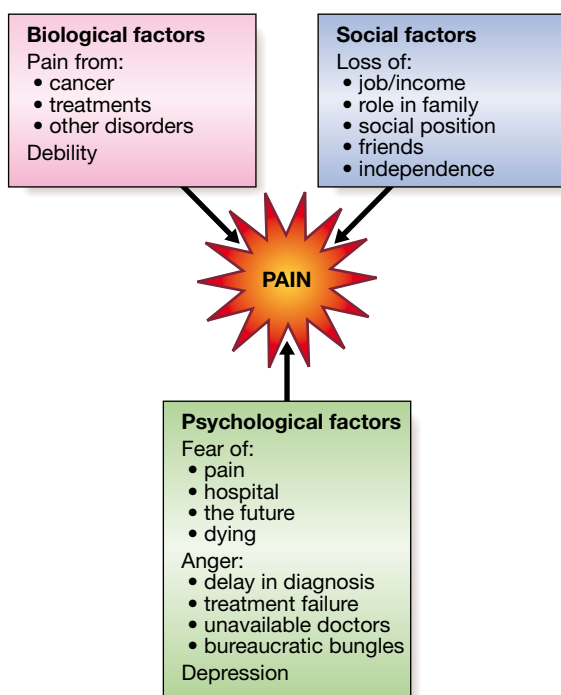

Fig. 12.1 Components of pain.

Management of pain

Many of the principles of pain management apply to any painful condition. Some interventions, such as strong opioids, have (or are perceived to have) a greater potential for harm in patients with a good prognosis. Acute pain post-surgery or following trauma should be controlled with medication without causing unnecessary

side-effects or risk to the patient (Fig. 12.2). Chronic, non-malignant pain is more difficult and it may be impossible to relieve pain completely. There is a greater emphasis on non-pharmacological treatments and on enabling the patient to cope with pain. Strong opioids may help chronic pain but need to be used with caution after full assessment.

Two-thirds of patients with cancer experience moderate or severe pain, and a quarter will have three or more different pains. Many of these are of mixed aetiology and 50% of pain from cancer has a neuropathic element. Careful evaluation to identify the likely pain mechanism facilitates appropriate treatment (see Box 12.2). It is vital that the patient's concerns about opioids are explored and reassurance given that, when they are used for pain, psychological dependence and tolerance are not a concern (Box 12.3).

12.3 Opioid myths

Myth	Fact
Pain is inevitable in cancer and many other diseases	Pain can usually be controlled
Opioids should be avoided because of dangerous side-effects	Opioids can cause side-effects and sometimes the therapeutic window is narrow. However, side-effects are treatable and reversible
The use of opioids commonly leads to addiction	Addiction is very rare in patients who have pain and no previous history of addiction
Taking opioids leads to more rapid decline and earlier death	Opioids do not cause organ damage or serious harm. NSAIDs and paracetamol are more likely to cause irreversible damage

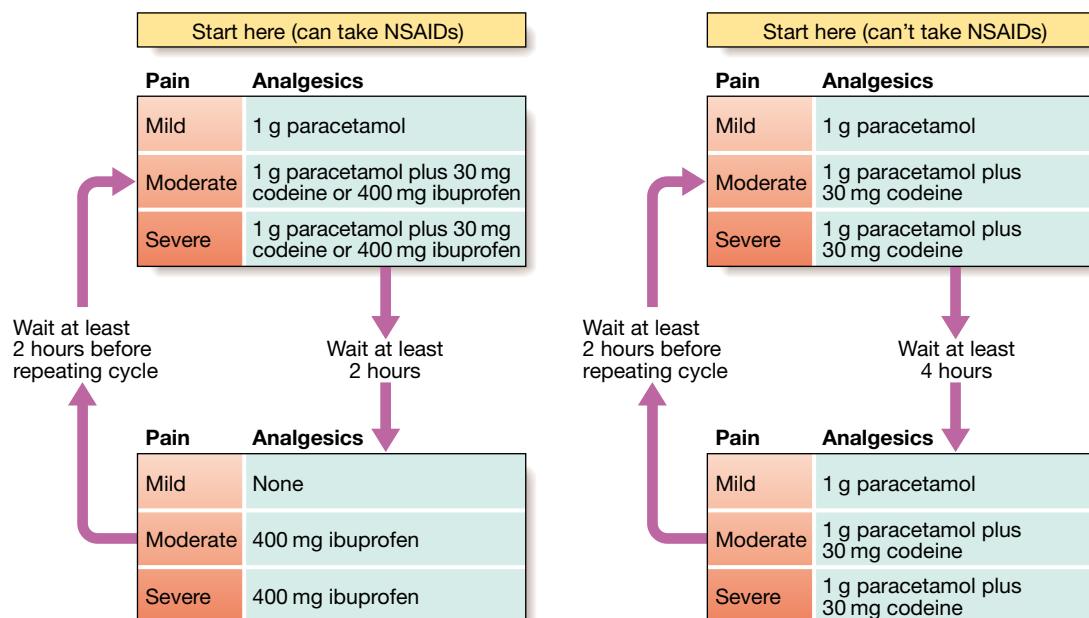

Fig. 12.2 Acute pain management. NSAIDs cannot be taken by those with renal impairment or peptic ulceration. This includes many older people.

Nearly all types of pain respond to morphine to some degree. Some are completely opioid-responsive but others, e.g. neuropathic and ischaemic pains, are relatively unresponsive. Opioid-unresponsive or poorly responsive pain will only be relieved by opioids at a dose which causes significant side-effects. In this situation, effective pain relief can only be achieved with the use of adjuvant analgesics (see below).

Pharmacological treatments

The WHO analgesic ladder

The basic principle of the WHO ladder (Fig. 12.3) is that analgesia which is appropriate for the degree of pain should be prescribed and the dose increased until pain is controlled. If pain is severe or remains poorly controlled, strong opioids should be prescribed.

A patient with mild pain is started on a non-opioid analgesic drug, e.g. paracetamol 1 g 6-hourly (step 1). If the maximum recommended dose is not sufficient or the patient has moderate pain, a weak opioid, e.g. codeine 60 mg 6-hourly, is added (step 2). If adequate pain relief is still not achieved with the maximum recommended dosages or if the patient has severe pain, a strong opioid is substituted for the weak opioid (step 3). It is important not to move 'sideways' (change from one drug to another of equal potency) on a particular step of the ladder. All patients with severe pain should receive a full trial of strong opioids with appropriate adjuvant analgesia, as described below.

Non-opioids

- **Paracetamol.** This is often effective for mild to moderate pain. For severe pain, it is inadequate alone, but remains a useful and well-tolerated adjunct.

- **NSAIDs.** These are effective in the treatment of mild to moderate pain, and are also useful adjuncts in the treatment of severe pain. Adverse effects may be serious, especially in the elderly (p. 173).

Weak opioids

Codeine and dihydrocodeine are weak opioids. They have lower analgesic efficacy than strong opioids and a ceiling dose. They are effective for mild to moderate pain.

Strong opioids

Immediate-release (IR) oral morphine takes about 20 minutes to have an effect and usually provides pain relief for 4 hours. Most patients with continuous pain

Fig. 12.3 The WHO analgesic ladder.

should be prescribed IR oral morphine every 4 hours (i.e. six times daily) initially, which will provide continuous pain relief over the whole 24-hour period. Controlled-release (CR) morphine lasts for 12 or 24 hours but takes much longer to take effect. It should only be used once the correct dose has been found through dose titration with IR morphine until adequate pain relief is achieved.

In addition to the regular dose, an extra dose of IR morphine should be prescribed 'as required' for when the patient has pain that is not controlled by the regular prescription ('breakthrough' pain). This should be the same as the regular 4-hourly dose. The frequency of breakthrough doses should be dictated by their efficacy and any side-effects, rather than by a fixed time interval. A patient may require breakthrough analgesia hourly if pain is severe, but this should lead to early review of the regular prescription. The patient and/or carer should note the timing of any breakthrough doses and the reason for them. These should be reviewed daily and the regular 4-hourly dose increased for the next 24 hours on the basis of:

- frequency of and reasons for breakthrough analgesia
- degree and acceptability of side-effects.

The regular 24-hour dose should then be increased by adding on the total of the breakthrough doses over the previous 24 hours, unless there are significant problems with unacceptable side-effects. When the correct dose has been established, a CR preparation can be prescribed, usually twice daily.

World-wide, the most effective and appropriate route of administration is oral, though transdermal preparations of strong opioids (usually fentanyl) are extremely useful in certain situations (e.g. patients with dysphagia or reluctance to take regular tablets). Diamorphine is a highly soluble strong opioid used for subcutaneous infusions, particularly in the last few days of life, but is only available in certain countries.

Common side-effects of opioids are shown in Box 12.4. Nausea and vomiting occur initially but usually settle after a few days. Confusion and drowsiness are

dose-related and reversible. In acute dosing, respiratory depression can occur but this is rare in those on regular opioids.

Opioid toxicity

All patients will develop dose-related side-effects such as nausea, drowsiness, confusion or myoclonus at some point; the dose at which this occurs varies from 10 to 5000 mg of morphine, depending on the patient and the type of pain. This is termed opioid toxicity, and is managed by reducing the dose and returning to IR morphine so that dose adjustments can be made rapidly. Parenteral rehydration may be necessary. Pain should be reassessed to ensure that appropriate adjuvants are being used, and switching to an alternative strong opioid may be helpful. These include oxycodone, transdermal fentanyl, alfentanil, hydromorphone and occasionally methadone, any of which may produce a better balance of benefit against side-effects. Fentanyl and alfentanil have no renally excreted active metabolites and may be particularly useful in patients with renal failure. Pethidine is used in acute pain management but not for chronic or cancer pain because of its short half-life and ceiling dose.

Adjuvant analgesics

An adjuvant analgesic is a drug with a primary indication other than pain but which is analgesic in some painful conditions and may enhance the effect of primary analgesia. At each step of the WHO analgesic ladder, an adjuvant analgesic should be considered, the choice depending on the type of pain (Boxes 12.5 and 12.6).

EBM 12.5 Treatment of neuropathic pain

'Tricyclic antidepressants, a variety of anticonvulsants, and gabapentin are effective treatments for neuropathic pain.'

• Guideline 106. Scottish Intercollegiate Guidelines Network; 2008.

For further information:  www.sign.ac.uk

12.4 Opioid side-effects

Side-effect	Management
Constipation	Regular laxative, e.g. co-danthramer or co-danthrusate (starting dose 2 capsules daily and titrate as needed)
Dry mouth	Frequent sips of iced water, soft white paraffin to lips, chlorhexidine mouthwashes 12-hourly, sugar-free gum, water or saliva sprays
Nausea/vomiting	Haloperidol 1.5–3 mg nocte or metoclopramide/domperidone 10 mg 8-hourly If constant, a parenteral antiemetic is necessary to break the nausea cycle
Sedation	Explanation very important Usually settles in 2–3 days Avoid other sedating medication where possible Ensure appropriate use of adjuvant analgesics which can have an opioid-sparing effect

Non-pharmacological and complementary treatments

Radiotherapy

Radiotherapy has a place in the management of bone metastases (see Box 12.2).

Physiotherapy

This helps to alleviate pain and restore function, through active mobilisation and specific physiotherapy techniques such as spinal manipulation, massage, application of heat or cold, and exercise. Immediate cold application (e.g. ice packs) reduces subsequent swelling and inflammation after sports injury.

Psychological techniques

These include simple relaxation, hypnosis, cognitive behavioural therapies and biofeedback (pp. 239–240), which train the patient to use coping strategies and behavioural techniques. This is more relevant in chronic non-malignant pain than in cancer pain.

12.6 Adjuvant analgesics			
Drug	Dosage	Indications	Side-effects*
NSAIDs (e.g. diclofenac)	50 mg oral 8-hourly (SR 75 mg 12-hourly) 100 mg per rectum once a day	Bone metastases, soft tissue infiltration, liver pain, inflammatory pain	Gastric irritation and bleeding, fluid retention, headache; caution in renal impairment
Corticosteroids (e.g. dexamethasone)	8–16 mg per day (titrate down to lowest dose which controls pain)	Raised intracranial pressure, nerve compression, soft tissue infiltration, liver pain	Gastric irritation if used together with NSAID, fluid retention, confusion, Cushingoid appearance, candidiasis, hyperglycaemia
Gabapentin	100–300 mg nocte (starting dose; titrate to 600 mg 8-hourly)	Neuropathic pain of any aetiology	Mild sedation, tremor, confusion
Carbamazepine (evidence for all anticonvulsants)	100–200 mg nocte (starting dose)	Neuropathic pain of any aetiology	Vertigo, sedation, constipation, rash
Amitriptyline (evidence for all tricyclics)	25 mg nocte (starting dose) 10 mg (elderly)	Neuropathic pain of any aetiology	Sedation, dizziness, confusion, dry mouth, constipation, urinary retention; avoid in cardiac disease
Ketamine	10–60 mg 6-hourly	Severe neuropathic pain (only under specialist supervision)	Confusion, anxiety, agitation, hypertension

*In old age, all drugs can cause confusion.

Stimulation therapies

Acupuncture (Fig. 12.4) has been used successfully in Eastern medicine for centuries. It causes release of endogenous analgesics (endorphins) within the spinal cord. Transcutaneous electrical nerve stimulation (TENS) may have a similar mechanism of action to acupuncture and can be used in both acute and chronic pain.

Herbal medicine and homeopathy

These are widely used for pain, but often with little evidence for efficacy (p. 15). Safety regulations for these

Fig. 12.4 Acupuncture.

treatments are limited compared with conventional drugs, and the doctor should be wary of unrecognised side-effects which may result.

PALLIATIVE CARE

There is a growing recognition that the principles of, and some specific interventions developed in the palliative care of patients with cancer are equally applicable to other conditions. The challenge is recognising when patients have entered this phase of their illness, as there are fewer clear markers and the course of the illness is much more variable. Different chronic disease states progress at different rates, allowing some general trajectories of illness or dying to be defined (Fig. 12.5). Traditionally, palliative care has been associated with cancer because the latter is typified by a progressive decline in function which is more predictable than

Fig. 12.5 Archetypal trajectories of dying.

in many other disease states, but provision of palliative care should be on the basis of need rather than diagnosis. It is relatively easy to provide palliative care to patients with illnesses other than cancer which fit this progressively deteriorating trajectory of dying: for example, motor neuron disease, or AIDS where highly active antiretroviral therapy (HAART) is not available.

Many chronic diseases other than cancer carry as high a burden of symptoms, as well as psychological and family distress. The 'palliative phase' of these illnesses (e.g. chronic obstructive pulmonary disease (COPD) or heart failure) may be more difficult to identify because of periods of relative stability interspersed with acute episodes of severe illness. However, it is still possible to recognise those patients who are close to the end of their lives and to adjust their treatment accordingly. The challenge is that symptom management needs to be delivered at the same time as treatment for acute exacerbations. This leads to difficult decisions as to the balance between symptom relief and aggressive management of the underlying disease.

The third major trajectory is categorised by years of very poor function and frailty before a relatively short terminal period, and is exemplified by dementia. As medical advances extend survival, this mode of dying is being experienced by increasing numbers. The main challenge lies in providing nursing care and ensuring that plans are agreed for the time when medical intervention is no longer beneficial.

Clearly, many of the principles of palliative care are applicable to all these disease states. Breathlessness from any cause can be alleviated, even when there is no reversible 'cause', appropriate drugs can be prescribed for nausea, and any predicted death can be managed effectively and compassionately.

Presenting problems in palliative care

Breathlessness

The sensation of breathlessness is the result of a complex interaction between different factors at the levels of production (the pathophysiological cause), perception (the severity of breathlessness perceived by the patient) and expression (the symptoms expressed by an individual patient). Perception and expression of breathlessness can be significantly improved, even if there is no reversible 'cause' (Box 12.7). Assessment and treatment should therefore be targeted at modifying this, particularly when there is no reversible pathophysiology.

Clearly reversible causes of breathlessness (p. 654) should be identified and managed, but investigation and treatment should be appropriate to the prognosis and stage of disease. A therapeutic trial of corticosteroids (dexamethasone 8 mg for 5 days) and/or nebulised salbutamol may be helpful.

EBM 12.7 Palliative treatment of breathlessness

'Interventions based on psychosocial support, breathing control and coping strategies can help patients to cope with the symptom of breathlessness and reduce physical and emotional distress.'

• Bredin M, et al. *BMJ* 1999; 318:901.

Perception of breathlessness may be affected by specific anxieties and beliefs about breathlessness, which should be explored. For patients with advanced disease, a common fear is that they will die during an attack of breathlessness. Although this is understandable, reassurance can be given that it is unlikely. Another frequently expressed fear is that breathlessness will continue to worsen until it is continuous and unbearable, leading to a distressing and undignified death. Reassurance should again be given that this is uncommon and can be effectively managed with opioids and benzodiazepines.

Some patients have specific panic-breathlessness cycles in which breathlessness leads to panic, which leads to worsening breathlessness and worsening panic. These should be identified and explained to the patient. A rapidly acting benzodiazepine such as sublingual lorazepam or non-drug measures such as relaxation techniques may help. Discussion with a physiotherapist about energy conservation and pacing of activity may also be useful.

Perception of breathlessness may also be improved by night-time or regular morphine, or by regular benzodiazepines. Oxygen may be no more effective than a fan or piped air for non-hypoxic breathlessness, and again the patient's perception of the need for oxygen can be gently explored and modified.

Cough

Intractable cough is a difficult symptom to manage. There are many causes (p. 652) in cancer and other intractable illnesses, e.g. motor neuron disease, cardiac failure and COPD. The underlying condition should be specifically treated. Antitussives, such as codeine linctus, are sometimes effective, particularly for cough at night.

Nausea and vomiting

Different causes of nausea and vomiting (p. 852) are associated with different clinical presentations. Large-volume vomiting with little nausea is common in intestinal obstruction, whereas constant nausea with little or no vomiting is often due to metabolic abnormalities or drugs. Vomiting related to raised intracranial pressure is worse in the morning.

Different receptors are activated, depending on the cause or causes of the nausea (Fig. 12.6). For example, dopamine receptors in the chemotactic trigger zone in the fourth ventricle are stimulated by metabolic and drug causes of nausea, whereas gastric irritation stimulates histamine receptors in the vomiting centre via the vagus nerve.

Reversible causes (e.g. hypercalcaemia, constipation) should be treated appropriately. Potential drug culprits should be considered and stopped if possible. As different classes of antiemetic drug act at different receptors, antiemetic therapy should be based on a careful assessment of the probable causes and a rational decision to use a particular class of drug (Box 12.8). The subcutaneous route is often required initially to overcome gastric stasis and poor absorption of oral medicines.

Gastrointestinal obstruction

Gastrointestinal obstruction is a frequent complication of intra-abdominal cancer. Patients may have multiple levels of obstruction and symptoms may vary greatly in nature and severity. Surgical mortality is high in patients

Fig. 12.6 Mechanisms of nausea. (ACh = acetylcholine; D₂ = dopamine; 5-HT = 5-hydroxytryptamine, serotonin; H₁ = histamine)

12.8 Receptor site activity of antiemetic drugs		
Area	Receptors	Drugs
Chemo trigger zone	Dopamine ₂ 5-HT	Haloperidol Metoclopramide
Vomiting centre	Histamine ₁ Acetylcholine	Cyclizine Levomopromazine Hyoscine
Gut (gastric stasis)		Metoclopramide
Gut distension (vagal stimulation)	Histamine ₁	Cyclizine
Gut (chemoreceptors)	5-HT	Levomopromazine

with advanced disease and obstruction may be effectively managed without surgery.

The key to effective management is to address the presenting symptoms—colic, abdominal pain, nausea, vomiting, intestinal secretions—individually or in combination, using drugs which do not cause or worsen other symptoms. Colic responds well to anticholinergic agents such as hyoscine butylbromide, and somatostatin analogues such as octreotide will reduce intestinal secretions and therefore large-volume vomits. Nausea will improve with metoclopramide, although this is

contraindicated in the presence of colic because of its prokinetic effect. Cyclizine will improve nausea but may reduce gut motility. There is some evidence that corticosteroids (dexamethasone 8 mg) shorten the length of obstructive episodes.

Weight loss and general weakness

Patients with cancer lose weight due to an alteration of metabolism by the tumour known as the cancer cachexia syndrome. NSAIDs and megestrol may be helpful in early-stage disease but are unlikely to be effective in advanced cancer. Corticosteroids can temporarily boost appetite and general well-being, but may cause false weight gain by promoting fluid retention. Their benefits in this situation need to be carefully weighed against the risk of side-effects.

Anxiety and depression

Even in patients with far advanced disease, anxiety and depression may still respond to treatment with a combination of drugs and psychotherapeutic approaches (p. 242). It should not be assumed that depression is 'understandable' because of an unpleasant physical symptom and therefore has no solution other than removing the symptom. It may improve with specific treatment, even if the underlying physical problem remains.

Delirium and terminal agitation

Many patients become confused or agitated in the last days of life. It is important to identify and treat potentially reversible causes (pp. 171 and 248), unless the patient is too close to death for this to be feasible. Effective management of any distressing confusion is extremely important. Patients should be prescribed a neuroleptic agent (haloperidol) for confusion and adequate doses of benzodiazepines (diazepam or midazolam) to relieve distress. If there is profound distress, large doses of benzodiazepines can be used. Opioids are not useful.

THE DYING PHASE

Talking about dying

Talking about dying is difficult for health professionals, as they may feel a sense of failure or a fear of causing distress and loss of hope. Some patients have a great fear of death and never wish to discuss the possibility; others welcome the chance to talk about death and the dying process, express their wishes and gain reassurance that these will be respected. In general, people wish for a dignified and peaceful death. Most people prefer to die at home and early discussion allows this to be planned. Families also are grateful for the chance to prepare themselves for the death of a relative, by timely and gentle discussion with their doctor or other health professionals.

Diagnosing dying

There comes a time when death is predictable and inevitable, and when further active intervention will be futile and will cause distress rather than benefit. At least

two-thirds of patients dying in hospital have a death that is predictable, and measures should be taken to plan good care for the patient and family.

When patients with cancer become bed-bound, semi-comatose, unable to take tablets and only able to take sips of water, they are likely to be dying and many will have died within 2 days. Patients with other conditions also reach a stage where death is predictable and imminent. Doctors are sometimes poor at recognising this, and should be alert to the views of other members of the multidisciplinary team. A clear decision that the patient is dying should be agreed and recorded.

Management

Once a decision has been reached, there is a significant shift in management. Symptom control, relief of distress and care for the family are the most important elements of care (Box 12.9). Medication and investigation are only justifiable if they contribute to these ends. When patients can no longer drink because they are dying, intravenous fluids are not necessary and may cause worsening of bronchial secretions. Medicines should always be prescribed for the relief of pain (e.g. morphine or diamorphine), nausea (e.g. levomepromazine), confusion (e.g. haloperidol), distress (e.g. diazepam or midazolam) and respiratory secretions (e.g. hyoscine hydrobromide). If these cause side-effects, such as drowsiness, it is reasonable to continue them none the less, if the principal aim of relieving distress is achieved.

Ethical issues at the end of life

In Europe, between 25 and 50% of all deaths are associated with some form of decision which may affect the length of a patient's life. The most common form of decision involves withdrawing or withholding further treatment: for example, not treating a chest infection in a patient who is clearly dying from advanced cancer. Occasionally, medicines are given which shorten a patient's life utilising the principle of double effect (see below). It is important to have a framework for considering such decisions (such as the four ethical principles: autonomy, beneficence, non-maleficence and justice, p. 10), which balances degrees of importance when there is conflict: for example, when a patient wishes to

receive treatment which a doctor judges to be harmful or which is illegal. A decision has to be taken as to which principle is most important. Is it better to respect a patient's wishes even if it causes harm, or to prevent harm by not respecting them?

A futile treatment is one which has no chance of achieving worthwhile benefit, i.e. it cannot achieve a result that the patient would consider, now or in the future, to be worthwhile. Doctors are not required to institute a futile treatment, such as resuscitation in the event of cardiac arrest in a patient with terminal cancer.

Incapacity and advance directives

Patients' wishes are very important in Western countries, although this is not true in all cultures. If a patient is unable to express his or her view because of communication or cognitive impairment, that person lacks 'capacity'. In order to decide what the patient would have wished, as much information as possible should be gained about any previously expressed wishes, along with the views of relatives and other health professionals. An advance directive is a previously recorded, written document of a patient's wishes (p. 169). It should carry the same weight in decision-making as a patient's contemporaneously expressed wishes, but may not be sufficiently specific to be used in a particular clinical situation.

Rehydration

Deciding whether to give intravenous fluids can be difficult when a patient is very unwell and the prognosis is uncertain. If a patient is clearly dying and has a prognosis of a few days, rehydration may cause harm by increasing bronchial secretions, and will not benefit the patient by prolonging life or relieving symptoms. A patient with a major stroke, who is unable to swallow but expected to survive the event, will develop renal impairment and thirst if not given fluids and should be hydrated, unless this is considered futile.

Double effect

At the end of life, the principle of double effect allows symptom control to be given to patients, even though it may shorten their life, provided the 'good' effect (control of symptoms) outweighs the 'bad' effect (shortening of life), and there is no other means to achieve the same result. The intention must be to control symptoms rather than shorten life and no more medication should be given than achieves symptom control.

Euthanasia

In the UK and Europe between 3 and 6% of dying patients ask a doctor to end their life. Many of these requests are transient; some are associated with poor control of physical symptoms or a depressive illness. All expressions of a wish to die are an opportunity to help the patient discuss and address unresolved issues and problems.

Reversible causes, such as pain or depression, should be treated. Sometimes patients may choose to discontinue life-prolonging treatments, such as angiotensin-converting enzyme (ACE) inhibitors or anticoagulation, following discussion and the provision of adequate alternative symptom control. However, there remain a small number of patients who have a sustained, competent wish to end their lives, despite good control of physical symptoms. Public ethical and legal debate over this issue is likely to continue.

12.9 Checklist for the dying phase

- Stop non-essential medication (i.e. that does not contribute to symptom control)
- Stop inappropriate investigations and interventions (e.g. parenteral fluids)
- Complete Do Not Attempt Resuscitation (DNAR) form
- Stop routine observations
- Ensure availability of parenteral medication for symptom relief
- Assess patient and family's awareness of condition
- Assess religious and spiritual needs
- Ensure family understands plan of care and provide ongoing support
- Ensure continued assessment and management of symptoms
- Arrange appropriate care after death

Fever

- **Documentation of fever.** 'Feeling hot' or sweaty is not synonymous with fever. Body temperature must be documented: $> 38.0^{\circ}\text{C}$ is a fever. Axillary and aural measurement is less accurate than oral or rectal. Outpatients may be trained to keep a temperature chart.
- **Rigors.** Shivering (followed by excessive sweating) implies a rapid rise in body temperature but rarely gives a clue to aetiology.
- **Night sweats.** These are characteristic of several infections (e.g. tuberculosis (TB), infective endocarditis), but sweating from any cause is worse at night.
- **Excessive sweating.** Alcohol, anxiety, thyrotoxicosis, diabetes mellitus, acromegaly, lymphoma and excessive environmental heat all cause sweating without temperature elevation.
- **Recurrent fever.** There are various causes of recurrent fever, e.g. *Borrelia recurrentis*, bacterial abscess.
- **Accompanying features**
 - Headache.** Severe headache and photophobia, although characteristic of meningitis, may accompany other infections.
 - Delirium.** Mental confusion during fever is more common in young children or the elderly.
 - Muscle pain.** Myalgia may occur with viral infections, such as influenza, and with septicaemia including meningococcal sepsis.
 - Shock.** Shock may accompany severe infections and sepsis (Ch. 8).

Documentation of temperature.

- A** Body temperature should be accurately recorded.
- B** Hand-held tympanic thermometer.

History-taking in suspected infectious disease (ID)*

Presenting complaint	Family and contact history	
<ul style="list-style-type: none"> • Diverse manifestations of ID make accurate assessment of features and duration critical; e.g. fever and cough lasting for 2 days imply an acute respiratory tract infection and for 2 months suggest TB 	<ul style="list-style-type: none"> • Note infections and their time course • Sensitively explore exposure to key infections, e.g. TB and human immunodeficiency virus (HIV)-1 	<ul style="list-style-type: none"> • Establish who else was exposed, e.g. to potential food-borne diarrhoea
Review of systems	Travel history	History of intravenous drug injection or receipt of blood products
<ul style="list-style-type: none"> • Must be comprehensive 	<ul style="list-style-type: none"> • Include countries visited and where previously resident (relevant to exposure and likely vaccination) 	<ul style="list-style-type: none"> • Risks for blood-borne viruses, such as HIV-1 and hepatitis B and C viruses (HBV and HCV)
Past medical history	Occupation	Sexual history
<ul style="list-style-type: none"> • Define the 'host' and likelihood of infection(s) • Include surgical and dental procedures involving prosthetic materials • Document previous infections 	<ul style="list-style-type: none"> • e.g. Anthrax in leather tannery workers 	<ul style="list-style-type: none"> • Explore in a confidential, polite and non-threatening way (Ch. 15), remembering that the most common mechanism of HIV-1 transmission is heterosexual contact (Ch. 14)
Medication history	Recreational pursuits	Vaccination history and use of prophylactic medicines
<ul style="list-style-type: none"> • Include non-prescription drugs, use of antimicrobials and immunosuppressive drugs 	<ul style="list-style-type: none"> • e.g. Leptospirosis in windsurfers 	<ul style="list-style-type: none"> • Consider occupation- or age-related vaccines • In a traveller or infection-predisposed patient, establish compliance with prophylactic treatments
Allergy history	Animal exposures	
<ul style="list-style-type: none"> • Especially to antimicrobials, noting the allergic manifestation (e.g. rash versus anaphylaxis) 	<ul style="list-style-type: none"> • Include pets, e.g. dog exposure and hydatid disease 	
	Dietary history	
	<ul style="list-style-type: none"> • Consider undercooked meats, shellfish, unpasteurised dairy products or well water 	

*Always consider whether a non-infectious aetiology explains the clinical syndrome.

1 Skin lesions in infectious diseases

- Diffuse erythema, e.g. panel A
- Migrating erythema, e.g. enlarging rash of erythema migrans in Lyme disease (see Fig. 13.19, p. 330)
- Purpuric or petechial rashes, e.g. panel B
- Macular or papular rashes, e.g. primary infection with HIV (see Box 14.3, p. 389)
- Vesicular or blistering rash, e.g. panel C
- Erythema multiforme (see Fig. 27.48 and Box 27.38, p. 1284)
- Nodules or plaques, e.g. Kaposi's sarcoma (p. 384)
- Erythema nodosum (panel D and Box 27.39, p. 1285)

Streptococcal toxic shock syndrome

Meningococcal sepsis

Shingles

Erythema nodosum

The principles of infection and its investigation and therapy are described in Chapter 6. This chapter and the following chapters on human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) and sexually transmitted infection (STI) describe the approach to patients with potential infectious disease, the individual infections and the syndromes they produce.

PRESENTING PROBLEMS IN INFECTIOUS DISEASES

Infectious diseases present with myriad clinical manifestations. Many of these are described in other chapters of this book. The most common scenarios presenting to specialists in infectious disease are described below.

Fever

'Fever' implies an elevated core body temperature $> 38.0^{\circ}\text{C}$, i.e. above the normal daily variation (p. 136). Fever is a response to cytokines and acute phase proteins (pp. 72 and 81) and is a common manifestation of infection, although it also occurs in other conditions.

Clinical assessment

The differential diagnosis is very broad and there is a long list of potential investigations, so any clues from the clinical features which help to focus the investigations are extremely valuable. The systematic approach described on pages 290–291 should be followed. Box 13.1 describes the assessment of elderly patients.

Investigations

If the cause is not obvious, e.g. in a patient with purulent sputum or symptoms of urinary tract infection, then initial screening investigations should include:

- a full blood count (FBC) with differential, including eosinophil count

13.1 Fever in old age

- **Temperature measurement:** fever may be missed because oral temperatures are unreliable in older people. Rectal measurement may be needed but core temperature is increasingly measured using eardrum reflectance.
- **Associated acute confusion:** common with fever, especially in those with underlying cerebrovascular disease or other causes of dementia.
- **Prominent causes of PUO:** include tuberculosis and intra-abdominal abscesses, complicated urinary tract infection and infective endocarditis. Non-infective causes include polymyalgia rheumatica/temporal arteritis and tumours. A smaller fraction of cases remain undiagnosed.
- **Pitfalls in the elderly:** certain conditions such as cerebrovascular accident/thromboembolic disease can cause fever but every effort must be made to exclude concomitant infection.
- **Common infectious diseases in the very frail** (e.g. nursing home residents): include pneumonia, urinary infection, soft tissue infection and gastroenteritis.

- urea and electrolytes, liver function tests (LFTs), blood glucose and muscle enzymes
- inflammatory markers, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)
- autoantibodies, including antinuclear antibodies (ANA)
- chest X-ray and electrocardiogram (ECG)
- urinalysis and urine culture
- blood culture (a minimum of 20 mL blood in three sets of blood culture bottles)
- throat swab for culture
- other specimens, as indicated by history and examination, e.g. wound swab; sputum culture; stool culture, microscopy for ova and parasites and *Clostridium difficile* toxin assay; if relevant, malaria films on 3 consecutive days or a malaria rapid diagnostic test (antigen detection by lateral flow immunochromatography, see Ch. 6).

Subsequent investigations in patients with HIV-related (p. 389), immune-deficient (p. 298), nosocomial or travel-related (p. 305) pyrexia, and in patients with associated symptoms or signs of involvement of the respiratory, gastrointestinal or neurological systems are described elsewhere.

Management

Fever and its associated systemic symptoms can be treated with paracetamol, and by tepid sponging to cool the skin. Replacement of salt and water is important in patients with drenching sweats. Further management is focused on the underlying cause.

Fever with localising symptoms or signs

In most patients, the potential site of infection is apparent after clinical evaluation (pp. 290–291), and the likelihood of infection may be reinforced by typical abnormalities on the initial screening investigations (e.g. neutrophilia and raised ESR and CRP in bacterial infections). Not all apparently localising symptoms are reliable, however; headache, breathlessness and diarrhoea can occur in sepsis without localised infection in the central nervous system (CNS), respiratory tract or gastrointestinal tract. Careful evaluation of the constellation of clinical features is vital (e.g. severe headache associated with photophobia, rash and neck stiffness suggests meningitis, whereas moderate headache with cough and rhinorrhoea is consistent with a viral upper respiratory tract infection).

Common infections that present with fever are shown in Figure 13.1. Many are described elsewhere in the book. Further investigation and management is specific to the cause, but may include empirical antimicrobial therapy (p. 148) pending confirmation of the microbiological diagnosis.

Pyrexia of unknown origin (PUO)

PUO is defined as a temperature persistently above 38.0°C for more than 3 weeks, without diagnosis despite initial investigation during 3 days of inpatient care or after more than two outpatient visits. Subsets of PUO are described by medical setting: HIV-related, immune-deficient or nosocomial. Up to one-third of cases of PUO remain undiagnosed.

Fig. 13.1 Common infectious syndromes presenting with fever and localised features. Major causes are grouped by approximate anatomical location and include central nervous system infection; respiratory tract infections; abdominal, pelvic or urinary tract infections; and skin and soft tissue infections (SSTI) or osteomyelitis. For each site of infection particular syndromes and their common causes are described elsewhere in the book. The causative organisms vary, depending on host factors, which include whether the patient has lived or resided in a tropical country or particular geographical location, has acquired the infection in a health-care environment or is immunocompromised.

Clinical assessment

Major causes of PUO are outlined in Box 13.2. Rare causes, such as periodic fever syndromes (p. 83), should be considered in those with a positive family history. Children and younger adults are more likely to have infectious causes, in particular viral infections. Older adults are more likely to have certain infections and non-infectious causes (see Box 13.1). Detailed examination should be repeated at regular intervals to detect emerging features, such as rashes, signs of infective endocarditis (p. 624) or features of vasculitis. In men the prostate deserves careful consideration as a potential source of infection.

Clinicians should be alert to the possibility of factitious fever, in which high temperature recordings are engineered by the patient (Box 13.3).

Investigations

If initial investigation of fever (see above) is negative, a series of further microbiological and non-microbiological investigations should be considered (Boxes 13.4 and 13.5). These will usually include:

- induced sputum or other specimens for mycobacterial stains and culture
- serological tests
- imaging of the abdomen by ultrasonography or computed tomography (CT)
- echocardiography.

Lesions identified on imaging should usually be biopsied to obtain material for culture, including for the diagnosis of tuberculosis, and histopathology, including special stains for pathogens associated with

13.2 Aetiology of pyrexia of unknown origin

Infections (~30%)

Specific locations

- Abscesses: hepatobiliary*, diverticular*, urinary tract* (including prostate), pulmonary, CNS
- Infections of oral cavity (including dental), head and neck (including sinuses)
- Bone and joint infections
- Infective endocarditis*

Specific organisms

- Tuberculosis (particularly extrapulmonary)*
- HIV-1 infection
- Other viral infections (cytomegalovirus (CMV), Epstein–Barr virus (EBV))
- Fungal infections (e.g. *Aspergillus* spp., *Candida* spp. or dimorphic fungi)
- Infections with fastidious organisms (e.g. *Bartonella* spp., *Tropheryma whippelii*)

Specific patient groups

- Imported infections
Malaria, dengue, rickettsial infections, *Brucella* spp., amoebic liver abscess, enteric fevers, *Leishmania* spp. (southern Europe, India, Africa and Latin America), *Burkholderia pseudomallei* (South-east Asia)
HIV and respiratory tract infections
- Nosocomial infections
Infections related to prosthetic materials and surgical procedures
- HIV-positive individuals
Acute retroviral syndrome
AIDS-defining infections (disseminated *Mycobacterium avium* complex (DMAC), *Pneumocystis jirovecii* (carinii) pneumonia (PCP), CMV and others)

Malignancy (~20%)

Haematological malignancy

- Lymphoma*, leukaemia and myeloma

Solid tumours

- Renal, liver, colon, stomach, pancreas, kidney

Connective tissue disorders (~15%)

Older adults

- Temporal arteritis/polymyalgia rheumatica*

Younger adults

- Still's disease (juvenile rheumatoid arthritis)*
- Systemic lupus erythematosus (SLE)
- Vasculitic disorders (including polyarteritis nodosa, rheumatoid disease with vasculitis and Wegener's granulomatosis)
- Polymyositis
- Behçet's disease

Geographically restricted

- Rheumatic fever

Miscellaneous (~20%)

Cardiovascular

- Atrial myxoma, aortitis, aortic dissection

Respiratory

- Sarcoidosis, pulmonary embolism and other thromboembolic disease, extrinsic allergic alveolitis

Gastrointestinal

- Inflammatory bowel disease, granulomatous hepatitis, alcoholic liver disease, pancreatitis

Endocrine/metabolic

- Thyrotoxicosis, thyroiditis, hypothalamic lesions, pheochromocytoma, adrenal insufficiency, hypertriglyceridaemia

Haematological

- Haemolytic anaemia, paroxysmal nocturnal haemoglobinuria, thrombotic thrombocytopenic purpura, myeloproliferative disorders, Castleman's disease, graft-versus-host disease (after allogeneic bone marrow transplantation)

Inherited

- Familial Mediterranean fever and periodic fever syndromes

Drug reactions*

- e.g. Antibiotic fever, drug hypersensitivity reactions etc.

Factitious fever*

Idiopathic (~15%)

*Most common causes within each group.

13.3 Clues to the diagnosis of factitious fever

- A patient who looks well
- Bizarre temperature chart with absence of diurnal variation and/or temperature-related changes in pulse rate
- Temperature > 41°C
- Absence of sweating during defervescence
- Normal ESR and CRP despite high fever
- Evidence of self-injection or self-harm
- Normal temperature during supervised (observed) measurement and of freshly voided urine

the clinical scenario. The chance of a successful diagnosis is greatest if procedures for obtaining and transporting the correct samples in the appropriate media are carefully planned in advance; this requires discussion between the clinical team, the radiologist or surgeon performing the procedure, and the local microbiologist and histopathologist. Liver biopsy may be justified, e.g. to identify idiopathic granulomatous hepatitis, if there are biochemical or radiological abnormalities. Bone marrow biopsies have a diagnostic yield of up to 15%. A biopsy is most useful in revealing haematological malignancy, myelodysplasia or tuberculosis, and may also identify brucellosis, typhoid fever or visceral leishmaniasis. Bone marrow should always be sent for culture as well as microscopy. Laparoscopy is occasionally undertaken with biopsy of abnormal tissues. Splenic aspiration in specialist centres is the diagnostic test of choice for suspected leishmaniasis. Temporal artery biopsy should be considered in patients over the age of 50 years, even in the absence of physical signs or a raised ESR. 'Blind' biopsy of other structures in the absence of localising signs, or laboratory or radiology results is unhelpful.

13.5 Additional investigations in PUO

Serological tests for connective tissue disorders

- Autoantibody screen
- Complement levels
- Immunoglobulins
- Cryoglobulins

Echocardiography

Ultrasound of abdomen

CT/MRI of thorax, abdomen and/or brain

Imaging of the skeletal system

- Plain X-rays
- CT/MRI spine
- Isotope bone scan

Labelled white cell scan

Positron emission tomography (PET)/single photon emission computed tomography (SPECT)

Biopsy

- Bronchoscopy and lavage ± transbronchial biopsy
- Lymph node aspirate or biopsy
- Biopsy of radiological lesion
- Biopsy of liver
- Bone marrow aspirate and biopsy
- Lumbar puncture
- Laparoscopy and biopsy
- Temporal artery biopsy

Prognosis

The overall mortality of PUO is 30–40%, mainly attributable to malignancy in older patients. If no cause is found, the long-term mortality is low and fever often settles spontaneously.

13.4 Microbiological investigation of PUO

Microscopy

- Blood for atypical lymphocytes (EBV, CMV, HIV-1, hepatitis viruses or *Toxoplasma gondii*), trypanosomiasis, malaria, *Borrelia* spp.
- Respiratory samples for mycobacteria, fungi
- Stool for ova, cysts and parasites
- Biopsy for light microscopy (bacteria, mycobacteria, fungi, *Leishmania* and other parasites) and/or electron microscopy (viruses, protozoa (e.g. microsporidia) and other fastidious organisms (e.g. *T. whipplei*))
- Urine for white or red blood cells, schistosome ova, mycobacteria (early morning urine × 3)

Culture

- Aspirates and biopsies (e.g. joint, deep abscess, debrided tissues)
- Blood, including prolonged culture and special media conditions
- Cerebrospinal fluid (CSF)
- Gastric aspirate for mycobacteria
- Stool

- Swabs
- Urine ± prostatic massage in older men

Antigen detection

- Blood
- CSF for cryptococcal antigen
- Nasopharyngeal aspirate/throat swab for respiratory viruses
- Urine, e.g. for *Legionella* antigen

Nucleic acid detection

- Blood for *Bartonella* spp. and viruses
- CSF for viruses and key bacteria (meningococcus, pneumococcus)
- Nasopharyngeal aspirate/throat swab for respiratory viruses
- Tissue specimens, e.g. for *Tropheryma whipplei*
- Urine, e.g. for *Chlamydia trachomatis*, *Neisseria gonorrhoeae*
- Stool, e.g. for norovirus, rotavirus

Immunological tests

- Serology (antibody detection) for viruses, dimorphic fungi and some bacteria and protozoa
- Interferon-γ release assay for diagnosis of tuberculosis

Note This list does not apply to every patient with a PUO. Appropriate tests should be selected in a stepwise manner, according to specific predisposing factors, epidemiological exposures and local availability, and should be discussed with a microbiologist.

Fever in the injection drug-user

Intravenous injection of drugs of abuse is endemic in many parts of the world (p. 237). Infective organisms are introduced by non-sterile (often shared) injection equipment (Fig. 13.2), while host defences against infection are overcome by direct access to the normally sterile blood stream and by immune deficiencies in poorly nourished addicts. The risks increase with prolonged drug use and injection into large veins of the groin and neck because of progressive thrombosis of superficial peripheral veins. A varied and unusual constellation of infectious diseases is encountered in this group of patients. Although the

differential diagnosis of fever is wide, the most common causes are soft tissue or respiratory infections.

Clinical assessment

The history should include consideration of the following risk factors:

- *Site of injection.* Femoral vein injection is associated with vascular complications such as deep venous thrombosis (50% of which are septic) and accidental arterial injection with false aneurysm formation or a compartment syndrome due to swelling within the fascial sheath. Local

Fig. 13.2 Fever in the injection drug-user: key features of clinical examination. Full examination (p. 290) is required but features most common amongst injection drug-users are shown here.

complications include ilio-psoas abscess, and septic arthritis of the hip joint or sacro-iliac joint. Injection of the jugular vein can be associated with cerebrovascular complications. Subcutaneous and intramuscular injection has been associated with infection by clostridial species, the spores of which contaminate heroin. *Clostridium novyi* causes a local lesion with significant toxin production leading to shock and multi-organ failure. Tetanus, wound botulism and gas gangrene also occur.

- **Technical details of injection.** Sharing of needles and other injecting paraphernalia (including spoons and filters) greatly increases the risk of blood-borne virus infection. Some users lubricate their needles by licking them prior to injection, thus introducing mouth organisms such as anaerobic streptococci, *Fusobacterium* spp. and *Prevotella* spp. Contamination of commercially available lemon juice, used to dissolve heroin before injection, has been associated with blood-stream infection with *Candida* spp.
- **Substances injected.** Injection of cocaine is associated with a variety of vascular events. Certain formulations of heroin have been associated with particular infections, e.g. wound botulism with black tar heroin. Drugs are often mixed with other substances, e.g. talc.
- **Blood-borne virus status.** Results of previous hepatitis B virus (HBV), HCV and HIV tests or vaccinations for HAV/HBV should be recorded.
- **Surreptitious use of antimicrobials.** Addicts may use antimicrobials to self-treat infections, masking initial blood culture results.

Key findings on clinical examination are shown in Figure 13.2. It can be difficult to distinguish effects of infection from the effects of drugs themselves or the agitated state of drug withdrawal (excitement, tachycardia, sweating, marked myalgia, confusion). Stupor and delirium may result from drug administration but may also signal meningitis or encephalitis. Non-infected venous thromboembolism is also common in this group.

Investigations

The initial investigations are as for any fever (see above), including a chest X-ray and blood cultures. Since blood sampling may be difficult, contamination is often a problem. Echocardiography to detect infective endocarditis should be performed in all injection drug-users: with bacteraemia due to *Staph. aureus* or other organisms associated with endocarditis (Fig. 13.3A); with thromboembolic phenomena; or with a new or previously undocumented murmur. Endovascular infection should also be suspected if lung abscesses or pneumatoceles are detected radiologically. Additional imaging should be focused on sites of symptoms and signs (Fig. 13.3B). Any pathological fluid collections should be sampled either under radiological guidance or by surgical means. In patients with suspected compartment syndrome (leg swelling and pain with neurological and ischaemic features), serum creatine kinase and urine myoglobin are useful.

Urinary toxicology may suggest a non-infectious cause of the presenting complaint. While being investigated, all injection drug-users should be offered testing for HBV, HCV and HIV-1.

Fig. 13.3 Causes of fever in the injection drug-user. **[A]** Endocarditis in an injection drug-user. Large vegetation on the tricuspid valve (arrow). **[B]** Septic arthritis of the left sternoclavicular joint (arrow A) (note the erosion of the bony surfaces at the sternoclavicular joint) with overlying soft tissue collection (arrow B). **[C]** CT of the thorax from an injection drug-user with haemoptysis, showing multiple embolic lesions with cavitation (arrows). The patient had *Staph. aureus* endocarditis of the tricuspid valve.

Microbiological results are crucial in guiding therapy. Injection drug-users may have more than one infection. Skin and soft tissue infections are most often due to *Staph. aureus* or streptococci, and sometimes to *Clostridium* spp. or anaerobes. Pulmonary infections are most often due to community-acquired pneumonia, pulmonary tuberculosis or septic pulmonary emboli (Fig. 13.3C). Endocarditis with septic emboli commonly involves *Staph. aureus* and viridans streptococci, but *Pseudomonas aeruginosa* and *Candida* spp. are also encountered.

Management

Empirical therapy of fever in the injection drug user includes an antistaphylococcal penicillin (e.g. flucloxacillin) or, if meticillin-resistant *Staph. aureus* (MRSA) is prevalent in the community, a glycopeptide. Once a particular pathogen is identified, specific therapy is commenced, with modification when antimicrobial

susceptibility is available. In injection drug-users, right-sided endocarditis due to *Staph. aureus* is customarily treated with high-dose intravenous flucloxacillin. In left-sided *Staph. aureus* endocarditis, aminoglycoside therapy may be added. Right-sided endocarditis caused by MRSA is usually treated with 4 weeks of vancomycin plus gentamicin for the first week. Specialist advice should be sought.

For localised infections of the skin and soft tissues, oral therapy with agents active against staphylococci, streptococci and anaerobes is appropriate (e.g. co-amoxiclav or clindamycin).

Fever in the immunocompromised host

Immunocompromised hosts include those with congenital immunodeficiency (p. 76), HIV infection (Ch. 14) and iatrogenic immunosuppression induced by chemotherapy (p. 94), transplantation (p. 1013) or immunosuppressant medicines, including high-dose corticosteroids. Metabolic abnormalities such as under-nutrition or hyperglycaemia may also contribute. Multiple elements of the immune system are potentially compromised. A patient may have impaired neutrophil function from chemotherapy, impaired T cell and/or B cell responses due to underlying malignancy, T cell and phagocytosis defects due to corticosteroids, mucositis from chemotherapy and an impaired skin barrier due to insertion of a central venous catheter.

Fever may result from infectious or from non-infectious causes, including drugs, vasculitis, neoplasm, organising pneumonitis, lymphoproliferative disease, graft-versus-host disease (in recipients of haematopoietic bone marrow transplants; p. 1013) and Sweet's syndrome (reddish nodules or plaques with fever and leucocytosis, in association with haematological malignancy).

Clinical assessment

The following should be addressed in the history:

- Identification of the immunosuppressant factors, and nature of the immune defect.
- Any past infections and their treatment. Infections may recur and antimicrobial resistance may have been acquired in response to prior therapy.
- Evidence of microbial colonisation, especially with antimicrobial-resistant organisms, in past surveillance cultures.
- Exposure to infections, including opportunistic infections that would not cause disease in an immunocompetent host.
- Prophylactic medicines and vaccinations administered.

Examination should include inspection of the normal physical barriers provided by skin and mucosal surfaces, in particular central venous catheters, the mouth, sinuses, ears and perianal area (though avoid digital rectal examination). Disseminated infections can manifest as cutaneous lesions; the areas around finger and toenails should be closely inspected.

Investigations

Initial screening tests are as described above (p. 292). Immunocompromised hosts often have decreased signs of inflammation. This manifests as attenuation of physical signs, such as neck stiffness with meningitis, or of

radiological and laboratory abnormalities, such as leucocytosis. In patients with respiratory symptoms, a high-resolution chest CT scan should be considered in addition to chest X-ray. Abdominal imaging may also be warranted, particularly if there is right lower quadrant pain. Blood cultures through the central venous catheter, urine cultures, and stool cultures if diarrhoea is present may also be helpful.

Additional investigations are shown in Box 13.4. (p. 295) Nasopharyngeal aspirates are sometimes diagnostic, as immunocompromised hosts may shed respiratory viruses for prolonged periods. Skin lesions should be biopsied if nodules are present and investigation should include fungal stains. Useful molecular techniques include polymerase chain reaction (PCR) for CMV and *Aspergillus* spp. DNA, and antigen assays (e.g. cryptococcal antigen (CrAg) for *Cryptococcus neoformans*, and galactomannan for *Aspergillus* spp. in blood or *Legionella pneumophila* type 1 in urine). Antibody detection is rarely useful in immunocompromised patients. Patients with respiratory signs or symptoms should be considered for a bronchoscopy to obtain bronchoalveolar lavage fluid for investigation of pathogens, including *Pneumocystis jirovecii* (carinii) as well as bacteria, fungi and viruses.

Neutropenic fever

Neutropenic fever is strictly defined as a neutrophil count of less than $0.5 \times 10^9/L$ (p. 999) and a single axillary temperature $> 38.5^\circ C$ or three recordings $> 38.0^\circ C$ over a 12-hour period, although the infection risk increases progressively as the neutrophil count drops below $1.0 \times 10^9/L$. Patients with neutropenia are particularly prone to bacterial or fungal infection. Gram-positive organisms are the most common pathogens, particularly in association with in-dwelling catheters. Empirical broad-spectrum antimicrobial therapy is commenced as soon as neutropenic fever occurs and cultures have been obtained.

The most common regimens for neutropenic sepsis are broad-spectrum penicillins such as piperacillin-tazobactam i.v. Although aminoglycosides are commonly used in combination, this practice is not supported by trial data (Box 13.6). If fever has not resolved after 3–5 days, empirical antifungal therapy (e.g. an amphotericin B preparation or caspofungin) is added (p. 157). An alternative antifungal strategy, which is gaining favour, is to use azole prophylaxis in high-risk patients, and to employ sensitive markers of early fungal infection to guide treatment initiation (a 'pre-emptive approach').

EBM 13.6 Treatment of neutropenic fever

'Broad spectrum β -lactam monotherapy is equivalent to β -lactam-aminoglycoside combination therapy for neutropenic fever in many settings.'

- Del Favero A, et al. Clin Infect Dis 2001; 33:1295–1301.

Post-transplantation fever

Fever in transplant recipients may be due to infection, or to episodes of graft rejection in solid organ transplant recipients or graft-versus-host disease in bone marrow transplant recipients.

13.7 Infections in transplant recipients	
Time post-transplantation	Infections
Solid organ recipients	
0–1 month	Bacterial or fungal infections related to the underlying condition or surgical complications
1–6 months	CMV, other opportunistic infections (e.g. PCP)
> 6 months	Bacterial pneumonia, other bacterial community-acquired infections, shingles, cryptococcal infection, post-transplant lymphoproliferative disorder (PTLD)
Bone marrow recipients	
Pre-engraftment (typically 0–4 weeks)	Bacterial and fungal infections (including moulds) or respiratory viruses
Post-engraftment	CMV, PCP, moulds, other opportunistic infections
Late (> 100 days)	Community-acquired bacterial infections, shingles, CMV, PTLD

Infections in solid transplant recipients are grouped according to the time of onset (Box 13.7). Those in the first month are related to the underlying condition or surgical complications. Those occurring 1–6 months after transplantation are characteristic of impaired T cell function. Risk factors for CMV infection have been identified and patients commonly receive either prophylaxis or intensive monitoring involving regular testing for CMV DNA by PCR and early initiation of anti-CMV therapy using intravenous ganciclovir or oral valganciclovir if tests become positive.

For bone marrow transplant recipients (p. 1013), infections in the first four weeks are more common in patients receiving a myeloablative conditioning regimen (see Box 13.7). Later infections are more common if an allogeneic procedure is performed.

Post-transplant lymphoproliferative disorder (PTLD) is an Epstein–Barr virus (EBV)-associated lymphoma that can complicate transplantation, particularly when primary EBV infection occurs after transplantation.

Positive blood culture

Blood-stream infection (BSI) or bacteraemia is a frequent presentation of infection. This can be community-acquired or may arise in hospital ('nosocomial'), although with increasing outpatient treatment 'community-acquired' BSI is more precisely 'community-onset' BSI since it may arise after hospital-based interventions. The most common causes are shown in Box 13.8. In immunocompromised hosts a wider range of microorganisms may be isolated, e.g. fungi in neutropenic hosts.

Primary bacteraemia refers to cases in which the site of infection is unknown; this applies in approximately 10% of community-acquired cases and approximately 30% of nosocomial cases, and is more common in *Staph. aureus* bacteraemias. In community-acquired *Staph. aureus* bacteraemia, 20–30% of cases are associated with infectious endocarditis and up to 10% are due to osteomyelitis. Peripheral and central venous catheter-related infections are an important source of nosocomial BSI.

13.8 Common causes of blood-stream infection	
Community-acquired	
<ul style="list-style-type: none"> <i>Staph. aureus</i> including MRSA <i>Strep. pneumoniae</i> 	<ul style="list-style-type: none"> Other streptococci <i>Escherichia coli</i>
Nosocomial	
<ul style="list-style-type: none"> <i>Staph. aureus</i> including MRSA Coagulase-negative staphylococci Enterococci including VRE 	<ul style="list-style-type: none"> Gram-negative bacteria <i>Candida</i> spp.
(MRSA = methicillin-resistant <i>Staph. aureus</i> ; VRE = vancomycin-resistant enterococci)	

BSI has an associated mortality of 15–40%, depending on the setting, host and microbial factors.

Clinical assessment

The history should determine the setting in which BSI has occurred. Host factors predisposing to infection include skin disease, diabetes mellitus, injection drug use, the presence of a central venous, urinary or haemodialysis catheter, and surgical procedures, especially involving implantation of prosthetic materials (in particular, endovascular prostheses).

Physical examination should focus on signs of endocarditis (p. 624), evidence of bone or joint infection (tenderness or restriction of movement), and abdominal or flank tenderness. Central venous catheters should be examined for erythema or purulence at the exit site. Particularly in cases with *Candida* spp. infection or suspected infectious endocarditis, fundoscopy after pupil dilatation should be performed.

Investigations

Positive blood cultures may be caused by contaminants. When isolated from only one bottle or from all bottles from one venesection, coagulase-negative staphylococci often represent contamination. Repeated isolation of this organism, however, should raise suspicion of infective endocarditis or, in a patient with any form of prosthetic material, prosthesis infection. Viridans streptococci occasionally contaminate blood cultures but, in view of their association with infective endocarditis, significant infection must always be excluded clinically. *Bacillus* spp. ('aerobic spore bearers') and *Clostridium* spp. often represent incidental transient bacteraemia or contamination, but certain species (e.g. *C. septicum*) may be genuine pathogens.

Further investigations are influenced by the causative organism and setting. Initial screening tests are similar to those for fever (p. 292) and should include chest X-ray, urine culture and, in many cases, ultrasound or other imaging of the abdomen. Imaging should also include any areas of bone or joint pain and any prosthetic material, e.g. a prosthetic joint or an aortic graft.

Echocardiography should be considered for patients with BSI who are at risk of endocarditis from underlying valvular heart disease, those with clinical features of endocarditis (including a heart murmur), those whose cultures reveal an organism that is a common cause of endocarditis (e.g. *Staph. aureus*, viridans streptococci or enterococci), and those in whom multiple blood cultures are positive for the same organism. The sensitivities of

transthoracic echocardiography (TTE) and transoesophageal echocardiography (TOE) for the detection of vegetations are 50–90% and > 95%, respectively. Therefore, if TTE is negative, TOE should be used (see Box 18.117, p. 626).

Certain rare causes of BSI have specific associations that warrant further investigation. Endocarditis caused by *Strep. bovis* and infection caused by *C. septicum* are both associated with colonic carcinoma and their isolation is considered to be an indication for colonoscopy.

Management

BSI requires antimicrobial therapy and attention to the source of infection, including surgical drainage if appropriate. Two weeks of therapy may be sufficient for *Staph. aureus* BSI from central and peripheral venous catheter infections when the source is identified and removed, for uncomplicated skin and soft tissue infections and for selected cases of uncomplicated right-sided infective endocarditis. Other *Staph. aureus* BSI is usually treated for 4–6 weeks.

Central venous catheter infections

Infections of central venous catheters typically involve the catheter lumen and are associated with fever, positive blood cultures and, in some cases, signs of purulence or exudate at the site of insertion. Infection is more common in temporary catheters inserted into the groin or jugular vein than those in the subclavian vein. Tunnelled catheters, e.g. Hickman catheters, may also develop tunnel site infections.

Staphylococci account for 70–90% of catheter infections, with coagulase-negative staphylococci more common than *Staph. aureus*. Other causes include enterococci and Gram-negative bacilli. Unusual Gram-negative organisms, such as *Citrobacter freundii* and *Pseudomonas fluorescens*, cause pseudo-outbreaks and raise the possibility of non-sterile infusion equipment or infusate. *Candida* spp. are a common cause of line infections, particularly in association with total parenteral nutrition. Nontuberculous mycobacteria may cause tunnel infections.

Investigations and management

In bacteraemic patients with fever and no other obvious source of infection, a catheter infection is likely. Local evidence of erythema, purulence or thrombophlebitis supports the diagnosis. However, microbiological confirmation is essential (p. 139). Catheter-related infection is suggested by higher colony counts or shorter time to positivity in blood cultures obtained through the catheter than in peripheral blood cultures. If the line is removed, a semi-quantitative culture of the tip should confirm the presence of 15 or more colony-forming units, but this is retrospective and does not detect luminal infection.

For coagulase-negative staphylococcal line infections, the options are to remove the line or, in the case of tunnelled catheters, to treat empirically with a glycopeptide antibiotic, e.g. vancomycin, with or without the use of antibiotic-containing lock therapy to the catheter for approximately 14 days. For *Staph. aureus* infection, the chance of curing an infection with the catheter in situ is low, and the risks from infection are high. Therefore, unless the risks of catheter removal outweigh the benefits, treatment should involve catheter removal followed by 14 days of appropriate antimicrobial therapy; the

same applies to infections with *Candida* spp. or *Bacillus* spp.

Infection prevention is a key component of the management of vascular catheters. Measures include strict attention to hand hygiene, optimal siting, full aseptic technique on insertion and subsequent interventions, skin antisepsis with chlorhexidine and isopropyl alcohol, daily assessment of catheter sites (e.g. with visual infusion phlebitis (VIP) score (p. 326)), and daily consideration of the continuing requirement for catheterisation. The use of catheters impregnated with antimicrobials such as chlorhexidine or silver is advocated in some settings.

Sepsis

Sepsis is defined and discussed on pages 188–190. It describes patients with signs of the systemic inflammatory response syndrome (SIRS: two of temperature > 38 °C or < 36 °C, pulse rate > 90 beats per minute, respiratory rate > 20 per minute or PCO_2 < 4.3 kPa (32.5 mmHg), and white blood cell count > 12 or < $4 \times 10^9/L$ —see Box 8.3, p. 184) and evidence of infection. Septic shock describes sepsis plus hypotension (systolic blood pressure < 90 mmHg systolic or a fall of > 40 mmHg from baseline that is not responsive to fluid challenge or due to another cause). It may be complicated by multi-organ failure and requires intensive care unit admission.

Sepsis largely results from host responses to microbial lipopolysaccharide, peptidoglycans, lipoproteins or superantigens, and there are many infectious causes (Box 13.9). The results of blood cultures and known host factors allow an initial assessment of likely sources of infection which should be the target of initial investigations. Patients who are immunocompromised may have a sepsis syndrome in association with a broader range of pathogens which may be harder to culture, including mycobacteria and fungi. In any individual who has recently visited the tropics, malaria must also be considered.

Severe skin and soft tissue infections (SSTI)

SSTIs are an important cause of sepsis. Cases can be classified as in Box 13.10, according to the clinical features and microbiological findings. In some cases severe systemic features may be out of keeping with mild local features.

Necrotising fasciitis

In this condition, cutaneous involvement with erythema and oedema progresses to bullae or areas of necrosis. However, in contrast to cellulitis, the cutaneous features are often minimal while the pain is severe. The infection spreads quickly along the fascial plane. It is a medical emergency, which requires immediate débridement in addition to antimicrobial therapy (Fig. 13.4). Although the infection may be diagnosed by imaging studies, its rapid spread means that surgical inspection of the involved muscle groups is urgently required to facilitate prompt diagnosis and treatment. Type 1 necrotising fasciitis is a mixed infection with Gram-negative bacteria and anaerobes, often seen post-operatively in diabetic or immunocompromised hosts. Subcutaneous gas may be present. Type 2 necrotising fasciitis is caused by group A or other

13.9 Causes of sepsis

Infection	Setting
Bacterial	
<i>Staph. aureus</i> , coagulase-negative staphylococci	Bacteraemia may be associated with endocarditis, intravascular cannula infection, or skin or bone foci
<i>Strep. pneumoniae</i>	Invasive pneumococcal disease, usually with pneumonia or meningitis
Other streptococci	Invasive streptococcal disease, especially necrotising fasciitis. <i>Viridans</i> streptococci in neutropenic host with severe mucositis
Staphylococcal or streptococcal toxic shock syndrome	Toxin-mediated, blood cultures negative; clues include erythroid rash and epidemiological setting
Enterococci	Most often with abdominal focus
<i>Neisseria meningitidis</i>	Sepsis in children or young adults with petechial rash and/or meningitis
<i>E. coli</i> , other Gram-negative bacteria	Urinary or biliary tract infection, or other abdominal infections
<i>Pseudomonas aeruginosa</i> , multidrug-resistant Gram-negative bacteraemia	Nosocomial infection
<i>Yersinia pestis</i>	In plague
<i>Burkholderia pseudomallei</i>	Endemic in areas of Thailand; more likely to involve patients with diabetes mellitus or immunocompromised
<i>Capnocytophaga canimorsus</i>	Associated with dog bites and asplenic individuals
<i>C. difficile</i>	Severe colitis, particularly in the elderly
Polymicrobial infection with Gram-negatives and anaerobes	Bowel perforation
<i>Mycobacterium tuberculosis</i> , <i>M. avium complex</i> (MAC)	HIV-positive or immunocompromised with miliary TB or disseminated MAC
Fungal	
<i>Candida</i> spp.	Line infection or post-operative complication, nosocomial or immunocompromised host
<i>Histoplasma capsulatum</i> , other dimorphic fungi	Immunocompromised host
Parasitic	
<i>Falciparum</i> malaria	Malaria with high-level parasitaemia and multi-organ failure or as a complication of bacterial superinfection
<i>Babesia microti</i>	Asplenic individual
<i>Strongyloides stercoralis</i> hyperinfection syndrome	Gram-negative infection complicating <i>Strongyloides</i> infection in immunocompromised host

13.10 Severe necrotising soft tissue infections

- Necrotising fasciitis (primarily confined to subcutaneous fascia and fat)
- Clostridial anaerobic cellulitis (confined to skin and subcutaneous tissue)
- Non-clostridial anaerobic cellulitis
- Progressive bacterial synergistic gangrene (*Staph. aureus* + micro-aerophilic streptococcus) ('Meleney's gangrene', primarily confined to skin)
- Pyomyositis (discrete abscesses within individual muscle groups)
- Clostridial myonecrosis (gas gangrene)
- Anaerobic streptococcal myonecrosis (non-clostridial infection mimicking gas gangrene)
- Group A streptococcal necrotising myositis

Fig. 13.4 Excision following necrotising fasciitis in an injection drug-user.

streptococci. Approximately 60% of cases are associated with streptococcal toxic shock syndrome (p. 328).

Empiric treatment is with broad-spectrum agents (e.g. piperacillin-tazobactam plus clindamycin plus ciprofloxacin; meropenem monotherapy; or third-generation cephalosporin plus metronidazole) and surgical débridement. Hyperbaric oxygen therapy may be considered for polymicrobial infection. Group A streptococcal infection is treated with benzylpenicillin plus clindamycin, and often immunoglobulin.

Gas gangrene

Although *Clostridium* spp. may colonise or contaminate wounds, no action is required unless there is evidence of spreading infection. In anaerobic cellulitis, usually due to *C. perfringens* or other strains infecting devitalised tissue following a wound, gas forms locally and extends along tissue planes, but bacteraemia and invasion of healthy tissue are not found. Prompt surgical débridement of devitalised tissue and therapy with penicillin or clindamycin usually result in an excellent outcome.

Gas gangrene (clostridial myonecrosis) is defined as acute invasion of healthy living muscle undamaged by previous trauma, and is most commonly caused by *C. perfringens*. In at least 70% of cases it follows deep penetrating injury sufficient to create an anaerobic (ischemic) environment and allow clostridial introduction

and proliferation. Severe pain at the site of the injury progresses rapidly over 18–24 hours. Skin colour changes from pallor to bronze/purple discoloration and the skin is tense, swollen, oedematous and exquisitely tender. Gas in tissues may be obvious with crepitus on clinical examination, or visible on X-ray, CT or ultrasound. Signs of systemic toxicity develop rapidly, with high leucocytosis, multi-organ dysfunction, raised creatine kinase and evidence of disseminated intravascular coagulation and haemolysis. Antibiotic therapy with high-dose intravenous penicillin and clindamycin is recommended, coupled with aggressive surgical débridement of the affected tissues. Alternative agents include cephalosporins and metronidazole. Hyperbaric oxygen has a putative but controversial role.

Other SSTIs

'Synergistic gangrene' is a combined infection with anaerobes and other bacteria (*Staph. aureus* or Gram-negatives). When this affects the genital/perineal area it is known as 'Fournier's gangrene'. Severe gangrenous cellulitis in immunocompromised hosts may involve Gram-negative bacteria or fungi. *Entamoeba histolytica* can cause soft tissue necrosis following abdominal surgery in areas of the world where infection is common. Contact with shellfish in tropical areas and regions such as the Gulf of Mexico can lead to infection with *Vibrio vulnificus*, which causes soft tissue necrosis and bullae. Patients with chronic liver disease are particularly susceptible.

Acute diarrhoea and vomiting

Acute diarrhoea (p. 856), sometimes with vomiting, is the predominant symptom in infective gastroenteritis (Box 13.11). Acute diarrhoea may also be a symptom of other infectious and non-infectious diseases (Box 13.12). Stress, whether psychological or physical, can also produce loose stools.

13.11 Causes of infectious gastroenteritis

Toxin in food: < 6 hours incubation

- *Bacillus cereus* (p. 336)
- *Clostridium* spp. enterotoxin (p. 336)
- *Staph. aureus* (p. 336)

Bacterial: 12–72 hours incubation

- *Vibrio cholerae* (p. 339)
- Enterotoxigenic *E. coli* (ETEC, p. 337)
- Shiga toxin-producing *E. coli* (EHEC, p. 337)*
- Enteroinvasive *E. coli* (EIEC, p. 337)*
- *Salmonella** (p. 337)
- *Shigella** (p. 339)
- *Campylobacter** (p. 336)
- *Clostridium difficile** (p. 338)

Viral: short incubation

- Rotavirus (p. 323)
- Norovirus (p. 323)

Protozoal: long incubation

- Giardiasis (p. 363)
- *Cryptosporidium* (pp. 363 and 393)
- Microsporidiosis (p. 393)
- Amoebic dysentery (p. 362)*
- Isosporiasis (p. 394)

*Associated with bloody diarrhoea.

13.12 Differential diagnosis of acute diarrhoea and vomiting

Infectious causes

- Gastroenteritis
- *C. difficile* infection (p. 338)
- Acute diverticulitis (p. 913)
- Sepsis (p. 300)
- Pelvic inflammatory disease (p. 415)
- Meningococcaemia (p. 1206)
- Pneumonia (especially 'atypical disease', p. 670)
- Malaria (p. 348)

Non-infectious causes

Gastrointestinal

- Inflammatory bowel disease (p. 895)
- Bowel malignancy (p. 907)
- Overflow from constipation (p. 913)

Metabolic

- Diabetic ketoacidosis (p. 809)
- Thyrotoxicosis (p. 738)
- Uraemia (p. 487)
- Neuroendocrine tumours releasing (e.g.) VIP or 5-HT

Drugs and toxins

- NSAIDs
- Cytotoxic agents
- Antibiotics
- Proton pump inhibitors
- Dinoflagellates (p. 304)
- Plant toxins (p. 304)
- Heavy metals (p. 304)
- Ciguatera fish poisoning (p. 304)
- Scombrototoxic fish poisoning (p. 304)

The World Health Organization (WHO) estimates that there are more than 1000 million cases of acute diarrhoea annually in developing countries, with 3–4 million deaths, most often in infants and young children. In developed countries diarrhoea remains an important problem and the elderly are most vulnerable (Box 13.13). The majority of episodes are due to infections spread by the faecal-oral route and transmitted either on fomites, on contaminated hands, or in food or water. Measures such as the provision of clean drinking water, appropriate disposal of human and animal sewage, and simple principles of food hygiene all limit gastroenteritis.

The clinical features of food-borne gastroenteritis depend on the pathogenic mechanisms involved. Some organisms (*Bacillus cereus*, *Staph. aureus* and *Vibrio cholerae*) elute exotoxins, which exert their major effects on the stomach and small bowel, and produce vomiting and/or so-called 'secretory' diarrhoea, which is watery diarrhoea without blood or faecal leucocytes. In general, the time from ingestion to the onset of symptoms is short and, other than dehydration, little systemic upset occurs. Other organisms, such as *Shigella* spp., *Campylobacter*

13.13 Infectious diarrhoea in old age

- **Incidence:** not increased, but the impact is greater.
- **Mortality:** most deaths due to gastroenteritis in the developed world are in adults aged over 70 years. Most are presumed to be caused by dehydration leading to organ failure.
- ***C. difficile* infection (CDI):** old age is associated with CDI, especially in hospital and nursing home settings, usually following antibiotic exposure.

spp. and enterohaemorrhagic *E. coli* (EHEC), may directly invade the mucosa of the small bowel or produce cytotoxins that cause mucosal ulceration, typically affecting the terminal small bowel and colon. The incubation period is longer and more systemic upset occurs, with prolonged bloody diarrhoea. *Salmonella* spp. are capable of invading enterocytes, and of causing both a secretory response and invasive disease with systemic features. This is seen with *Salmonella typhi* and *S. paratyphi* (enteric fever), and, in the immunocompromised host, with non-typhoidal *Salmonella* spp.

Clinical assessment

The history should include questioning about foods ingested (Box 13.14), the duration and frequency of diarrhoea, the presence of blood or steatorrhoea, abdominal pain and tenesmus, and whether family or community members have been affected. Fever and bloody diarrhoea suggest an invasive, colitic, dysenteric process. Incubation periods of less than 18 hours suggest toxin-mediated food poisoning; a period longer than 5 days suggests diarrhoea caused by protozoa or helminths.

Examination includes assessment of the degree of dehydration by skin turgor, with pulse and blood pressure measurement. The urine output and ongoing stool losses should be monitored.

Investigations

These include stool inspection for blood and microscopy for leucocytes, and also an examination for ova, cysts and parasites if the history indicates former tropical residence or travel. Stool culture should be performed, if possible. FBC and serum electrolytes indicate the degree of inflammation and dehydration. In a malarious area, a blood film for malaria parasites should be obtained. Blood and urine cultures and a chest X-ray may identify alternative sites of infection, particularly if the clinical

examination is suggestive of a syndrome other than gastroenteritis.

Management

All patients with acute, potentially infective diarrhoea should be appropriately isolated to minimise person-to-person spread of infection. If the history suggests a food-borne source, public health measures must be implemented to identify the source and whether other linked cases exist (p. 144).

Fluid replacement

Replacement of fluid losses in diarrhoeal illness is crucial and may be life-saving.

Although normal daily fluid intake in an adult is only 1–2 L, there is considerable additional fluid movement in and out of the gut in secretions (see Fig. 22.7, p. 842). Infective and toxic processes in the gut disturb or reverse resorption in the small intestine and colon, potentially resulting in substantial fluid loss. Cholera is the archetype of this process, in which 10–20 L of fluid may be lost in 24 hours.

The fluid lost in diarrhoea is isotonic, so both water and electrolytes need to be replaced. Absorption of electrolytes from the gut is an active process requiring energy. Infected mucosa is capable of very rapid fluid and electrolyte transport if carbohydrate is available as an energy source. Oral rehydration solutions (ORS) therefore contain sugars, as well as water and electrolytes (Box 13.15). ORS can be just as effective as intravenous replacement fluid, even in the management of cholera. In mild to moderate gastroenteritis, adults should be encouraged to drink fluids and, if possible, continue normal dietary food intake. If this is impossible, e.g. due to vomiting, intravenous fluid administration will be required. In very sick patients, or those with cardiac or renal disease, monitoring of urine output and central venous pressure may be necessary.

The volume of fluid replacement required should be estimated based on the following considerations.

- **Replacement of established deficit.** After 48 hours of moderate diarrhoea (6–10 stools per 24 hours) the average adult will be 1–2 L depleted from diarrhoea alone. Associated vomiting will compound this. Adults with this symptomatology should therefore be given rapid replacement of 1–1.5 L, either orally (ORS) or by intravenous infusion (normal saline), within the first 2–4 hours of presentation.

13.14 Foods associated with infectious illness, including gastroenteritis	
Raw seafood	
• Norovirus	• Hepatitis A
• <i>Vibrio</i> spp.	
Raw eggs	
• <i>Salmonella</i> spp.	
Undercooked meat or poultry	
• <i>Salmonella</i> spp.	• EHEC
• <i>Campylobacter</i> spp.	• <i>C. perfringens</i>
Unpasteurised milk or juice	
• <i>Salmonella</i> spp.	• EHEC
• <i>Campylobacter</i> spp.	• <i>Y. enterocolitica</i>
Unpasteurised soft cheeses	
• <i>Salmonella</i> spp.	• <i>Y. enterocolitica</i>
• <i>Campylobacter</i> spp.	• <i>L. monocytogenes</i>
• ETEC	
Home-made canned goods	
• <i>C. botulinum</i>	
Raw hot dogs, pâté	
• <i>L. monocytogenes</i>	

13.15 Composition of oral rehydration solution and other replacement fluids*				
Fluid	Na	K	Cl	Energy
WHO	90	20	80	54
Dioralyte	60	20	60	71
Pepsi®	6.5	0.8	–	400
7UP®	7.5	0.2	–	320
Apple juice	0.4	26	–	480
Orange juice	0.2	49	–	400
Breast milk	22	36	28	670
*mmol/L for electrolyte and Kcal/L for energy components.				

Longer symptomatology or more persistent/severe diarrhoea rapidly produces fluid losses comparable to diabetic ketoacidosis and is a metabolic emergency requiring active intervention.

- *Replacement of ongoing losses.* The average adult's diarrhoeal stool accounts for a loss of 200 mL of isotonic fluid. Stool losses should be carefully charted and an estimate of ongoing replacement fluid calculated. Commercially available rehydration sachets are conveniently produced to provide 200 mL of ORS; one sachet per diarrhoea stool is an appropriate estimate of supplementary replacement requirements.
- *Replacement of normal daily requirement.* The average adult has a daily requirement of 1–1.5 L of fluid in addition to the calculations above. This will be increased substantially in fever or a hot environment.

Antimicrobial agents

In non-specific gastroenteritis, antibiotics have been shown to shorten symptoms by only 1 day in an illness usually lasting 1–3 days. This benefit, when related to the potential for the development of antimicrobial resistance or side-effects, does not justify treatment, except if there is systemic involvement and a host with immunocompromise or significant comorbidity.

Evidence suggests that, in EHEC infections, the use of antibiotics may make the complication of haemolytic uraemic syndrome (HUS; p. 498) more likely due to increased toxin release. Antibiotics should therefore not be used routinely in bloody diarrhoea.

Conversely, antibiotics are indicated in *Sh. dysenteriae* infection and in invasive salmonellosis, in particular typhoid fever. Antibiotics may also be advantageous in cholera epidemics, reducing infectivity and controlling the spread of infection.

Antidiarrhoeal, antimotility and antisecretory agents

In general, these agents are not recommended in acute infective diarrhoea and their use may even be contra-indicated. Loperamide, diphenoxylate and opiates are potentially dangerous in dysentery in childhood, causing intussusception. Antisecretory agents such as bismuth and chlorpromazine may be effective but can cause significant sedation. They do not reduce stool fluid losses, although the stools may appear more bulky. Adsorbents such as kaolin or charcoal have little effect.

Non-infectious causes of food poisoning

Whilst acute food poisoning and gastroenteritis are most frequently caused by bacteria or their toxins, a number of non-infectious causes must be considered in the differential diagnosis.

Plant toxins

Legumes and beans produce oxidants which are toxic to people with glucose-6-phosphate dehydrogenase (G6PD) deficiency (p. 1024). Consumption produces headache, nausea and fever, progressing to potentially severe haemolysis, haemoglobinuria and jaundice (favism). Red kidney beans, if incompletely cooked, cause acute abdominal pain and diarrhoea from their lectin content. Adequate cooking abolishes this.

Alkaloids develop in potato tubers exposed to light, causing green discoloration. Ingestion induces acute vomiting and anticholinesterase-like activity.

Fungi and mushrooms of the *Psilocybe* spp. produce hallucinogens. Many fungal species induce a combination of gastroenteritis and cholinergic symptoms of blurred vision, salivation, sweating and diarrhoea. *Amanita phalloides* ('death cap') causes acute abdominal cramps and diarrhoea, followed by inexorable hepatorenal failure, often fatal.

Chemical toxins

Paralytic shellfish toxin

Saxitoxin from dinoflagellates, responsible for 'red tides', is concentrated in bivalve molluscs, e.g. mussels, clams, oysters, cockles and scallops. Consumption produces gastrointestinal symptoms within 30 minutes, followed by perioral paraesthesia and even respiratory paralysis. The UK water authorities ban the harvesting of molluscs at times of the year associated with excessive dinoflagellate numbers.

Ciguatera fish poisoning

Warm-water coral reef fish acquire ciguatoxin from dinoflagellates in their food chain. Consumption produces gastrointestinal symptoms 1–6 hours later, with associated paraesthesiae of the lips and extremities, distorted temperature sensation, myalgia and progressive flaccid paralysis. Autonomic dysfunction with hypotension may occur. In the South Pacific and Caribbean there are 50 000 cases per year, with a case fatality of 0.1%. The gastrointestinal symptoms resolve rapidly but the neuropathic features may persist for months.

Scombrototoxic fish poisoning

Under poor storage conditions, histidine in scombroid fish—tuna, mackerel, bonito, skipjack and the canned dark meat of sardines—may be converted by bacteria to histamine and other chemicals. Consumption produces symptoms within minutes, with flushing, burning, sweating, urticaria, pruritus, headache, colic, nausea and vomiting, diarrhoea, bronchospasm and hypotension. Management is with salbutamol and antihistamines. Occasionally, intravenous fluid replacement is required.

Heavy metals

Thallium and cadmium can cause acute vomiting and diarrhoea resembling staphylococcal enterotoxin poisoning.

Antibiotic-associated diarrhoea (AAD)

AAD is a common complication of antibiotic therapy, especially with broad-spectrum agents. It is most common in the elderly but can occur at all ages. Although the specific mechanism is unknown in most AAD, *C. difficile* is implicated in 20–25% of cases and is the most common cause amongst patients with evidence of colitis. Infection is diagnosed by detection of *C. difficile* toxins and is usually treated with metronidazole or vancomycin (p. 338). *C. perfringens* is a rarer cause which usually remains undiagnosed, and *Klebsiella oxytoca* is an occasional cause of antibiotic-associated haemorrhagic colitis.

Infections acquired in the tropics

Recent decades have seen unprecedented increases in long-distance business and holiday travel, as well as extensive migration. Although certain diseases retain their relatively fixed geographical distribution, being dependent on specific vectors or weather conditions, many travel with their human hosts and some may then be transmitted to other people. This means that the pattern of infectious diseases seen in each country changes constantly and travel history is crucial.

In general, the diversity of infectious diseases is greater in tropical than in temperate countries, and people in temperate countries have less immunity to many infections, so that the most common travel-associated infections are those which are acquired by residents of temperate countries during visits to the tropics.

Most travel-associated infections can be prevented. Pre-travel advice is tailored to the destination and the traveller (Box 13.16). It includes avoidance of insect bites (using at least 20% diethyltoluamide (DEET), sun protection (sunscreen with a sun protection factor (SPF) of at least 15), food and water hygiene ('Boil it, cook it, peel it or forget it!'), how to respond to travellers' diarrhoea (seek medical advice if bloody or lasts more than 48 hours) and, if relevant, safe sex (condom use).

Fever in travellers returning from the tropics

Presentation with unexplained fever is common in returning travellers. Frequent final diagnoses in such patients are malaria, typhoid fever, viral hepatitis and dengue fever. Travellers returning from West Africa may have viral haemorrhagic fevers (VHF), such as Lassa fever, Crimean-Congo haemorrhagic fever, Marburg and Ebola (Box 13.37, p. 320). Those from South-east Asia may have avian influenza (H5N1), which may pose an infection control risk and require special isolation precautions to be taken.

13.16 How to assess health needs in travellers before departure*

- Destination
- Personal details, including previous travel experience
- Dates of trip
- Itinerary and purpose of trip
- Personal medical history, including pregnancy, medication and allergies (e.g. to eggs, vaccines, antibiotics)
- Past vaccinations
 - Childhood schedule followed? Diphtheria, tetanus, pertussis, polio, *N. meningitidis* type C, *Haemophilus influenzae* B (HiB)
 - Travel-related? Typhoid, yellow fever, hepatitis A, hepatitis B, meningococcal ACW135Y, rabies, Japanese B encephalitis, tick-borne encephalitis
- Malaria prophylaxis: questions influencing the choice of antimalarial drugs are destination, past experience with antimalarials, history of epilepsy or psychiatric illness

*Further information is available at www.fitfortravel.nhs.uk/

Clinical assessment

The approach to unexplained fever is described above. Vital questions to ask anyone returning from the tropics are listed in Box 13.17. Note that medicines purchased while travelling may not be reliable, e.g. for malaria prophylaxis. Consult reliable up-to-date sources about resistance to antimalarial drugs in the country in question. Vaccinations against yellow fever and hepatitis A and B are sufficiently effective to virtually rule out these infections. Oral and injectable typhoid vaccinations are 70–90% effective.

Specific exposures worth documenting are shown in Box 13.18. The incubation period of important pathogens, together with the clinical scenario, also guides the differential diagnosis (Box 13.19). *Falciparum* malaria tends to present between 7 and 28 days after return from an endemic area. VHF, dengue and rickettsial infection can usually be excluded if more than 21 days have passed between return from the affected area and the onset of illness.

Clinical examination is summarised on pages 290–291. Particular attention should be paid to the skin, throat, eyes, nail beds, lymph nodes, abdomen and heart. Patients may be unaware of tick bites or eschars (p. 345). Body temperature should be measured at least twice daily.

13.17 How to obtain a history from travellers to the tropics with fever

Questions	Factors to ascertain
Countries visited and dates of travel	Relate travel to known outbreaks of infection or antimicrobial resistance
Determine the environment visited	Travel to rural environments, forests, rivers or lakes
Clarify where the person slept	Sleeping in huts, use of bed nets, sleeping on the ground
Establish what he/she was doing	Exposure to people with medical illness, animals, soil, lakes or rivers
History of insect bites	Type of insect responsible, circumstances (location, time of day etc.), preventive measures
Dietary history	Ingestion of uncooked foods, salads and vegetables, meats (especially if undercooked), shellfish, molluscs, unpasteurised dairy products, unbottled water and sites at which food prepared
Sexual history	History of sexual intercourse with commercial sex workers, local population
Malaria prophylaxis	Type of prophylaxis
Vaccination history	Receipt of pre-travel vaccines and appropriateness to area visited
History of any treatments received while abroad	Receipt of medicines, local remedies, blood transfusions or surgical procedures

13.18 Specific exposures and causes of fever in the tropics

Exposure	Infection or disease
Mosquito bite	Malaria, dengue fever, Chikungunya, filariasis, tularaemia
Tsetse fly bite	African trypanosomiasis
Tick bite	Rickettsial infections, including typhus, Lyme disease, tularaemia, Crimean–Congo haemorrhagic fever, Kyasanur forest disease, babesiosis, tick-borne encephalitis
Louse bite	Typhus
Flea bite	Plague
Sandfly bite	Leishmaniasis, arbovirus infection
Reduviid bug	Chagas' disease
Animal contact	Q fever, brucellosis, anthrax, plague, tularaemia, viral haemorrhagic fevers, rabies
Fresh-water swimming	Schistosomiasis, leptospirosis, <i>Naegleria fowleri</i>
Exposure to soil	Inhalation: dimorphic fungi Inhalation or inoculation: <i>Burkholderia pseudomallei</i> Inoculation (most often when barefoot): hookworms, <i>Strongyloides stercoralis</i>
Raw or undercooked fruit and vegetables	Enteric bacterial infections, hepatitis A or E virus, <i>Fasciola hepatica</i> , <i>Toxocara</i> spp., <i>Echinococcus granulosus</i> (hydatid disease), <i>Entamoeba histolytica</i>
Undercooked pork	<i>Taenia solium</i> (cysticercosis)
Crustaceans or molluscs	Paragonimiasis, gnathostomiasis, <i>Angiostrongylus cantonensis</i> infection, hepatitis A virus, cholera
Unpasteurised dairy products	Brucellosis, salmonellosis, abdominal tuberculosis, listeriosis
Untreated water	Enteric bacterial infections, giardiasis, <i>Cryptosporidium</i> spp. (chronic in immunocompromised), hepatitis A or E virus

Investigations and management

Initial investigations should start with thick and thin blood films for malaria parasites, FBC, urinalysis and chest X-ray if indicated. Box 13.20 gives the diagnoses and further investigations that should be considered in acute fever in the absence of strong clues from the clinical assessment.

Management is directed at the underlying cause. In patients with suspected VHF (p. 319), strict infection control measures with isolation and barrier nursing should be implemented to prevent any contact with the patient's body fluids. The risk of VHF should be determined using epidemiological risk factors and clinical signs (Fig. 13.5), and further management undertaken as described on page 321.

Diarrhoea acquired in the tropics

Gastrointestinal illness is the most commonly reported imported infection, with *Salmonella* spp., *Campylobacter* spp. and *Cryptosporidium* spp. infections common world-

13.19 Incubation times and illnesses in travellers*

< 2 weeks

Non-specific fever

- Malaria
- Chikungunya
- Dengue
- Scrub typhus
- Spotted group rickettsiae
- Acute HIV
- Acute hepatitis C virus
- *Campylobacter*
- Salmonellosis
- Shigellosis
- East African trypanosomiasis
- Leptospirosis
- Relapsing fever
- Influenza
- Yellow fever

Fever and coagulopathy (usually thrombocytopenia)

- Malaria
- Viral haemorrhagic fever (VHF)
- Meningococcaemia
- Enteroviruses
- Leptospirosis and other bacterial pathogens associated with coagulopathy

Fever and central nervous system involvement

- Malaria
- Typhoid fever
- Rickettsial typhus (epidemic caused by *Rickettsia prowazekii*)
- Meningococcal meningitis
- Arboviral encephalitis
- East African trypanosomiasis
- Encephalitis or meningitis
- Angiostrongyliasis
- Rabies

Fever and pulmonary involvement

- Influenza
- Pneumonia due to atypical pathogens
- *Legionella* pneumonia
- Acute histoplasmosis
- Acute coccidioidomycosis
- Q fever
- Severe acute respiratory syndrome (SARS)

Fever and rash

- Viral exanthems (rubella, measles, varicella, mumps, human herpes virus 6 (HHV-6), enteroviruses)
- Chikungunya
- Dengue
- Spotted or typhus group rickettsiosis
- Typhoid fever
- Parvovirus B19

2–6 weeks

- Malaria
- Tuberculosis
- Hepatitis A, B, C and E viruses
- Visceral leishmaniasis
- Acute schistosomiasis
- Amoebic liver abscess
- Leptospirosis
- African trypanosomiasis
- Viral haemorrhagic fever (VHF)
- Q fever
- Acute American trypanosomiasis
- Viral causes of mononucleosis syndromes

> 6 weeks

- Non-*falciparum* malaria
- Tuberculosis
- Hepatitis B and E viruses
- Visceral leishmaniasis
- Filariasis
- Onchocerciasis
- Schistosomiasis
- Amoebic liver abscess
- Chronic mycoses
- African trypanosomiasis
- Rabies
- Typhoid fever

*Adapted from Traveller's Health Yellow Book, CDC Health Information for International Travel 2008.

wide, including in Europe (Box 13.21). For typhoid, paratyphoid, *Shigella* spp. and *Entamoeba histolytica* (amoebiasis), the Indian subcontinent and sub-Saharan and southern Africa are the most commonly reported regions of travel.

13.20 Further investigations in the absence of localising signs in acute fever acquired in the tropics	
Features on FBC	Further investigations
Neutrophil leucocytosis	
Bacterial sepsis	Blood culture
Leptospirosis	Culture of blood and urine, serology
Borreliosis (tick- or louse-borne relapsing fever)	Blood film
Amoebic liver abscess	Ultrasound
Normal white cell count and differential	
Typhoid fever	Blood, stool and culture
Typhus	Serology
Arboviral infection	Serology (PCR and viral culture)
Lymphocytosis	
Viral fevers	Serology
Infectious mononucleosis	Monospot test
Rickettsial fevers	Serology

The approach to patients with acute diarrhoea is described on pages 302–304. The benefits of treating travellers' diarrhoea with antimicrobials are marginal (Box 13.22). The differential diagnosis of diarrhoea persisting for more than 14 days is wide (Box 22.21, p. 856). Parasitic and bacterial causes, tropical malabsorption, inflammatory bowel disease and neoplasia should all be considered. Box 13.23 lists causes encountered particularly in the tropics. The work-up should include tests for parasitic causes of chronic diarrhoea, e.g. examination of stool and duodenal aspirates for ova and parasites, and serological investigation.

Tropical sprue is a malabsorption syndrome (p. 881) with no defined aetiology. It was typically associated with a long period of residence in the tropics or with overland travel but is now rarely seen. *Giardia lamblia* infection may progress to a malabsorption syndrome that mimics tropical sprue. If no cause is found, empirical treatment for *Giardia lamblia* infection with metronidazole is often helpful.

HIV has now emerged as a major cause of chronic diarrhoea. This may be due to HIV enteropathy or infection

13.21 Most common causes of travellers' diarrhoea	
<ul style="list-style-type: none"> Enterotoxigenic <i>E. coli</i> (ETEC) <i>Shigella</i> spp. <i>Campylobacter jejuni</i> <i>Salmonella</i> spp. 	<ul style="list-style-type: none"> <i>Plesiomonas shigelloides</i> Non-cholera <i>Vibrio</i> spp. <i>Aeromonas</i> spp.

<ul style="list-style-type: none"> <i>Giardia lamblia</i> Strongyloidiasis Hypolactasia (primary and secondary) Enteropathic <i>E. coli</i> Tropical sprue 	<ul style="list-style-type: none"> Chronic calcific pancreatitis HIV enteropathy Intestinal flukes Chronic intestinal schistosomiasis

with agents such as *Cryptosporidium* spp., *Isospora belli* or microsporidia (pp. 393–395). However, many other causes of chronic AIDS-associated diarrhoea seen in the developed world are less common in tropical settings, e.g. CMV or disseminated *Mycobacterium avium* complex infections.

Eosinophilia acquired in the tropics

Eosinophilia occurs in a variety of haematological, allergic and inflammatory conditions discussed on pages 1000–1001. It may also occur in HIV and human T cell lymphotropic virus (HTLV)-1 infection. However, eosinophils are important in the immune response to parasitic infections, in particular those parasites with a tissue migration phase. In the context of travel or residence in the tropics, a patient with an eosinophil count of $> 0.4 \times 10^9/L$ should be investigated for both non-parasitic (see Box 24.10, p. 1000) and parasitic causes (Box 13.24).

Fig. 13.5 Approach to the patient with suspected viral haemorrhagic fever (VHF). See pages 319–321. *Epidemiological risk factors: staying with a febrile individual, caring for a sick individual or contact with body fluids from a suspected human or animal case of VHF. (PCR = polymerase chain reaction).

13.24 Parasite infections that cause eosinophilia

Infestation	Pathogen	Clinical syndrome with eosinophilia
Strongyloidiasis	<i>Strongyloides stercoralis</i>	Larva currens
Soil-transmitted helminthiasis		
Hookworm	<i>Necator americanus</i>	Anaemia
	<i>Ancylostoma duodenale</i>	Anaemia
Ascariasis	<i>Ascaris lumbricoides</i>	Löffler's syndrome
Toxocariasis	<i>Toxocara canis</i>	Visceral larva migrans
Schistosomiasis	<i>Schistosoma haematobium</i>	Katayama fever
	<i>S. mansoni</i> , <i>S. japonicum</i>	Chronic infection
Filariases		
Loiasis	<i>Loa loa</i>	Skin nodules
<i>Wuchereria bancrofti</i>	<i>W. bancrofti</i>	Lymphangitis, lymphadenopathy, orchitis, intermittent bouts of cellulitis, lymphoedema and elephantiasis
<i>Brugia malayi</i>	<i>B. malayi</i>	Brugian elephantiasis similar but typically less severe than that caused by <i>W. bancrofti</i>
<i>Mansonella perstans</i>	<i>M. perstans</i>	Asymptomatic infection, occasionally subconjunctival nodules
Onchocerciasis	<i>Onchocerca volvulus</i>	Visual disturbance, dermatitis
Other nematode infections	<i>Trichinella spiralis</i>	Myositis
Cestode infections	<i>Taenia saginata</i> , <i>T. solium</i>	Usually asymptomatic; eosinophilia associated with migratory phase
	<i>Echinococcus granulosus</i>	Lesions in liver or other organ; eosinophilia associated with leakage from cyst
Liver flukes	<i>Fasciola hepatica</i>	Hepatic symptoms; eosinophilia associated with migratory phase
	<i>Clonorchis sinensis</i>	As for fascioliasis
	<i>Opisthorchis felinus</i>	As for fascioliasis
Lung fluke	<i>Paragonimus westermani</i>	Lung lesions

The response to parasite infections is often different when travellers to and residents of endemic areas are compared. Travellers often have recent and light infections associated with eosinophilia. Residents have often been infected for a long time, have evidence of chronic pathology and no longer have an eosinophilia.

Clinical assessment

Comparison of where the patient has travelled and the known endemic areas for diseases such as schistosomiasis, onchocerciasis and the filariases will indicate

possible causes. Establish how long patients have spent in endemic areas and take a thorough history, including all the elements in Box 13.17.

Physical signs or symptoms that suggest a parasitic cause for eosinophilia include transient rashes (schistosomiasis or strongyloidiasis), fever (Katayama syndrome—p. 371), pruritus (onchocerciasis) or migrating subcutaneous swellings (loiasis, gnathostomiasis) (see Box 13.24). Paragonimiasis can give rise to haemoptysis and the migratory phase of intestinal nematodes or lymphatic filariasis to cough, wheezing and transient pulmonary infiltrates. Schistosomiasis induces transient respiratory symptoms with infiltrates in the acute stages and, when eggs reach the pulmonary vasculature in chronic infection, can result in shortness of breath with features of right heart failure due to pulmonary hypertension. Fever and hepatosplenomegaly are seen in schistosomiasis, *Fasciola hepatica* and toxocariasis (visceral larva migrans). Intestinal worms such as *Ascaris lumbricoides* and *Strongyloides stercoralis* can cause abdominal symptoms, including intestinal obstruction and diarrhoea. In the case of heavy infestation with ascariasis this may be due to fat malabsorption and there may be associated nutritional deficits. *Schistosoma haematobium* can cause haematuria or haematospermia. *Toxocara* spp. can give rise to choroidal lesions with visual field defects. *Angiostrongylus cantonensis* and gnathostomiasis induce eosinophilic meningitis, and the hyperinfection syndrome caused by *Strongyloides stercoralis* in immunocompromised hosts induces meningitis due to Gram-negative bacteria. Myositis is a feature of trichinellosis and cysticercosis, while periorbital oedema is a feature of trichinellosis.

Investigations

To establish the diagnosis of a parasitic infestation, direct visualisation of adult worms, larvae or ova is required. Serum antibody detection may not distinguish between active and past infection and is often unhelpful in those born in endemic areas. Radiological investigations may provide circumstantial evidence of parasite infestation. Box 13.25 describes initial investigations for eosinophilia.

Management

A specific diagnosis guides therapy. In the absence of a specific diagnosis, many clinicians will give an empirical

13.25 Initial investigation of eosinophilia	
Investigation	Pathogens sought
Stool microscopy	Ova, cysts and parasites
Terminal urine	Ova of <i>Schistosoma haematobium</i>
Duodenal aspirate	Filariform larvae of <i>Strongyloides</i> , liver fluke ova
Day bloods	Microfilariae <i>Brugia malayi</i> , <i>Loa loa</i>
Night bloods	Microfilariae <i>Wuchereria bancrofti</i>
Skin snips	<i>Onchocerca volvulus</i>
Slit lamp examination	<i>Onchocerca volvulus</i>
Serology	Schistosomiasis, filariases, strongyloidiasis, hydatid, trichinosis etc.

13.26 Rash in tropical travellers/residents

Maculopapular rash

- Dengue
- HIV-1
- Typhoid
- *Spirillum minus*
- Rickettsial infections
- Measles

Petechial or purpuric rash

- VHF
- Yellow fever
- Meningococcal sepsis
- Leptospirosis
- Rickettsial spotted fevers
- Malaria

Vesicular rash

- Monkeypox
- Insect bites
- Rickettsial pox

Urticarial rash

- Katayama fever (schistosomiasis)
- *Toxocara* spp.
- *Strongyloides stercoralis*
- Fascioliasis

Ulcers

- Leishmaniasis
- *Mycobacterium ulcerans* (Buruli ulcer)
- Dracunculosis
- Tropical ulcer (*Fusobacterium ulcerans* and *Treponema vincentii*)
- Anthrax
- Rickettsial eschar
- Ecthyma (staphylococci streptococci)

Papules

- Scabies
- Insect bites
- Prickly heat
- Ringworm
- Onchocerciasis

Nodules or plaques

- Leprosy
- Chromoblastomycosis
- Dimorphic fungi
- Trypanosomiasis
- Onchocerciasis
- Myiasis (larvae of Tumbu or bot fly)
- Tungiasis (*Tunga penetrans*)

Migratory linear rash

- Cutaneous larva migrans (dog hookworms)
- *Strongyloides stercoralis*

Migratory papules/nodules

- Loa loa
- Gnathosomiasis
- Schistosomiasis

Thickened skin

- Elephantiasis (filariasis)
- Mycetoma (fungi/*Nocardia* spp.)

course of praziquantel if the individual has been potentially exposed to schistosomiasis, or with albendazole/ivermectin if strongyloidiasis or intestinal nematodes are likely causes.

Skin conditions acquired in the tropics

Community-based studies in the tropics consistently show that skin infections (bacterial and fungal), scabies and eczema are the most common skin problems (Box 13.26). Scabies and eczema are discussed on pages 1273 and 1256. Cutaneous leishmaniasis and onchocerciasis have defined geographical distributions (pp. 356 and 368). In travellers, secondarily infected insect bites, pyoderma, cutaneous larva migrans and non-specific dermatitis are common.

When investigating skin lesions, enquire about habitation, activities undertaken and regions visited (see Box 13.17). Examples of skin lesions in tropical disease are shown in Figure 13.6.

Skin biopsies are helpful in diagnosing fungal or parasitic infections and persistent reactions to insect bites. Culture of biopsy material may be needed to diagnose bacterial, fungal, parasitic and mycobacterial infections.

Infections in pregnancy

Box 13.27 shows some of the common infections encountered in pregnancy, with their consequences and management.

VIRAL INFECTIONS

Systemic viral infections with exanthem

Exanthem is the term classically used to describe a widespread rash associated with fever in childhood. Maternal antibody gives protection for the first 6–12 months of life and infection occurs thereafter. Comprehensive immunisation programmes have eradicated many of these conditions but lapses in vaccination result in continued infections, which now often present in older children and adults.

Measles

Before immunisation campaigns, measles occurred in almost 100% of children world-wide. The WHO has set the objective of eradicating measles globally by 2010, using the live attenuated vaccine. However, vaccination of only 70–80% of the population, as is currently the case in the UK, for example, is insufficient to prevent outbreaks in older children and adults, who are more

13.27 Infections during pregnancy

Infection	Consequence	Prevention and management
Rubella	Congenital malformation	Vaccination of non-immune mothers
Cytomegalovirus	Neonatal infection, congenital malformation	Limited prevention strategies
Varicella zoster virus	Neonatal infection, congenital malformation, severe infection in mother	VZ immune globulin (see Box 13.33, p. 314), or aciclovir if exposure > 4 days previously
Herpes simplex virus	Congenital or neonatal infection	Aciclovir and consideration of caesarean section for mothers who shed HSV from the genital tract at the time of delivery. Aciclovir for infected neonates
Hepatitis B virus	Chronic infection of neonate	Hepatitis B immune globulin and active vaccination of newborn
HIV	Chronic infection of neonate	Antiretrovirals to mother and infant and consideration of caesarean section if HIV viral load detectable. Avoidance of breastfeeding
Parvovirus B19	Congenital infection	Avoid contact with individuals with acute infection if pregnant
Measles	More severe infection in mother and neonate	Immunisation of mother
Syphilis	Congenital malformation	Serological testing in pregnancy with prompt treatment of infected mothers
<i>Neisseria gonorrhoeae</i> and <i>Chlamydia trachomatis</i>	Neonatal conjunctivitis (<i>ophthalmia neonatorum</i>)	Treatment of infection in mother and neonate
Listeriosis	Neonatal meningitis or bacteraemia, bacteraemia or PUO in mother	Avoidance of unpasteurised cheeses and other dietary sources
Brucellosis	Possibly increased incidence of fetal loss	Avoidance of unpasteurised dairy products
Group B streptococcal infection	Neonatal meningitis and sepsis. Sepsis in mother after delivery	Risk- or screening-based antimicrobial prophylaxis in labour (recommendations vary between countries)
Toxoplasmosis	Congenital malformation	Diagnosis and prompt treatment of cases, avoidance of undercooked meat while pregnant
Malaria	Fetal loss, intrauterine growth retardation, severe malaria in mother	Avoidance of insect bites. Intermittent preventative treatment during pregnancy to decrease incidence in high-risk countries

susceptible to complications. Natural illness produces lifelong immunity.

Clinical features

Infection is by respiratory droplets with an incubation period of 6–19 days. A prodromal illness, 1–3 days before the rash, occurs with upper respiratory symptoms, conjunctivitis and the presence of Koplik's spots on the inter-

nal buccal mucosa (Fig. 13.7A). These small white spots surrounded by erythema are pathognomonic of measles. As natural antibody develops, the maculopapular rash appears, spreading from the face to the extremities (Fig. 13.7B). Generalised lymphadenopathy and diarrhoea are common, with otitis media and bacterial pneumonia recognised complications. Clinical encephalitis occurs in approximately 0.1% of children. A rare late complication is

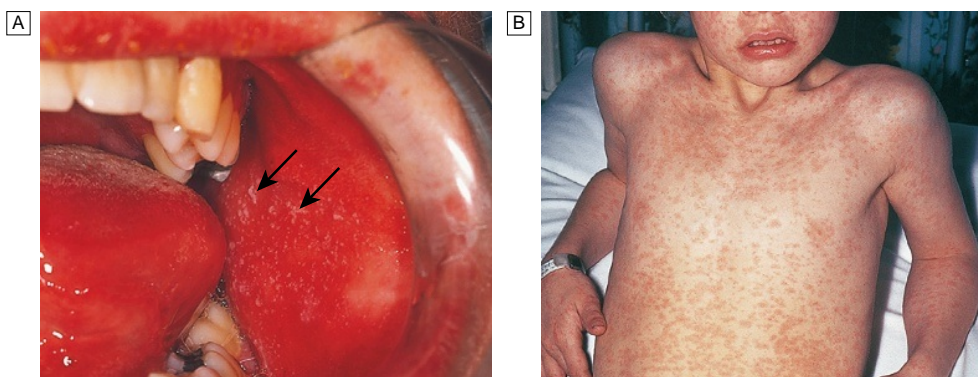

Fig. 13.7 Measles. **A** Koplik's spots (arrows) seen on buccal mucosa in the early stages of clinical measles. **B** Typical measles rash.

subacute sclerosing panencephalitis (SSPE), which occurs up to 7 years after infection. Diagnosis is clinical (although this is unreliable in areas where measles is no longer common) and by detection of antibody (serum IgM, seroconversion or salivary IgM).

Disease is more severe and prolonged in adults and complications include pneumonitis, hepatitis and encephalitis. Measles is a serious disease in the malnourished, vitamin-deficient or immunocompromised, in whom the typical rash may be missing and persistent infection with a giant cell pneumonitis or encephalitis may occur. In tuberculosis infection, measles suppresses cell-mediated immunity and may exacerbate disease; for this reason, measles vaccination should be deferred until after commencing antituberculous treatment. Measles does not cause congenital malformation but may be more severe in pregnant women.

Mortality clusters at the extremes of age, averaging 1:1000 in developed countries and up to 1:4 in developing countries. Death usually results from bacterial superinfection such as pneumonia, diarrhoeal disease or noma/cancrum oris.

Management and prevention

Normal immunoglobulin attenuates the disease in the immunocompromised (regardless of vaccination status) and in non-immune pregnant women, but must be given within 6 days of exposure. Vaccination can be used in outbreaks and vitamin A may improve the outcome in uncomplicated disease. Antibiotic therapy is reserved for bacterial complications.

All children aged 12–15 months (when maternal antibody will no longer be present) should receive measles vaccination (as combined measles, mumps and rubella (MMR), a live attenuated vaccine), and a further MMR dose at the age of 4 years.

Rubella (German measles)

Rubella is an endemic exanthem in countries without universal vaccination. In non-immunised communities 80–85% of young adults have evidence of past infection.

Clinical features

Rubella is spread by respiratory droplet, with infectivity from up to 10 days before to 2 weeks after the onset of the rash. The incubation period is 15–20 days. In childhood, most cases are subclinical, although clinical features may include fever, maculopapular rash spreading from the face, and lymphadenopathy. Complications are rare but

include thrombocytopenia and hepatitis. Encephalitis and haemorrhage are occasionally reported. In adults, arthritis involving hands or knees is relatively common, especially in women.

If transplacental infection takes place in the first trimester or later, persistence of the virus is likely and severe congenital disease may result (Box 13.28). Even if normal at birth, the infant has an increased incidence of other diseases developing later, such as diabetes mellitus.

Diagnosis

Laboratory confirmation of rubella is required if there has been contact with a pregnant woman. This is achieved either by detection of rubella IgM in serum or by IgG seroconversion. In the exposed pregnant woman, absence of rubella-specific IgG confirms the potential for congenital infection.

Prevention

MMR should be administered as for measles. Rubella is one of a number of infections that can occur during pregnancy with potentially serious consequences to mother or child (see Box 13.27). All women of child-bearing age should also be tested for rubella and vaccinated if seronegative.

Parvovirus B19 (erythrovirus B19)

This virus causes a variety of clinical syndromes (Box 13.29). Approximately 50% of children and 60–90% of older adults are seropositive world-wide. Most infections are spread by the respiratory route, although spread via contaminated blood is also possible. The virus has particular tropism for red cell precursors.

13.29 Clinical features of parvovirus B19 infection

Affected age group	Clinical manifestations
Fifth disease (erythema infectiosum)	
Small children	Three clinical stages: a 'slapped cheek' appearance, followed by a maculopapular rash progressing to a reticulate eruption on the body and limbs, then a final stage of resolution. Often the child is quite well throughout
Gloves and socks syndrome	
Young adults	Fever and an acral purpuric eruption with a clear margin at the wrists and ankles. Mucosal involvement also occurs
Arthropathies	
Adults and occasionally children	Symmetrical small-joint polyarthropathy. In children it tends to involve the larger joints in an asymmetrical distribution
Impaired erythropoiesis	
Adults, those with haematological disease, or the immunosuppressed	Mild anaemia; in an individual with an underlying haematological abnormality can precipitate transient aplastic crisis, or in the immunocompromised a more sustained but often milder pure red cell aplasia
Hydrops fetalis	
Transplacental fetal infection	Asymptomatic or symptomatic maternal infection can cause fetal anaemia with an aplastic crisis, leading to non-immune hydrops fetalis and spontaneous abortion

13.28 Rubella infection: risk of congenital malformation

Stage of gestation	Likelihood of malformations
1–2 months	65–85% chance of illness, multiple defects/spontaneous abortion
3 months	30–35% chance of illness, usually a single congenital defect (most frequently deafness, cataract, glaucoma, mental retardation, congenital heart disease, especially pulmonary stenosis, patent ductus arteriosus)
4 months	10% risk of congenital defects, most commonly deafness
> 20 weeks	Occasional deafness

Clinical features

Many infections are subclinical. Clinical manifestations result after an incubation period of 14–21 days (see Box 13.29). The classic exanthem (erythema infectiosum) is preceded by a prodromal fever and coryzal symptoms. A 'slapped cheek' rash is characteristic but the rash is very variable (Fig. 13.8). In adults, polyarthropathy is common. Infected individuals have a transient block in erythropoiesis for a few days, which is of no clinical consequence, except in individuals with increased red cell turnover due to haemoglobinopathy or haemolytic anaemia. These individuals develop an acute anaemia which may be severe (transient aplastic crisis; p. 1028). Erythropoiesis usually recovers spontaneously after 10–14 days. Immunocompromised individuals, including those with congenital immunodeficiency or AIDS, can develop a more sustained block in erythropoiesis in response to the chronic viraemia that results from their inability to clear the infection. Infection during the first two trimesters of pregnancy can result in intrauterine infection and impact on fetal bone marrow; it causes 10–15% of non-immune (non-Rhesus-related) hydrops fetalis, a rare complication of pregnancy.

Diagnosis

IgM responses to parvovirus B19 suggest recent infection but may persist for months and false positives occur. Seroconversion to IgG positivity confirms infection but in isolation a positive IgG is of little diagnostic utility. Detection of parvovirus B19 DNA in blood is particularly useful in the immunocompromised host. Giant pronormoblasts or haemophagocytosis may be demonstrable in the bone marrow.

Management

Infection is usually self-limiting. Symptomatic relief for arthritic symptoms may be required. Severe anaemia requires transfusion. Immunocompromised hosts should have immunosuppression decreased, if possible, and if viraemia persists should receive immunoglobulin to aid clearance.

Pregnant women should avoid contact with cases of parvovirus B19 infection; if they are exposed, serology should be performed to establish whether they are non-

Fig. 13.8 Slapped cheek syndrome. The typical facial rash of parvovirus B19 infection.

immune. Passive prophylaxis with normal immunoglobulin has been suggested for non-immune pregnant women exposed to infection but there are limited data to support this recommendation. The pregnancy should be closely monitored by ultrasound scanning, so that hydrops fetalis can be treated by fetal transfusion.

Human herpesvirus 6 and 7 (HHV-6 and HHV-7)

Herpesviruses are classified in Box 13.30.

HHV-6 is a lymphotropic virus that causes a childhood viral exanthem (exanthem subitum), rare cases of an infectious mononucleosis-like syndrome and infection in the immunocompromised host. Infection is almost universal, with approximately 95% of children acquiring this virus by 2 years of age. Transmission is via saliva.

HHV-7 is very closely related to HHV-6, and is believed to be responsible for a proportion of cases of exanthem subitum. Like HHV-6, HHV-7 causes an almost universal infection in childhood, with subsequent latent infection and occasional infection in the immunocompromised host.

13.30 Herpesvirus infections

Virus	Infection
<i>Herpesvirus hominis</i> (herpes simplex, HSV)	
HSV-1 (p. 321)	Herpes labialis ('cold sores') Stomatitis, pharyngitis Corneal ulceration Finger infections ('whitlows') Eczema herpeticum
HSV-2 (p. 321)	Genital ulceration and neonatal infection (acquired during vaginal delivery) Encephalitis, acute meningitis or transverse myelitis
Varicella zoster virus (VZV) (p. 313)	Chickenpox (varicella) Shingles (herpes zoster)
Cytomegalovirus (CMV) (p. 317)	Congenital infection Infectious mononucleosis (heterophile antibody-negative) Hepatitis Disease in immunocompromised patients: retinitis, encephalitis, pneumonitis, hepatitis, enteritis Fever with abnormalities in haematological parameters
Epstein-Barr virus (EBV) (p. 316)	Infectious mononucleosis Burkitt's lymphoma Nasopharyngeal carcinoma Oral hairy leucoplakia (AIDS patients) Other lymphomas
Human herpesvirus 6 and 7 (HHV-6, HHV-7)	Exanthem subitum Disease in immunocompromised patients
Human herpesvirus 8 (HHV-8) (p. 322)	Kaposi's sarcoma, primary effusion lymphoma, multicentric Castleman's disease

Clinical features

Exanthem subitum is also known as roseola infantum or sixth disease (Box 13.30). A high fever is followed by a maculopapular rash as the fever resolves. Fever and/or febrile convulsions may also occur without a rash. Rarely, older children or adults may develop an infectious mononucleosis-like illness, hepatitis or rash. In the immunocompromised infection is rare but can cause fever, rash, hepatitis, cytopenia or encephalitis.

Diagnosis and management

Exanthem subitum is usually a clinical diagnosis. Laboratory diagnosis can be made by antibody and/or DNA detection, although these tests are not widely available. The disease is self-limiting. Treatment with ganciclovir has been used in immunocompromised hosts infected with HHV-6.

Chickenpox (varicella)

Varicella zoster virus (VZV) is a dermatropic and neurotropic virus that produces primary infection, usually in childhood, which may reactivate in later life. VZV is spread by aerosol and direct contact. It is highly infectious to non-immune individuals. Disease in children is usually well tolerated. Manifestations are more severe in adults, pregnant women and the immunocompromised.

Clinical features

The incubation period is 11–20 days, after which a vesicular eruption begins (Fig. 13.9), often on mucosal surfaces first, followed by rapid dissemination in a centripetal distribution (most dense on trunk and sparse on limbs). New lesions occur every 2–4 days and each crop is associated with fever. The rash progresses from small pink macules to vesicles and pustules within 24 hours. Infectivity lasts from up to 4 days (but usually 48 hours) before the lesions appear until the last vesicles crust over. Due to intense itching, secondary bacterial infection from scratching is the most common complication of primary chickenpox. Self-limiting cerebellar ataxia and encephalitis are rare complications.

Adults, pregnant women and the immunocompromised are at increased risk of visceral involvement, which presents as pneumonitis, hepatitis or encephalitis. Pneumonitis can be fatal and is more likely to occur in smokers. Maternal infection in early pregnancy carries a 3% risk of neonatal damage with developmental abnor-

malities of eyes, CNS and limbs. Chickenpox within 5 days of delivery leads to severe neonatal varicella with visceral involvement and haemorrhage.

Diagnosis

Diagnosis is primarily clinical, by recognition of the rash. If necessary, this can be confirmed by detection of antigen (direct immunofluorescence), DNA (PCR) or by viral culture of aspirated vesicular fluid. Serology is used to identify seronegative individuals at risk of infection.

Management and prevention

Antivirals, although effective if commenced within 48 hours of rash appearance, are not licensed in the UK for uncomplicated primary VZV infection, since published evidence suggests the benefits are marginal (Box 13.31). They are, however, widely used around the world for uncomplicated chickenpox in adults. Treatment is required in individuals with complications and those who are immunocompromised, including pregnant women (Box 13.32). More severe disease, particularly in immunocompromised hosts, requires initial parenteral therapy. Immunocompromised patients may have prolonged viral shedding and may require prolonged treatment until all lesions crust over.

Human VZ immunoglobulin (VZIG) is used to attenuate infection in people who have had significant contact with VZV, are susceptible to infection (i.e. have no history of chickenpox or shingles and are negative for serum VZV IgG) and are at risk of severe disease (e.g. immunocompromised, steroid-treated or pregnant) (Box 13.33). Ideally, VZIG should be given within 7 days of exposure, but it may attenuate disease even if given up to 10 days afterwards. Susceptible contacts who

EBM 13.31 Aciclovir for chickenpox/shingles

'Aciclovir shortens symptoms in chickenpox by an average of 1 day. In shingles aciclovir reduces pain by 10 days and the risk of post-herpetic neuralgia by 8%. Aciclovir is therefore cost-effective in shingles but not chickenpox.'

- Nathwani D, et al. *Infect Dis Clin Prac* 1995; 4:138–145.
- Trying SK. *Arch Fam Med*; 2000; 9:863–869.

Fig. 13.9 Varicella zoster virus infection. [A] Chickenpox. [B] Shingles in a thoracic dermatome.

13.32 Therapy for herpes simplex and varicella zoster virus infection	
Disease state	Treatment options
Primary genital HSV	Famciclovir 250 mg 8-hourly for 7–10 days Valaciclovir 1 g 12-hourly for 7–10 days Oral aciclovir 200 mg 5 times daily or 400 mg 8-hourly for 7–10 days
Severe and preventing oral intake	Aciclovir 5 mg/kg 8-hourly i.v. until patient can tolerate oral therapy
Recurrent genital HSV-1 or 2	Oral aciclovir 200 mg 5 times daily or 400 mg 8-hourly for 5 days Famciclovir 125 mg 12-hourly for 5 days Valaciclovir 500 mg 12-hourly for 5 days
Primary or recurrent oral HSV	Usually no treatment If required, usually shorter duration and lower dose than for genital lesions, e.g. valaciclovir 500 mg 12-hourly for 3–5 days
Mucocutaneous HSV infection in immuno-compromised host	Aciclovir 5 mg/kg 8-hourly i.v. for 7–10 days Oral aciclovir 400 mg 6-hourly for 7–10 days Famciclovir 500 mg 8-hourly for 7–10 days Valaciclovir 1 g 12-hourly for 7–10 days
Chickenpox in adult or child	Oral aciclovir 800 mg 5 times a day for 5 days Famciclovir 500 mg 8-hourly for 5 days Valaciclovir 1 g 8-hourly for 5 days
Immunocompromised host/pregnant woman	Aciclovir 5 mg/kg 8-hourly i.v. until patient is improving, then complete therapy with oral therapy until all lesions crusting over
Shingles	Treatment and doses as for chickenpox but duration typically 7–10 days
Visceral involvement (non-CNS) in HSV	Aciclovir i.v. 5 mg/kg 8-hourly for 14 days
Visceral involvement (non-CNS) in VZV	Aciclovir i.v. 5 mg/kg 8-hourly for 7 days
Severe complications (encephalitis, disseminated infection)	Aciclovir i.v. 10 mg/kg 8-hourly (up to 20 mg/kg in neonates) for 14–21 days
HSV disease suppression	Aciclovir 400 mg 12-hourly Famciclovir 250 mg 12-hourly Valaciclovir 500 mg daily

develop severe chickenpox after receiving VZIG should be treated with aciclovir.

A live, attenuated VZV vaccine is available and in routine use in the USA and other countries. Children receive one dose after 1 year of age and seronegative adults two doses. The vaccine may also be used in patients prior to planned iatrogenic immunosuppression, e.g. before a transplant procedure.

Shingles (herpes zoster)

After initial infection VZV persists in latent form in the dorsal root ganglion of sensory nerves and can reactivate in later life as a localised rash or with other clinical manifestations. Commonly seen in the elderly, shingles

13.33 Indications for varicella zoster immunoglobulin (VZIG) in adults	
An adult should satisfy all three of the following conditions.	
1. Significant contact	
With exposed zoster, disseminated zoster, localised zoster (if index case is immunocompromised) or chickenpox, defined as:	
<ul style="list-style-type: none"> • Prolonged household contact, sharing a room for ≥ 15 minutes or face-to-face contact (includes direct contact with zoster lesions) at any time from 48 hrs before development of rash to crusting of lesions (chickenpox) or from development of rash to crusting (zoster) • Hospital contact with chickenpox in another patient, health-care worker or visitor • Intimate contact (e.g. touching) with person with shingles lesions • Newborn whose mother develops chickenpox no more than 5 days before delivery or 2 days after delivery 	
2. Susceptible contact	
<ul style="list-style-type: none"> • Individual with no history of chickenpox, ideally confirmed by negative test for VZV IgG 	
3. Predisposition to severe chickenpox	
<ul style="list-style-type: none"> • Immunocompromised due to disease (e.g. acute leukaemia, HIV, other primary or secondary immunodeficiency) • Medically immunosuppressed (e.g. following solid organ transplant or other indication, current or recent (≤ 6 months) cytotoxic chemotherapy or radiotherapy, current or recent (≤ 3 months) high-dose corticosteroids, bone marrow transplant • Pregnant (any stage) • Infants: newborn whose mother has had chickenpox as above, premature infants < 28 weeks 	

may also present in younger patients with immune deficiency.

Clinical features

Burning discomfort occurs in the affected dermatome, where discrete vesicles appear 3–4 days later. This is associated with a brief viraemia and can produce distant satellite 'chickenpox' lesions. Severe disease, a prolonged duration of rash, multiple dermatomal involvement or recurrence suggests underlying immune deficiency, including HIV. Chickenpox may be contracted from a case of shingles but not vice versa.

Although thoracic dermatomes are most commonly involved (Fig. 13.9B), the ophthalmic division of the trigeminal nerve is also frequently affected; vesicles may appear on the cornea and lead to ulceration. This condition can lead to blindness and urgent ophthalmology review is required. Geniculate ganglion involvement causes the Ramsay Hunt syndrome of facial palsy, ipsilateral loss of taste and buccal ulceration, plus a rash in the external auditory canal. This may be mistaken for Bell's palsy (p. 1228). Bowel and bladder dysfunction occur with sacral nerve root involvement. The virus occasionally causes myelitis or encephalitis. Granulomatous cerebral angiitis is a cerebrovascular complication that leads to a stroke-like syndrome in association with shingles, especially in an ophthalmic distribution.

Post-herpetic neuralgia causes troublesome persistence of pain for 1–6 months or longer, following healing of the rash. It is more common with advanced age.

Management and prevention

Early therapy with aciclovir or related agents has been shown to reduce both early- and late-onset pain, especially in patients over 65 years (see Box 13.31, p. 313). Post-herpetic neuralgia requires aggressive analgesia, along with agents such as amitriptyline 25–100 mg daily or gabapentin (commencing at 300 mg daily and building slowly to 300 mg 12-hourly or more). Capsaicin cream (0.075%) may be helpful. Studies are investigating the role of corticosteroids to reduce post-herpetic neuralgia.

Enteroviral exanthems

Coxsackie or echovirus infections can lead to a maculopapular eruption or roseola-like rash that occurs after fever falls. Enteroviral infections are discussed further under viral infections of the skin (see below).

Systemic viral infections without exanthem

Other systemic viral infections present with features other than a rash suggestive of exanthem. Rashes may occur in these conditions but differ from those seen in exanthems or are not the primary presenting feature.

Mumps

Mumps is a systemic viral infection characterised by swelling of the parotid glands. Infection is endemic world-wide and peaks at 5–9 years of age. Vaccination has reduced the incidence in children but incomplete coverage has increased susceptibility amongst older non-immune adults. Infection is spread by respiratory droplets.

Clinical features

The median incubation period is 19 days, with a range of 15–24 days. Classical tender parotid enlargement, which is bilateral in 75%, follows a prodrome of pyrexia and headache (Fig. 13.10). In non-vaccinated communities, mumps is the most common cause of sporadic viral meningitis, and meningitis complicates up to 10% of cases. The cerebrospinal fluid (CSF) reveals a lymphocytic pleocytosis, or less commonly neutrophils. Rare

complications include encephalitis, transient hearing loss, labyrinthitis, electrocardiographic abnormalities, pancreatitis and arthritis.

Approximately 25% of post-pubertal males with mumps develop epididymo-orchitis but, although testicular atrophy occurs, sterility is unlikely. Oophoritis is much less common. Abortion may occur if infection takes place in the first trimester of pregnancy. Complications may occur in the absence of parotitis.

Diagnosis

The diagnosis is usually clinical. In atypical presentations without parotitis, serology for mumps-specific IgM or IgG seroconversion (four-fold rise in IgG convalescent titre) confirms the diagnosis. Virus can also be cultured from urine in the first week of infection or detected by PCR in urine, saliva or CSF.

Management and prevention

Treatment is with analgesia. There is no evidence that corticosteroids are of value for orchitis. Mumps vaccine is one of the components of the combined MMR vaccine.

Influenza

Influenza is an acute systemic viral infection that primarily affects the respiratory tract (p. 671); it carries a significant mortality. It is caused by influenza A virus or, in milder form, influenza B virus. Infection is seasonal, and variation in the haemagglutinin (H) and neuraminidase (N) glycoproteins on the surface of the virus leads to disease of variable intensity each year. Minor changes in haemagglutinin are known as 'genetic drift', whereas a switch in the haemagglutinin or neuraminidase antigen is termed 'genetic shift'. Nomenclature of influenza strains is based on these glycoproteins, e.g. H1N1, H3N2 etc. Genetic shift results in the circulation of a new influenza strain within a community to which few people are immune, potentially initiating an influenza epidemic or pandemic in which there is a high attack rate and there may be increased disease severity.

Clinical features

After an incubation period of 1–3 days, uncomplicated disease leads to fever, malaise and cough. Viral pneumonia may occur, although pulmonary complications are most often due to superinfection with *Strep. pneumoniae*, *Staph. aureus* or other bacteria. Rare extrapulmonary manifestations include myositis, myocarditis, pericarditis and neurological complications (Reye's syndrome in children, encephalitis or transverse myelitis).

Diagnosis

Acute infection is diagnosed by viral culture, or by antigen or RNA detection (reverse transcription (RT)-PCR) in a nasopharyngeal sample. The disease may also be diagnosed retrospectively on the basis of seroconversion.

Management and prevention

Administration of the neuraminidase inhibitors, oral oseltamivir (75 mg 12-hourly) or inhaled zanamivir (10 mg 12-hourly) for 5 days can reduce the severity of symptoms if started within 48 hours of symptom onset (or possibly later in immunocompromised individuals). These agents have superseded amantadine and

Fig. 13.10 Typical unilateral mumps. **A** Note the loss of angle of the jaw on the affected (right) side. **B** Comparison showing normal (left) side.

rimantadine. Antiviral drugs can also be used as prophylaxis in high-risk individuals during the 'flu' season. Resistance can emerge to all of these agents.

The major mechanism of prevention is seasonal vaccination of the elderly and of individuals with chronic medical illnesses which place them at increased risk of the complications of influenza, such as chronic cardiopulmonary diseases or immune compromise. Healthcare workers should also receive annual vaccination. The vaccine composition changes each year to reflect the predominant strains circulating but is of limited efficacy when a new pandemic strain emerges.

Avian influenza

Avian influenza is caused by influenza A viruses with alternative haemagglutinin antigens, including the H5N1 strain. These viruses have an increased ability to bind to lower respiratory tract epithelium, causing more severe disease with increased incidence of viral pneumonia and respiratory failure. The majority of cases have occurred in individuals with a history of exposure to poultry, predominantly in South-east Asia. However, in recent 'flu' seasons, cases have spread further west and infection has been identified in Europe in migrating birds and imported poultry. Existing strains have been associated with infrequent person-to-person transmission but there is a concern that adaptation of an avian strain to allow effective person-to-person transmission is likely to lead to a global pandemic of life-threatening influenza.

Vaccination against seasonal 'flu' does not adequately protect against avian influenza. Cases are diagnosed by recognising the relevant epidemiological factors and should be confirmed with specific tests. Avian strains are susceptible to the neuraminidase inhibitors, although strains resistant to oseltamivir have been reported.

Swine influenza

Occasional cases of influenza are transmitted from pigs to humans. An outbreak of swine 'flu' began in 2009, initially in Mexico and then spreading around the world. The causative strain was shown to be an H1N1 strain which showed significant genetic variation from human strains of H1N1. Clinical features of infections with this strain are typical of influenza A infection, although some cases have more pronounced enteric features. Mortality can occur, in particular in individuals with medical comorbidities. Management of such an outbreak involves good infection control with an emphasis on hand hygiene and preventing dissemination of infection by coughing and sneezing. Neuraminidase inhibitors (oseltamivir and zanamivir), but not amantadine or rimantadine, were active against the initial strains of swine flu isolated in 2009 and have been used for treatment and prophylaxis of key contacts.

Infectious mononucleosis (IM) and Epstein-Barr virus (EBV)

IM is an acute viral illness characterised by pharyngitis, cervical lymphadenopathy, fever and lymphocytosis. A variety of medical complications may ensue. It is most often caused by EBV infection, but a variety of other viral infections (CMV, HHV-6, HIV-1) and toxoplasmosis can produce a similar clinical syndrome.

EBV is a gamma herpesvirus. In developing countries, subclinical infection in childhood is virtually

universal. In developed countries, primary infection may be delayed until adolescence or early adult life. Under these circumstances about 50% of infections result in typical IM. The virus is usually acquired from asymptomatic excretors via saliva, either by droplet infection or environmental contamination in childhood, or by kissing among adolescents and adults. EBV is not highly contagious and isolation of cases is unnecessary.

Clinical features

IM has a prolonged and undetermined incubation period, followed in some cases by a prodrome of fever, headache and malaise. This is followed by severe pharyngitis, which may include tonsillar exudates, and non-tender anterior and posterior cervical lymphadenopathy. Palatal petechiae, periorbital oedema, splenomegaly, inguinal or axillary lymphadenopathy, and macular, petechial or erythema multiforme rashes may occur. In most cases fever resolves over 2 weeks, and fatigue and other abnormalities settle over a further few weeks. Complications are listed in Box 13.34. Death is rare but can occur due to respiratory obstruction, haemorrhage from splenic rupture or thrombocytopenia, or encephalitis.

The diagnosis of IM outside the usual age in adolescence and young adulthood is difficult. In children under 10 years the illness is mild and short-lived, but in adults over 30 years of age it can be severe and prolonged. In both groups pharyngeal symptoms are often absent. IM may present with jaundice, as a PUO or with a complication.

<ul style="list-style-type: none"> Nasopharyngeal carcinoma Burkitt's lymphoma Primary CNS lymphoma 	<ul style="list-style-type: none"> Hodgkin's disease (certain subtypes only) Lymphoproliferative disease in immunocompromised

Long-term complications of EBV infection

Lymphoma complicates EBV infection in immunocompromised hosts, and some forms of Hodgkin's disease are EBV-associated (p. 1037). The endemic form of Burkitt's lymphoma complicates EBV infection in areas of sub-Saharan Africa where *falciparum* malaria is endemic. Nasopharyngeal carcinoma is a geographically restricted tumour seen in China and Alaska that is associated with EBV infection. X-linked lymphoproliferative (Duncan's) syndrome is a familial lymphoproliferative disorder that follows primary EBV infection in boys without any other history of immunodeficiency. The course is frequently fatal due to liver failure, haemophagocytosis, lymphoma or progressive agammaglobulinaemia, complicated by infection. The disorder is due to mutation of the *SAP* gene, involved in cell signalling in lymphocytes, and results in failure to contain EBV infection.

Investigations

Atypical lymphocytes are common in EBV infection but also occur in other causes of IM, acute retroviral syndrome with HIV infection, viral hepatitis, mumps and rubella (Fig. 13.11A). A 'heterophile' antibody is present during the acute illness and convalescence, which is detected by the Paul-Bunnell or 'Monospot' test. Sometimes antibody production is delayed, so an initially negative test should be repeated. However, many children and 10% of adolescents with IM do not produce heterophile antibody at any stage.

Specific EBV serology (immunofluorescence) can be used to confirm the diagnosis if necessary. Acute infection is characterised by IgM antibodies against the viral capsid, antibodies to EBV early antigen and the initial absence of antibodies to EBV nuclear antigen (anti-EBNA). Seroconversion of anti-EBNA at approximately 1 month after the initial illness may confirm the diagnosis in retrospect. CNS infections may be diagnosed by detection of viral DNA in cerebrospinal fluid.

Management

Treatment is largely symptomatic. If a throat culture yields a β -haemolytic streptococcus, a course of penicillin should be prescribed. Administration of ampicillin or amoxicillin in this condition commonly causes an itchy macular rash, and should be avoided (Fig. 13.11B). When pharyngeal oedema is severe, a short course of corticosteroids, e.g. prednisolone 30 mg daily for 5 days, may help. Antivirals are not sufficiently active against EBV.

Return to work or school is governed by the patient's physical fitness rather than laboratory tests. However, contact sports should be avoided until splenomegaly has completely resolved because of the danger of splenic rupture. Unfortunately, about 10% of patients with IM suffer a chronic relapsing syndrome.

Cytomegalovirus (CMV)

CMV, like EBV, circulates readily among children. A second period of virus acquisition occurs among teenagers and young adults, peaking between the ages of 25 and 35 years, rather later than with EBV infection. CMV infection is persistent, and is characterised by subclinical cycles of active virus replication and by persistent low-level virus shedding. Most post-childhood infections are therefore acquired from asymptomatic excretors who shed virus in saliva, urine, semen and genital secretions. Sexual transmission and oral spread are common among adults, but infection may also be acquired by women caring for children with asymptomatic infections.

Clinical features

Most post-childhood CMV infections are subclinical, although some young adults develop an IM-like syndrome and some have a prolonged influenza-like illness lasting 2 weeks or more. Physical signs resemble those of IM, but in CMV mononucleosis hepatomegaly is relatively more common, while lymphadenopathy, splenomegaly, pharyngitis and tonsillitis are found less often. Jaundice is uncommon and usually mild. Unusual complications include meningoencephalitis, Guillain-Barré syndrome, autoimmune haemolytic anaemia, thrombocytopenia, myocarditis and skin eruptions such as ampicillin-induced rash. Immunocompromised patients can develop hepatitis, oesophagitis, colitis, pneumonitis, retinitis, encephalitis and polyradiculitis.

Women who develop a primary CMV infection during pregnancy have about a 40% chance of passing CMV to the fetus, causing congenital infection and disease at any stage of gestation. Features include petechial rashes, hepatosplenomegaly and jaundice; 10% of infected infants will have long-term CNS sequelae such as microcephaly, cerebral calcifications, chorioretinitis and deafness. Infections in the newborn usually are asymptomatic or have features of an IM-like illness, although some studies suggest subtle sequelae affecting hearing or mental development may occur.

Fig. 13.11 Features of infectious mononucleosis. **A** Atypical lymphocytes in peripheral blood. **B** Skin reaction to ampicillin.

Investigations

Atypical lymphocytosis is not as prominent as in IM and heterophile antibody tests are negative. LFTs are often abnormal, with an alkaline phosphatase level raised out of proportion to transaminases. Serological diagnosis depends on the detection of CMV-specific IgM antibody plus a four-fold rise or seroconversion of IgG. In the immunocompromised, antibody detection is unreliable and detection of CMV in an involved organ by PCR, culture or histopathology establishes the diagnosis. A positive culture of CMV in the blood may be useful in transplant populations but not in HIV-positive individuals, since in HIV infection CMV reactivates at regular intervals but these episodes do not correlate well with episodes of clinical disease. Detection of CMV in urine is not helpful in diagnosing infection, except in neonates, since viruses are intermittently shed in the urine throughout life following infection.

Management

Only symptomatic treatment is required in the immunocompetent patient. Immunocompromised individuals are treated with ganciclovir 5 mg/kg i.v. 12-hourly or with oral valganciclovir 900 mg 12-hourly for at least 14 days. Foscarnet or cidofovir is also used in CMV treatment of immunocompromised patients who are resistant or intolerant of ganciclovir-based therapy.

Dengue

The dengue flavivirus is a common cause of fever and acute systemic illness in the tropics. It is endemic in South-east Asia and India, and is also seen in Africa, the Caribbean and the Americas (Fig. 13.12). The principal vector is the mosquito *Aedes aegypti*, which breeds in standing water; collections of water in containers, water-based air coolers and tyre dumps are a good environment for the vector in large cities. *Aedes albopictus* is a vector in some South-east Asian countries. There are four serotypes of dengue virus, all producing a similar clinical syndrome; homotypic immunity after infection with one of the serotypes is life-long, but heterotypic immunity against the other serotypes lasts only a few months after infection.

Clinical features

The incubation period from being bitten by an infected mosquito is usually 2–7 days. Clinical features are listed in Box 13.35. Asymptomatic infections are common but the disease is more severe in infants and the elderly. A morbilliform rash, which characteristically blanches under pressure, may occur, often as the fever is settling.

A more severe illness, called dengue haemorrhagic fever or dengue shock syndrome, occurs mainly in children in South-east Asia (see Box 13.35). In mild forms, there is thrombocytopenia and haemoconcentration. In the most severe form, after 3–4 days of fever, hypotension and circulatory failure develop with pleural effusions, ascites, hypoalbuminaemia and features of acute respiratory distress syndrome (ARDS, p. 187). Minor

13.35 Clinical features of dengue fever

Prodrome

- 2 days of malaise and headache

Acute onset

- Fever, backache, arthralgias, headache, generalised pains ('break-bone fever'), pain on eye movement, lacrimation, anorexia, nausea, vomiting, relative bradycardia, prostration, depression, lymphadenopathy, scleral injection

Fever

- Continuous or 'saddle-back', with break on 4th or 5th day and then recrudescence; usually lasts 7–8 days

Rash

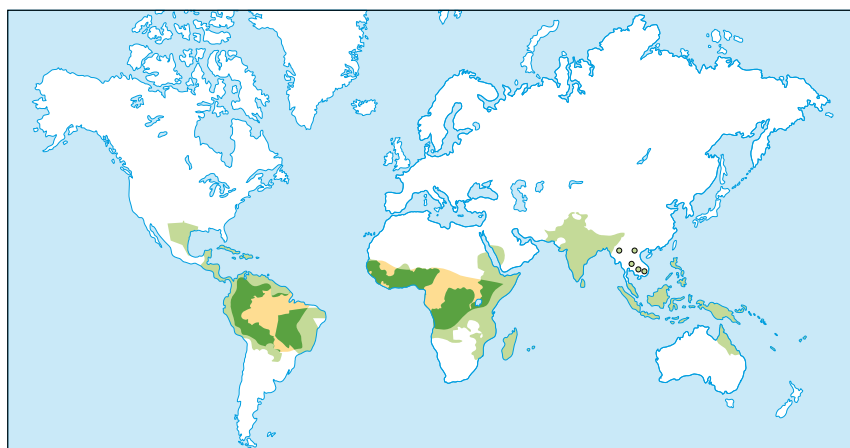

- Initial flushing faint macular rash in first 1–2 days. Maculopapular, scarlet morbilliform rash from days 3–5 on trunk, spreading centrifugally and sparing palms and soles, onset often with fever defervescence. May desquamate on resolution or give rise to petechiae on extensor surfaces

Convalescence

- Slow

Complications

- Minor bleeding from mucosal sites, hepatitis, cerebral haemorrhage or oedema, rhabdomyolysis

- Dengue
- Yellow fever
- Dengue + yellow fever
- Outbreaks of dengue haemorrhagic fever

Fig. 13.12 Endemic zones of yellow fever and dengue.

(petechiae, ecchymoses, epistaxis) or major (gastrointestinal or cerebrovascular) haemorrhagic signs may occur. The pathogenesis is unclear but pre-existing active or passive immunity to a dengue virus serotype different to the one causing the current infection is a predisposing factor; these heterotypic antibodies cause enhanced virus entry and replication in monocytes in vitro. Cytokine release is thought to be the cause of capillary leak causing effusions, and disseminated intravascular coagulation (DIC, p. 190) may contribute to haemorrhage. Adults rarely have classical dengue shock syndrome but they may have a stormy and fatal course characterised by elevated liver enzymes, haemostatic abnormalities and gastrointestinal bleeding.

Diagnosis

Diagnosis of dengue is easier in an endemic area when a patient has the characteristic symptoms and signs. However, mild cases may have a similar presentation to other viral infections. Leucopenia is usual and thrombocytopenia common. The diagnosis is confirmed by either a fourfold rise in IgG antibody titres, isolation of dengue virus from blood or detection of dengue virus RNA by PCR (p. 138). Serological tests may detect cross-reacting antibodies against other flaviviruses, including yellow fever vaccine.

Management and prevention

Treatment is symptomatic. Aspirin should be avoided due to bleeding risk. Volume replacement and blood transfusions may be indicated in patients with shock. With intensive care support, mortality rates are 1% or less. Corticosteroids have not been shown to help. No existing antivirals are effective.

Breeding places of *Aedes* mosquitoes should be abolished and the adults destroyed by insecticides. There is no licensed vaccine available.

Yellow fever

Yellow fever is a haemorrhagic fever of the tropics, caused by a flavivirus. It is a zoonosis of monkeys in West and Central African, and South and Central American tropical rainforests, where it may cause devastating epidemics (see Fig. 13.12). Transmission is by tree-top mosquitoes *Aedes africanus* (Africa) and *Haemagogus* spp. (America). The infection is introduced to humans either by infected mosquitoes when trees are felled, or by monkeys raiding human settlements. In towns, yellow fever may be transmitted between humans by *Aedes aegypti*, which breeds efficiently in small collections of water. The distribution of this mosquito is far wider than that of yellow fever and more widespread infection is a continued threat.

Yellow fever causes between 200 000 and 300 000 deaths each year, mainly in sub-Saharan Africa, where it remains a major public health problem. Overall mortality is around 15%, although this varies widely. Humans are infectious during the viraemic phase, which starts 3–6 days after the bite of the infected mosquito and lasts for 4–5 days.

Clinical features

After an incubation period of 3–6 days, yellow fever is often a mild febrile illness lasting less than 1 week with headache, myalgia, conjunctival erythema and bradycardia. This is followed by fever resolution (defervescence), but in some cases fever recurs after a few hours to days. In more severe disease, fever recrudescence is associated

13.36 Diagnosis of yellow fever

- Clinical features in endemic area
- Virus isolation from blood in first 24 days
- IgM or fourfold rise in IgG antibody titre
- Post-mortem liver biopsy
- Differentiation from malaria, typhoid, viral hepatitis, leptospirosis, haemorrhagic fevers, aflatoxin poisoning

with lower back pain, abdominal pain and somnolence, prominent nausea and vomiting, bradycardia and jaundice. Liver damage and DIC lead to bleeding with petechiae, mucosal haemorrhages and gastrointestinal bleeding. Shock, hepatic failure, renal failure, seizures and coma may ensue.

Diagnosis

Diagnostic procedures are listed in Box 13.36. Leucopenia is characteristic. Liver biopsy should be avoided in life due to the risk of fatal bleeding. Post-mortem features, such as acute mid-zonal necrosis and Councilman bodies with minimal inflammation in the liver, are suggestive but not specific. Immunohistochemistry for viral antigens improves specificity.

Management and prevention

Treatment is supportive, with meticulous attention to fluid and electrolyte balance, urine output and blood pressure. Blood transfusions, plasma expanders and peritoneal dialysis may be necessary. Patients should be isolated, as their blood and body products may contain virus particles.

A single vaccination with a live attenuated vaccine gives full protection for at least 10 years. Potential side-effects include hypersensitivity, encephalitis and systemic features of yellow fever caused by the attenuated virus. Vaccination is not recommended in people who are significantly immunosuppressed. The risk of vaccine side-effects must be balanced against the risk of infection for less immunocompromised hosts, pregnant women and older patients. An internationally recognised certificate of vaccination is sometimes necessary when crossing borders.

Viral haemorrhagic fevers (VHF)

VHF are zoonoses caused by several different viruses (Box 13.37). They are geographically restricted and occur in rural settings or in health-care facilities.

Serological surveys have shown that Lassa fever is widespread in West Africa and may lead to up to 500 000 infections annually. Mortality overall may be low, as 80% of cases are asymptomatic, but in hospitalised cases mortality averages 15%. Ebola outbreaks have occurred at a rate of approximately 1 outbreak per year, involving up to a few hundred cases. The largest outbreaks have been in the Democratic Republic of Congo, Uganda and Sudan. Marburg has been documented less frequently, with outbreaks in the Democratic Republic of Congo and Uganda, but the largest outbreak to date involved 163 cases in Angola in 2005. Mortality rates of Ebola and Marburg are high.

VHF have extended into Europe, with an outbreak of Congo-Crimean haemorrhagic fever in Turkey in 2006, and cases of haemorrhagic fever with renal syndrome in

13.37 Viral haemorrhagic fevers

Disease	Reservoir	Transmission	Incubation period	Geography	Mortality rate	Clinical features of severe disease ¹
Lassa fever	Multimammate rats (<i>Mastomys natalensis</i>)	Urine from rat Body fluids from patients	6–21 days	West Africa	15%	Haemorrhage, shock, encephalopathy, ARDS (responds to ribavirin) Deafness in survivors
Ebola fever	Undefined (?bats)	Body fluids from patients Handling infected primates	2–21 days	Central Africa Outbreaks as far north as Sudan	25–90%	Haemorrhage, hepatic and renal failure
Marburg fever	Undefined	Body fluids from patients Handling infected primates	3–9 days	Central Africa Outbreak in Angola	25–90%	Haemorrhage, diarrhoea, encephalopathy, orchitis
Yellow fever	Monkeys	Mosquitoes	3–6 days	Tropical Africa, South and Central America	~15%	Hepatic failure, renal failure, haemorrhage
Dengue	Humans	<i>Aedes aegypti</i>	2–7 days	Tropical and subtropical coasts; Asia, Africa, Americas	< 10% ²	Haemorrhage, shock
Crimean–Congo haemorrhagic fever	Small vertebrates Domestic and wild animals	<i>Ixodes</i> tick Body fluids	1–3 days up to 9 days 3–6 days up to 13 days	Africa, Asia, Eastern Europe	30%	Encephalopathy, haemorrhage, hepatic or renal failure, ARDS
Rift Valley fever	Domestic livestock	Contact with animals, mosquito or other insect bites	2–6 days	Africa, Arabian peninsular	1%	Haemorrhage, blindness, meningoencephalitis (complications only in a minority)
Kyasanur fever	Monkeys	Ticks	3–8 days	Karnataka State, India	5–10%	Haemorrhage, pulmonary oedema, neurological features Iridokeratitis in survivors
Bolivian and Argentinian haemorrhagic fever (Junin and Machupo viruses)	Rodents (<i>Calomys</i> spp.)	Urine, aerosols Body fluids from case (rare)	5–19 days (3–6 days for parenteral)	South America	15–30%	Haemorrhage, shock, cerebellar signs (may respond to ribavirin)
Haemorrhagic fever with renal syndrome (Hantaan fever)	Rodents	Aerosols from faeces	5–42 days (typically 14 days)	Northern Asia, northern Europe, Balkans	5%	Acute renal impairment, cerebrovascular accidents, pulmonary oedema, shock (hepatic failure and haemorrhagic features only in some variants)

¹All potentially have circulatory failure.

²Mortality of uncomplicated and haemorrhagic dengue fever, respectively.

the Balkans and Russia. These conditions remain very rare in the UK, with about 1 case of Lassa fever arriving in the country every 2 years.

Kyasanur forest disease is a tick-borne VHF currently confined to a small focus in Karnataka, India; there are about 500 cases annually. Monkeys are the principal hosts, but with forest felling there are fears that this disease will increase.

All of these viral illnesses, except Ebola and Marburg, have mild self-limiting forms. Details on recent disease

outbreaks can be found at the WHO website (www.who.int).

Clinical features

All VHF have similar non-specific presentations with fever, malaise, body pains, sore throat and headache. On examination conjunctivitis, throat injection, an erythematous or petechial rash, haemorrhage, lymphadenopathy and bradycardia may be noted. The viruses cause endothelial dysfunction with the development of capillary

leak. Bleeding is due to endothelial damage and platelet dysfunction. Hypovolaemic shock and ARDS may develop (p. 187).

Haemorrhage is a late feature of VHF and most patients present with earlier features. In Lassa fever, joint and abdominal pain are prominent. A macular blanching rash may be present but bleeding is unusual, occurring in only 20% of hospitalised patients. Encephalopathy may develop and deafness affects 30% of survivors.

The clue to the viral aetiology comes from the travel and exposure history. Travel to an outbreak area, activity in a rural environment and contact with sick individuals or animals within 21 days all increase the risk of VHF. Enquiry should be made about insect bites, hospital visits and attendance at ritual funerals (Ebola virus infection). For Lassa fever retrosternal pain, pharyngitis and proteinuria have a positive predictive value of 80% in West Africa.

Investigations and management

Non-specific findings include leucopenia, thrombocytopenia and proteinuria. In Lassa fever an aspartate aminotransferase (AST) > 150 U/L is associated with a 50% mortality. It is important to exclude other causes of fever, especially malaria, typhoid and respiratory tract infections. Most patients suspected of having a VHF in the UK turn out to have malaria.

In patients with suspected VHF, strict infection control is important (see Fig. 13.5, p. 307). The diagnosis of VHF must be considered in all individuals who present with fever within 21 days of leaving an endemic area or who present with haemorrhage or organ failure. A febrile patient from an endemic area within the incubation period, who has specific epidemiological risk factors (see Fig. 13.5, p. 307) or who has signs of organ failure or haemorrhage, should be treated as being at high risk of VHF. These patients must be transferred to a centre with the appropriate biosafety facilities to care for them. Individuals with a history of travel within 21 days and fever, but without the relevant epidemiological features or signs of VHF, are classified as medium-risk and should have an initial blood sample tested to exclude malaria. If this is negative, relevant specimens (blood, throat swab, urine and pleural fluid (if available)) are collected and sent to an appropriate reference laboratory for nucleic acid detection (PCR), virus isolation, and serology. If patients are felt to be at high risk of VHF or if infection is confirmed, they should be transferred to a specialised high-

security infectious disease unit. All further laboratory tests should be performed at biosafety level 4. Transport requires an ambulance with biosafety level 3 facilities.

In addition to general supportive measures, ribavirin is given intravenously (100 mg/kg, then 25 mg/kg daily for 3 days and 12.5 mg/kg daily for 4 days) when Lassa fever or South American haemorrhagic fevers are suspected.

Prevention

Ribavirin has been used as prophylaxis in close contacts in Lassa fever but there are no formal trials of its efficacy.

Viral infections of the skin

Herpes simplex virus 1 and 2 (HSV)

These cause widespread recurrent mucocutaneous infection; HSV-1 typically involves the mucocutaneous surfaces of the head and neck (Fig. 13.13), whilst HSV-2 predominantly involves the genital mucosa (pp. 416 and 421), although there is overlap (see Box 13.30, p. 312). The seroprevalence of HSV-1 is 30–100%, varying by socioeconomic status, while that of HSV-2 is 20–60%. Infection is acquired by inoculation of viruses shed by an infected individual on to a mucosal surface in a susceptible person. The virus infects sensory and autonomic neurons and establishes latent infection in the nerve ganglia. Primary infection is followed by episodes of reactivation throughout life.

Clinical features

Primary HSV-1 or 2 infection is more likely to be symptomatic later in life, causing gingivostomatitis, pharyngitis or painful genital tract lesions. The primary attack may be associated with fever and regional lymphadenopathy.

Recurrence

Recurrent attacks occur throughout life, most often in association with concomitant medical illness, menstruation, mechanical trauma, immunosuppression, psychological stress or, for oral lesions, ultraviolet light exposure. HSV reactivation in the oral mucosa produces the classical 'cold sore' or 'herpes labialis'. Prodromal hyperaesthesia is followed by rapid vesiculation, pustulation and crusting. Recurrent HSV genital disease is a common cause of recurrent painful genital ulceration (p. 421). An inoculation lesion on the finger gives rise to

Fig. 13.13 Cutaneous manifestations of herpes simplex virus-1 (HSV-1). **A** Acute HSV-1. There were also vesicles in the mouth—herpetic stomatitis. **B** Herpetic whitlow. **C** Eczema herpeticum. HSV-1 infection spreads rapidly in eczematous skin.

a paronychia termed a 'whitlow' in contacts of patients with herpetic lesions (Fig. 13.13B). It was formerly seen in health-care workers and dentists, but is prevented by protective gloves.

Complications

Complications include disseminated cutaneous lesions in individuals with underlying dermatological diseases such as eczema (eczema herpeticum) (Fig. 13.13C). Herpes keratitis presents with pain and blurring of vision; characteristic dendritic ulcers are visible on slit-lamp examination and may produce corneal scarring and permanent visual impairment.

Primary HSV-2 can cause meningitis or transverse myelitis. HSV is the leading cause of sporadic viral encephalitis (p. 1209); this serious complication may occur following either primary or secondary disease, usually with HSV-1. A haemorrhagic necrotising temporal lobe cerebritis produces temporal lobe epilepsy and altered consciousness/coma. Without treatment, mortality is 80%. HSV is also implicated in the pathogenesis of Bell's palsy with a lower motor neuron VII nerve palsy.

Neonatal HSV disease is usually associated with primary infection of the mother at term (see Box 13.27, p. 310). In excess of two-thirds of cases develop disseminated disease with cutaneous lesions, hepatitis, pneumonitis and frequently encephalitis.

Immunocompromised hosts can develop visceral disease with oesophagitis, hepatitis, pneumonitis, encephalitis or retinitis.

Diagnosis

Differentiation from other vesicular eruptions is achieved by demonstration of virus in vesicular fluid by direct immunofluorescence or culture, or of virus DNA by PCR. HSV encephalitis is diagnosed by detection of virus DNA in CSF. Serology is of limited value, only confirming whether an individual has had previous infection.

Management

The acyclic antivirals are the treatment of choice for HSV infection (see Box 13.32, p. 314). Therapy must commence in the first 48 hours of clinical disease (primary or recurrent); thereafter it is unlikely to influence clinical outcome. Oral lesions in an immunocompetent individual may be treated with topical aciclovir. All severe manifestations should be treated, regardless of the time of presentation. Any reasonable suspicion of HSV encephalopathy is an indication for immediate empiric antiviral therapy. Aciclovir resistance is encountered occasionally in immunocompromised hosts, in which case foscarnet is the treatment of choice.

Human herpesvirus 8 (HHV-8)

This virus (see Box 13.30, p. 421) causes Kaposi's sarcoma in both AIDS-related and endemic non-AIDS-related forms (p. 402). HHV-8 is spread via saliva and men who have sex with men have increased incidence of infection. Seroprevalence varies widely, being highest in sub-Saharan Africa. HHV-8 also causes two rare haematological malignancies: primary effusion lymphoma and multicentric Castleman's disease. Current antivirals are not effective.

Enterovirus infections

Hand, foot and mouth disease

This systemic infection is usually caused by Coxsackie viruses or occasionally echoviruses. It affects children and occasionally adults, resulting in local or household outbreaks, particularly in the summer months. A relatively mild illness with fever and lymphadenopathy develops after an incubation period of approximately 10 days; 2–3 days later a painful papular or vesicular rash appears on palmoplantar surfaces of hands and feet, with associated oral lesions on the buccal mucosa and tongue that ulcerate rapidly. A papular erythematous rash may appear on buttocks and thighs. Antiviral treatment is not available and management consists of symptom relief with analgesics.

Herpangina

This infection, caused by Coxsackie viruses, primarily affects children and teenagers in the summer months. It is characterised by a small number of vesicles at the soft/hard palate junction, often associated with high fever, an extremely sore throat and headache. The lesions are short-lived, rupturing after 2–3 days and rarely persisting for more than 1 week. Treatment is with analgesics if required. Culture of the virus from vesicles or DNA detection by PCR differentiates herpangina from HSV.

Poxviruses

These DNA viruses are rare but potentially important pathogens.

Smallpox (variola)

This severe disease, which has high mortality, was eradicated world-wide by a global vaccination programme. Interest in the disease has re-emerged due to its potential as a bioweapon. The virus is spread by the respiratory route or contact with lesions, and is highly infectious.

The incubation period is 7–17 days. A prodrome with fever, headache and prostration leads in 1–2 days to the rash, which develops through macules and papules to vesicles and pustules, worst on the face and distal extremities. Lesions in one area are all at the same stage of development with no cropping (unlike chickenpox). Vaccination can lead to a modified course of disease with milder rash and lower mortality.

If a case of smallpox is suspected, national public health authorities must be contacted. Electron micrography (like Fig. 13.14) and DNA detection tests (PCR) are used to confirm smallpox or, using specific primers, an alternative poxvirus.

Monkeypox

Despite the name, the animal reservoirs for this virus are probably small squirrels and rodents. It causes a rare zoonotic infection in communities in the rainforest belt of central Africa, producing a vesicular rash indistinguishable from smallpox, but differentiated by the presence of lymphadenopathy. Little person-to-person transmission occurs. Recent outbreaks outside Africa have been linked to importation of African animals as exotic pets. Diagnosis is by EM and/or DNA detection (PCR).

Fig. 13.14 Electron micrograph of molluscum contagiosum, a poxvirus.

Cowpox

Humans in contact with infected cows develop large vesicles, usually on the hands or arms and associated with fever and regional lymphadenitis. The reservoir is thought to be wild rodents, and the virus also produces symptomatic disease in cats and a range of other animals.

Vaccinia virus

This laboratory strain is the basis of the existing vaccine to prevent smallpox. Widespread vaccination is no longer recommended due to the likelihood of local spread from the vaccination site (potentially life-threatening in those with eczema (eczema vaccinatum) or immune deficiency) and of encephalitis. However, vaccination may still be recommended for key medical staff.

Orf

See page 1273.

Molluscum contagiosum

See page 1273 and Figure 13.14.

Gastrointestinal viral infections

Norovirus (Norwalk agent)

Noroviruses have been associated with outbreaks of gastroenteritis in closed communities such as long-stay hospital wards, cruise ships and military camps. Food handlers may also transmit this virus, which is relatively resistant to decontamination procedures. Incubation periods are 24–48 hours. High attack rates and prominent vomiting are characteristic. Diagnosis is by electron microscopy, antigen or DNA detection (PCR) in stool samples.

Astrovirus

Astroviruses cause diarrhoea in small children and occasionally in immunocompromised adults.

Rotavirus

Rotaviruses are the major cause of diarrhoeal illness in young children world-wide and cause 10–20% of deaths due to gastroenteritis in developing countries. There are

winter epidemics in developed countries, particularly in nurseries. Adults are less often infected but those in close contact with cases may develop disease. The virus infects enterocytes, causing decreased surface absorption. The incubation period is 48 hours and patients present with watery diarrhoea, vomiting, fever and abdominal pain. Dehydration is prominent. Diagnosis is aided by commercially available enzyme immunoassay kits, which require fresh or refrigerated stool samples. Immunity develops to natural infection. A licensed vaccine is effective but is associated with increased rates of intussusception and so its use is not recommended. Other vaccines are in development.

Hepatitis viruses (A–E)

See Chapter 23.

Other viruses

Adenoviruses are frequently identified from stool culture and implicated as a cause of diarrhoea in children. They have also been linked to cases of intussusception.

Respiratory viral infections

These infections are described on pages 680–681.

Adenoviruses, rhinoviruses and enteroviruses (Coxsackie viruses and echoviruses) (Box 19.40, p. 680) often produce non-specific symptoms. Parainfluenza and respiratory syncytial viruses cause upper respiratory tract disease, croup and bronchiolitis in small children and pneumonia in the immunocompromised. Respiratory syncytial virus also causes pneumonia in nursing home residents and may be associated with nosocomial pneumonia. Metapneumovirus and bocavirus have emerged as new causes of upper respiratory tract infection and occasionally lower respiratory tract infection. They may also cause pneumonia in immunosuppressed individuals, such as recipients of allogeneic bone marrow transplants. The severe acute respiratory syndrome (SARS) caused by the SARS coronavirus emerged as a major respiratory pathogen during an outbreak in 2002–3, with 8000 cases and 10% mortality (p. 682).

Viral infections with neurological involvement

See also page 1209.

Japanese B encephalitis

This flavivirus is an important cause of endemic encephalitis in Japan, China, Russia, South-east Asia, India and Pakistan; outbreaks also occur elsewhere. There are 10 000–20 000 cases reported to the WHO annually. Pigs and aquatic birds are the virus reservoirs and transmission is by mosquitoes. Exposure to rice paddies is a recognised risk factor.

Clinical features

The incubation period is 4–21 days. Most infections are probably subclinical in childhood and only around 1% of infections lead to encephalitis. There is an initial

systemic illness with fever, malaise and anorexia, followed by photophobia, vomiting, headache and changes in brain-stem function. Neurological features other than encephalitis include meningitis, seizures, cranial nerve palsies, flaccid or spastic paralysis, and extrapyramidal features. Mortality with neurological disease is 25%. Most children die from respiratory failure with infection of brain-stem nuclei. Approximately 50% of survivors are left with neurological sequelae.

Investigations, management and prevention

Other infectious causes of encephalitis should be excluded (p. 1209). There is neutrophilia and often hyponatraemia. CSF analysis reveals lymphocytosis and elevated protein. Serological testing may be helpful and there is a CSF antigen test.

Treatment is supportive, anticipating and treating complications. Vaccination for travellers to endemic areas during the monsoon period is effective prophylaxis. Some endemic countries include this vaccination in their childhood schedules.

West Nile virus

This flavivirus has emerged as an important cause of neurological disease in an area that extends from Australia, India and Russia through Africa and Southern Europe and across to North America. The disease has an avian reservoir and a mosquito vector. The elderly are at increased risk of neurological disease.

Clinical features

Most infections are asymptomatic. After 2–6 days' incubation, a mild febrile illness and arthralgia constitute the most common clinical presentation. A prolonged incubation may be seen in immunocompromised individuals. Children may develop a maculopapular rash. Neurological disease is seen in 1% and is characterised by encephalitis, meningitis or asymmetric flaccid paralysis with 10% mortality.

Diagnosis and management

Diagnosis is by serology or detection of viral RNA in blood or CSF. Serological tests may show cross-reactivity with other flaviviruses, including vaccine strains. Treatment is supportive.

Enterovirus 71

Enterovirus 71 has caused outbreaks around the globe of enteroviral disease with hand, foot and mouth disease (p. 322) and aseptic meningitis. Some cases have been complicated by encephalitis with flaccid paralysis or by brain-stem involvement and death. The virus can be isolated from vesicle fluid, stool or CSF, and viral RNA can be detected in CSF by RT-PCR.

Nipah virus encephalitis

In 1999 a newly discovered paramyxovirus in the Hendra group, the Nipah virus, caused an epidemic of encephalitis amongst Malaysian pig farmers. Infection is through direct contact with pig secretions. Mortality is around 30%. Antibodies to the Hendra virus are present in 76% of cases.

Human T cell lymphotropic virus type I (HTLV-1)

HTLV-I is a retrovirus which causes chronic infection with development of adult T-cell leukaemia/lymphoma or HTLV-1-associated myelopathy (HAM) in a subset of those infected (p. 1039). It is found mainly in Japan, the Caribbean, Central and South America, and the Seychelles. HAM or tropical spastic paraparesis occurs in < 5% of those with chronic infection, and presents with gait disturbance, spasticity of the lower extremities, urinary incontinence, impotence and sensory disturbance. Myositis and uveitis may also occur with HTLV-1 infection. Serology confirms the diagnosis. Treatment is supportive.

Viral infections with rheumatological involvement

Rheumatological syndromes characterise a variety of viral infections ranging from exanthems, such as rubella and parvovirus B19 (p. 311), to blood-borne viruses, such as HBV and HIV-1.

Chikungunya virus

Chikungunya is an alphavirus that causes fever, rash and arthropathy. It is found principally in Africa and Asia, including India. Humans and non-human primates are the main reservoir and the main vector is the *Aedes aegypti* mosquito. Cases occur in epidemics on a background of sporadic cases. In 2007 an outbreak extended as far north as Italy.

The incubation period is 2–12 days. A period of fever may be followed by an afebrile phase and then recrudescence of fever. Children may develop a maculopapular rash. Adults are susceptible to arthritis, which causes early morning pain and swelling, most often in the small joints. Arthritis can persist for months and may become chronic in HLA-B27-positive individuals. Related alphaviruses causing similar syndromes include Sindbis virus (Scandinavia and Africa), O'nyong-nyong virus (Central Africa), Ross River virus (Australia) and Mayaro virus (Caribbean and South America).

Diagnosis is by serology but cross-reactivity between alphaviruses occurs. Treatment is symptomatic.

PRION DISEASES

Prions (p. 132) cause spongiform encephalopathies in humans, sheep, cows and cats (Box 13.38 and see p. 1214). The prion protein is not inactivated by cooking or conventional sterilisation, and transmission is thought to occur by consumption of infected CNS tissue or by inoculation (e.g. via depth EEG electrodes, corneal grafts, cadaveric dura mater grafts and pooled cadaveric growth hormone preparations). The same diseases can occur in an inherited form, due to mutations in the PrP gene.

The apparent transmission of bovine spongiform encephalopathy (BSE) to humans following an outbreak of BSE in the UK beginning in the late 1980s has caused great concern, leading to precautionary measures in the UK, such as leucodepletion of all blood used for transfusion, and the mandatory use

13.38 Prion diseases affecting humans

Disease	Mechanism
Creutzfeldt–Jakob disease	
Sporadic	Spontaneous PrP ^c to PrP ^{Sc} conversion or somatic mutation
Familial	Mutations in the PrP gene
Variant	Infection from bovine spongiform encephalopathy
Gerstmann–Sträussler–Scheinker disease	Mutations in the PrP gene
Fatal familial insomnia	Mutations in the PrP gene
Sporadic fatal insomnia	Spontaneous PrP ^c to PrP ^{Sc} conversion or somatic mutation
Kuru	Cannibalism

of disposable surgical instruments wherever possible for tonsillectomy, appendectomy and ophthalmological procedures.

BACTERIAL INFECTIONS

Bacterial infections of the skin, soft tissues and bones

Most infections of the skin, soft tissues and bone are caused by either staphylococci (mainly *Staph. aureus*) or streptococci (mainly *Strep. pyogenes*). Clinical manifestations are also described in Chapters 25 and 27.

Staphylococcal infections

Staphylococci are usually found colonising the anterior nares and skin. Traditionally, staphylococci were divided into two groups according to their ability to produce coagulase, an enzyme that converts fibrinogen to fibrin in rabbit plasma, causing it to clot. *Staph. aureus* is coagulase-positive, and most other species coagulase-negative. The coagulase test is now less commonly undertaken, with identification of *Staph. aureus* often achieved by other methods.

Staph. aureus is the main cause of staphylococcal infections. *Staph. intermedius* is another coagulase-positive staphylococcus, which causes infection following dog bites. Among coagulase-negative organisms, *Staph. epidermidis* is the predominant commensal organism of the skin, and can cause severe infections in those with central venous catheters or implanted prosthetic materials. *Staph. saprophyticus* is part of the normal vaginal flora and causes urinary tract infections in sexually active young women. Others implicated in human infections include *Staph. lugdunensis*, *Staph. schleiferi*, *Staph. haemolyticus* and *Staph. caprae*. Coagulase-negative staphylococci are not usually identified to species level.

Staphylococci are particularly dangerous if they gain access to the blood stream, having the potential to cause disease in many sites (Fig. 13.15). In any patient with staphylococcal bacteraemia, especially injection drug-users, the possibility of endocarditis must be considered (p. 624). Growth of *Staph. aureus* in blood cultures should not be dismissed as a 'contaminant' unless

Fig. 13.15 Infections caused by *Staphylococcus aureus*.

all possible underlying sources have been excluded and repeated blood culture is negative. Any evidence of spreading cellulitis indicates the urgent need for an antistaphylococcal antibiotic such as flucloxacillin. This is particularly true for mid-facial cellulitis, which can result in cavernous sinus thrombophlebitis.

In addition, *Staph. aureus* can cause severe systemic disease due to the effects of toxin produced at superficial sites in the absence of tissue invasion by bacteria.

Skin infections

Staphylococcal infections cause ecthyma, folliculitis, furuncles, carbuncles, bullous impetigo and the scalded skin syndrome (pp. 1269–1270). They may also be involved in necrotising infections of the skin and subcutaneous tissues (p. 300).

Wound infections

Many wound infections are caused by staphylococci and may significantly prolong hospital stays in otherwise uncomplicated surgery (Fig. 13.16A). Prevention involves paying careful attention to hand hygiene, skin preparation and aseptic technique, and the use of topical and systemic antibiotic prophylaxis.

Treatment is by drainage of any abscesses plus adequate dosage of antistaphylococcal antibiotics. These should be instituted early, particularly if prosthetic implants of any kind have been inserted.

Cannula-related infection

Staphylococcal infection associated with cannula sepsis (Fig. 13.16B and see p. 300) and thrombophlebitis is an important and, unfortunately, extremely common reason for morbidity following hospital admission. The Visual Infusion Phlebitis (VIP) score is a useful way of monitoring cannulae (Box 13.39). Staphylococci have a predilection for plastic, rapidly forming a biofilm

Fig. 13.16 Manifestations of skin infection with *Staph. aureus*.

A Wound infection. **B** Cannula-related infection.

which remains as a source of bacteraemia as long as the plastic is in situ. Local poultice application may relieve symptoms but cannula removal and antibiotic treatment with flucloxacillin (or a glycopeptide if MRSA is suspected) are necessary if there is any suggestion of spreading infection.

 13.39 How to assess an i.v. cannula using the Visual Infusion Phlebitis score (VIP)		
Clinical features	Score	Assessment and management
I.v. site appears healthy	0	No signs of phlebitis Observe cannula
One of the following is evident: Slight pain near i.v. site Slight redness near i.v. site	1	Possible first signs of phlebitis Observe cannula
Two of the following are evident: Pain near i.v. site Erythema Swelling	2	Early stage of phlebitis Resite cannula
ALL of the following are evident and extensive: Pain along path of cannula Erythema Induration	3	Medium stage of phlebitis Resite cannula Consider treatment
ALL of the following are evident and extensive: Pain along path of cannula Erythema Induration Palpable venous cord	4	Advanced stage of phlebitis or start of thrombophlebitis Resite cannula Consider treatment
ALL of the following are evident: Pain along path of cannula Erythema Induration Palpable venous cord Pyrexia	5	Advanced stage of thrombophlebitis Initiate treatment Resite cannula

*Adapted from Jackson A, Nursing Times 1997; 94:68–71.

Meticillin-resistant *Staph. aureus* (MRSA)

Resistance to meticillin, due to a penicillin-binding protein mutation, has been recognised in *Staph. aureus* for more than 30 years. The recent recognition of resistance to vancomycin/teicoplanin (glycopeptides) in either glycopeptide intermediate *Staph. aureus* (GISA) or, rarely, vancomycin-resistant (VRSA) strains threatens the ability to manage serious infections produced by such organisms. MRSA is now a major world-wide health care-acquired pathogen, accounting for up to 40% of staphylococcal bacteraemia in developed countries. Community-acquired MRSA (c-MRSA) currently accounts for 50% of all MRSA infections in the USA. These organisms have also acquired other virulence factors such as Panton–Valentine leukocidin (PVL), which can cause rapidly fatal infection in young people. Clinicians must be aware of the potential danger of these infections and be prepared to take whatever appropriate infection control measures are locally advised (p. 143–144).

Treatment options for MRSA are shown in Box 6.18 (p. 150). Treatment should always be based on the results of antimicrobial susceptibility testing since resistance to all these agents occurs. Milder MRSA infections may be treated with clindamycin, tetracyclines or co-trimoxazole. Glycopeptides, linezolid and daptomycin are reserved for treatment of more severe infections. PVL-producing *Staph. aureus* infections should be treated with protein-inhibiting antibiotics (clindamycin, linezolid).

Staphylococcal toxic shock syndrome (TSS)

This serious and life-threatening disease is associated with infection by *Staph. aureus*, which produces a specific toxin (toxic shock syndrome toxin 1, TSST1). It was commonly seen in young women associated with the use of highly absorbent intravaginal tampons but can occur with any *Staph. aureus* infection involving a relevant toxin-producing strain. The toxin acts as a 'super-antigen', triggering significant T-helper cell activation and massive cytokine release.

TSS has an abrupt onset with high fever, generalised systemic upset (myalgia, headache, sore throat and vomiting), a generalised erythematous blanching rash resembling scarlet fever, and hypotension. It rapidly

Fig. 13.17 Full-thickness desquamation after staphylococcal toxic shock syndrome.

progresses over a matter of hours to multisystem involvement with cardiac, renal and hepatic compromise, leading to death in 10–20%. Recovery is accompanied at 7–10 days by desquamation (Fig. 13.17).

The diagnosis is clinical and may be confirmed in menstrual cases by vaginal examination, the finding of a retained tampon and microbiological examination by Gram stain demonstrating typical staphylococci. Subsequent culture and demonstration of toxin production are confirmatory.

Management

Treatment is with immediate and aggressive fluid resuscitation and an intravenous antistaphylococcal antibiotic (flucloxacillin or vancomycin), usually with the addition of a protein synthesis inhibitor (e.g. clindamycin) to inhibit toxin production. Intravenous immunoglobulin is occasionally added in the most severe cases on the basis of efficacy in streptococcal toxic shock. Women who recover should be advised not to use tampons for at least 1 year and should also be warned that, due to an inadequate antibody response to TSST1, the condition can recur.

Streptococcal infections

Streptococci are nasopharyngeal and gut commensals, which appear as Gram-positive cocci in chains (Fig. 6.3, p. 134). They are classified by the haemolysis they produce on blood agar (Fig. 6.4, p. 134) and by their serotypes (Box 13.40). Some streptococci (e.g. *milleri* group) defy simple classification.

Skin presentations of streptococcal infections

Group A streptococci (GAS) are the major cause of cellulitis, erysipelas and impetigo (p. 1269–1271). Groups C and G streptococci cause cellulitis in particular in elderly, diabetic or immunocompromised patients. Group B streptococcal (GBS) infection is an increasing problem at the extremes of age.

Streptococcal scarlet fever

Group A (or occasionally groups C and G) streptococci causing pharyngitis, tonsillitis or other infection may lead to scarlet fever, if the infecting strain produces a

Fig. 13.18 Clinical features of scarlet fever. **A** Characteristic rash with blanching on pressure. **B** 'Strawberry tongue'. **C** Pastia's sign: a petechial rash in the cubital fossa.

streptococcal pyrogenic exotoxin. Common in school-age children, scarlet fever can occur in young adults who have contact with young children. A diffuse erythematous rash occurs, which blanches on pressure (Fig. 13.18A), classically with circumoral pallor. The tongue, initially coated, becomes red and swollen ('strawberry tongue' – Fig. 13.18B). The disease lasts about 7 days, the rash disappearing in 7–10 days followed by a fine desquamation. Residual petechial lesions in the antecubital fossa may be seen ('Pastia's sign' – Fig. 13.18C).

Treatment involves active therapy for the underlying infection (benzylpenicillin or orally available penicillin) plus symptomatic measures.

Streptococcal toxic shock syndrome

This is associated with severe group A (or occasionally group C or G) streptococcal skin infections producing one of a variety of toxins such as pyogenic exotoxin A. Like staphylococcal toxic shock syndrome toxin (see above), these act as superantigens, stimulating T-helper cells and a dramatic cytokine response. Initially, an influenza-like illness occurs with, in 50% of cases, signs of localised infection, most often involving the skin and soft tissues. A faint erythematous rash, mainly on the chest, rapidly progresses to circulatory shock. Without aggressive management, multi-organ failure will develop.

Fluid resuscitation must be undertaken, with parenteral antistreptococcal antibiotic therapy, usually with benzylpenicillin and a protein inhibitor such as clindamycin to inhibit toxin production. Intravenous immunoglobulin is usually administered in addition. If necrotising fasciitis is present, it should be treated as described on page 300 with urgent débridement.

Treponematoses

Syphilis

This disease is described on page 417.

Endemic treponematoses

Yaws

Yaws is a granulomatous disease, mainly involving the skin and bones, which is caused by *Treponema pertenue*, morphologically and serologically indistinguishable from the causative organisms of syphilis and pinta. It is important to establish the geographical origin and sexual history of patients to exclude a false-positive syphilis serology due to the endemic treponemal infections. WHO campaigns between 1950 and 1960 treated over 60 million people and eradicated yaws from many areas, but the disease has persisted patchily throughout the tropics; there was resurgence in the 1980s and 1990s in West and Central Africa and the South Pacific.

Organisms are transmitted by bodily contact from a patient with infectious yaws through minor abrasions of the skin of another patient, usually a child. After an incubation period of 3–4 weeks, a proliferative granuloma containing numerous treponemes develops at the site of inoculation. This primary lesion is followed by secondary eruptions. In addition, there may be hypertrophic periosteal lesions of many bones, with underlying cortical rarefaction. Lesions of late yaws are characterised by destructive changes which closely resemble the osteitis and gummas of tertiary syphilis and which heal with much scarring and deformity. Investigations and management are outlined in Box 13.41.

13.41 Diagnosis and treatment of yaws, pinta and bejel

Diagnosis of early stages

- Detection of spirochaetes in exudate of lesions by dark ground microscopy

Diagnosis of latent and early stages

- Positive serological tests, as for syphilis (Box 15.7, p. 419)

Treatment of all stages

- Single intramuscular injection of 1.2 g long-acting (e.g. benzathine) benzylpenicillin

The disease disappears with improved housing and cleanliness. In few fields of medicine have chemotherapy and improved hygiene achieved such dramatic success as in the control of yaws.

Pinta and bejel

These two treponemal infections occur in poor rural populations with low standards of domestic hygiene, but are found in separate parts of the world. They have features in common, notably that they are transmitted by contact, usually within the family and not sexually, and in the case of bejel, through common eating and drinking utensils. Their diagnosis and management are as for yaws (see Box 13.41).

- *Pinta*. Pinta is probably the oldest of the human treponemal infections. It is found only in South and Central America, where its incidence is declining. The infection is confined to the skin. The early lesions are scaly papules or dyschromic patches on the skin. The late lesions are often depigmented and disfiguring.
- *Bejel*. Bejel is the Middle Eastern name for non-venereal syphilis, which has a patchy distribution across sub-Saharan Africa, the Middle East, Central Asia and Australia. It has been eradicated from Eastern Europe. Transmission is most commonly from the mouth of the mother or child and the primary mucosal lesion is seldom seen. The early and late lesions resemble those of secondary and tertiary syphilis (pp. 417–418) but cardiovascular and neurological disease are rare.

Tropical ulcer

Tropical ulcer is due to a synergistic bacterial infection caused by a fusobacterium (*F. ulcerans*, an anaerobe) and *Treponema vincentii*. It is common in hot humid regions. The ulcer is most common on the lower legs and develops as a papule that rapidly breaks down to a sharply defined, painful ulcer. The base of the ulcer has a foul slough. Penicillin and metronidazole are useful in the early stages but rest, elevation and dressings are the mainstays of treatment.

Buruli ulcer

This ulcer is caused by *Mycobacterium ulcerans* and occurs widely in tropical rainforests. In 1999 a survey in Ghana found 6500 cases; there are an estimated 10 000 cases in West Africa as a whole.

The initial lesion is a small subcutaneous nodule on the arm or leg. This breaks down to form a shallow, necrotic ulcer with deeply undermined edges which

extends rapidly. Healing may occur after 6 months, but granuloma formation and the accompanying fibrosis cause contractures and deformity. Clumps of acid-fast bacilli can be detected in the ulcer floor.

A combination of rifampicin and streptomycin can cure the infection. Infected tissue should be removed surgically. Health campaigns in Ghana have successfully focused on early removal of the small, pre-ulcerative nodules.

Systemic bacterial infections

Brucellosis

Brucellosis is an enzootic infection (i.e. endemic in animals). Although six species of *Brucella* Gram-negative bacilli are known, only four are important to humans: *B. melitensis* (goats, sheep and camels in Europe, especially the Mediterranean basin, the Middle East, Africa, India, Central Asia and South America), *B. abortus* (cattle, mainly in Africa, Asia and South America), *B. suis* (pigs in South Asia) and *B. canis* (dogs). *B. melitensis* causes the most severe disease; *B. suis* is often associated with abscess formation.

Infected animals may excrete *Brucella* spp. in their milk for prolonged periods and human infection is acquired by ingesting contaminated dairy products, uncooked meat or offal. Animal urine, faeces, vaginal discharge and uterine products may act as sources of infection through abraded skin or via splashes and aerosols to the respiratory tract and conjunctiva.

Clinical features

Brucella spp. are intracellular organisms that survive for long periods within the reticulo-endothelial system. This explains many of the clinical features, including the chronicity of disease and tendency to relapse even after antimicrobial therapy.

Acute illness is characterised by a high swinging temperature, rigors, lethargy, headache, joint and muscle pains, and scrotal pain. Occasionally, there is delirium, abdominal pain and constipation. Physical signs are non-specific, e.g. enlarged lymph nodes. Enlargement of the spleen may lead to hypersplenism and thrombocytopenia.

Localised infection (Box 13.42), which occurs in about 30% of patients, is more likely if diagnosis and treatment are delayed.

Diagnosis

Definitive diagnosis of brucellosis depends on the isolation of the organism. Blood cultures are positive in 75–80% of infections caused by *B. melitensis* and 50% of those caused by *B. abortus*. Bone marrow culture should not be used routinely but may increase the diagnostic yield, particularly if antibiotics have been given before specimens are taken. CSF culture in neurobrucellosis is positive in about 30% of cases. The laboratory should be alerted to a suspected diagnosis of brucellosis, as the organism has a propensity for infecting laboratory workers and must be cultured at an enhanced containment level.

Serum tests are also used to detect brucellosis antibodies. In endemic areas a single high titre of $>1/320$ or a fourfold rise in titre is needed to support a diagnosis

13.42 Focal manifestations of brucellosis

Musculoskeletal

- Suppurative arthritis; synovitis, bursitis
- Osteomyelitis
- Spinal spondylitis or sacro-iliitis
- Paravertebral or psoas abscess

Central nervous system

- Meningitis
- Intracranial or subarachnoid haemorrhage
- Stroke
- Myelopathy
- Radiculopathy
- Cranial nerve palsies

Ocular

- Uveitis
- Retinal thrombophlebitis

Cardiac

- Myocarditis
- Endocarditis

Respiratory

- Pneumonitis or abscesses
- Hilar adenopathy

Abdominal

- Splenic abscesses or calcification
- Hepatitis

Genitourinary

- Epididymo-orchitis

Haematological

- Pancytopenia

of acute infection. The test usually takes several weeks to become positive but should eventually detect 95% of acute infections.

Management

Aminoglycosides show synergistic activity with tetracyclines against brucellae; standard therapy in acute infection consists of doxycycline 100mg 12-hourly for 6 weeks, with streptomycin 1g i.m. daily for the first 2 weeks. The relapse rate with this treatment is about 5%. An alternative oral regimen consists of doxycycline 100mg 12-hourly plus rifampicin 900mg (15mg/kg) daily for 6 weeks, but failure and relapse rates are higher, particularly with spondylitis. Rifampicin may antagonise doxycycline activity by reducing serum levels through enzyme induction. Rifampicin and cotrimoxazole are potential agents to use in pregnancy. Endocarditis is often treated with three active drugs, usually doxycycline, rifampicin and streptomycin, but surgery is often required.

Chronic illness or neurobrucellosis should be treated for a minimum of 3 months and many authorities would extend this to 6 months, depending upon the response.

Borrelia infections

Borrelia are flagellated spirochaetal bacteria which infect humans after bites from ticks or lice. They cause a variety of human infections world-wide (Box 13.43).

Lyme disease

Lyme disease (named after the town of Old Lyme in Connecticut, USA) is caused by *B. burgdorferi*, which

13.43 Clinical diseases caused by *Borrelia* spp.

Species	Vector	Geographic distribution
Lyme disease		
<i>B. burgdorferi</i> <i>sensu stricto</i>	Tick: <i>Ixodes</i> <i>scapularis</i>	Northern and eastern USA

	<i>I. persulcatus</i>	Asia
Louse-borne relapsing fever		
<i>B. recurrentis</i>	Human louse: <i>Pediculus humanus</i> <i>corporis</i>	World-wide
Tick-borne relapsing fever		
<i>B. hermsii</i>	Tick: <i>Ornithodoros</i> <i>hermsii</i>	Western North America
<i>B. turicatae</i>	<i>O. turicatae</i>	Southwestern North America and northern Mexico
<i>B. venezuelensis</i>	<i>O. rudis</i>	Central America and northern South America
<i>B. hispanica</i>	<i>O. erraticus</i>	Iberian peninsula and northwestern Africa
<i>B. crocidurae</i>	<i>O. erraticus</i>	North Africa and Mediterranean region
<i>B. duttonii</i>	<i>O. moubata</i>	Central, eastern and southern Africa
<i>B. persica</i>	<i>O. tholozani</i>	Western China, India, central Asia, Middle East
<i>B. latyschewii</i>	<i>O. tartakovskyi</i>	Tajikistan, Uzbekistan

occurs in the USA, Europe, Russia, China, Japan and Australia. In Europe two additional genospecies are also encountered, *B. afzelii* and *B. garinii*. The reservoir of infection is ixodid (hard) ticks that feed on a variety of large mammals, particularly deer. Birds may spread ticks over a wide area. The organism is transmitted to humans via the bite of infected ticks; larval, nymphal and adult forms are all capable of spreading infection.

Ehrlichiosis is a common co-infection with Lyme disease (*Anaplasma phagocytophila*, human granulocytic anaplasmosis (HGA); *Ehrlichia chaffeensis*, human monocytic ehrlichiosis (HME)).

Clinical features

There are three stages of disease. Progression may be arrested at any stage.

- **Early localised disease:** The characteristic feature is a skin reaction around the site of the tick bite, known as erythema migrans (Fig. 13.19). Initially, a red 'bull's eye' macule or papule appears 2–30 days after the bite. It then enlarges peripherally with central clearing, and may persist for months. Atypical forms are fairly common. The lesion is not pathognomonic of Lyme disease since similar lesions can occur after tick bites in areas where Lyme disease does not occur. Other acute manifestations such as fever, headache and regional

Fig. 13.19 Rash of erythema migrans in Lyme disease with metastatic secondary lesions.

lymphadenopathy may develop with or without the rash.

- **Early disseminated disease:** Dissemination occurs via the blood stream and lymphatics. There may be a systemic reaction with malaise, arthralgia, and occasionally metastatic areas of erythema migrans (see Fig. 13.19). Neurological involvement may follow weeks or months after infection. Common features include lymphocytic meningitis, cranial nerve palsies (especially unilateral or bilateral facial nerve palsy) and peripheral neuropathy. Radiculopathy, often painful, may present a year or more after initial infection. Carditis, sometimes accompanied by atrioventricular conduction defects, is not uncommon in the USA but appears to be rare in Europe.
- **Late disease:** Late manifestations include arthritis, polyneuritis and encephalopathy. Prolonged arthritis, particularly affecting large joints, and brain parenchymal involvement causing neuropsychiatric abnormalities may occur, but are rare in the UK. Acrodermatitis chronica atrophicans is an uncommon late complication seen more frequently in Europe than North America. Doughy, patchy discoloration occurs on the peripheries, eventually leading to shiny atrophic skin. The lesions are easily mistaken for those of peripheral vascular disease. In patients from an endemic area or with risk factors, who have facial nerve palsy, Lyme disease should be considered.

Diagnosis

The diagnosis of early Lyme borreliosis is often clinical. Culture from biopsy material is not generally available, has a low yield, and may take longer than 6 weeks. Antibody detection is frequently negative early in the course of the disease, but sensitivity increases to 90–100% in disseminated or late disease. Immunofluorescence or ELISA can give false positive reactions in a number of conditions, including other spirochaetal infections, infectious mononucleosis, rheumatoid arthritis and systemic lupus erythematosus (SLE). Immunoblot (Western blot) techniques are more specific and, although technically demanding, should be used to confirm the diagnosis. Microorganism DNA detection by PCR has been applied to blood, urine, CSF, and biopsies of skin and synovium.

Management

Recent evidence suggests that asymptomatic patients with positive antibody tests should not be treated. However, erythema migrans always requires therapy because organisms may persist and cause progressive disease, even if the skin lesions resolve. Standard therapy consists of a 14-day course of doxycycline (200 mg daily) or amoxicillin (500 mg 8-hourly). Some 15% of patients with early disease will develop a mild Jarisch-Herxheimer reaction (JHR) during the first 24 hours of therapy (p. 419). In pregnant women and small children, or in those allergic to amoxicillin and doxycycline, 14-day treatment with cefuroxime axetil (500 mg 12-hourly) or erythromycin (250 mg 6-hourly) may be used.

Disseminated disease and arthritis require therapy for a minimum of 28 days. Arthritis may respond poorly, and prolonged or repeated courses may be necessary. Neuroborreliosis is treated with parenteral β -lactam antibiotics for 3–4 weeks; the cephalosporins may be superior to penicillin in this situation.

Prevention

Protective clothing and insect repellents should be used in tick-infested areas. Since the risk of borreliac transmission is lower in the first few hours of a blood feed, prompt removal of ticks is advisable. Unfortunately, larval and nymphal ticks are tiny and may not be noticed. Where risk of transmission is high, a single 200 mg dose of doxycycline, given within 72 hours of exposure, has been shown to prevent erythema migrans. A recombinant vaccine, OspA, in adjuvant was developed but withdrawn due to side-effects.

Louse-borne relapsing fever

The human body louse, *Pediculus humanus*, causes itching. Borreliae (*B. recurrentis*) are liberated from the infected lice when they are crushed during scratching, which also inoculates the borreliae into the skin. The disease occurs world-wide, with epidemic relapsing fever most often seen in Central and East Africa, and in South America.

The borreliae multiply in the blood, where they are abundant in the febrile phases, and invade most tissues, especially the liver, spleen and meninges. Hepatitis and thrombocytopenia are common.

Clinical features

Onset is sudden with fever. The temperature rises to 39.5–40.5°C, accompanied by a tachycardia, headache, generalised aching, injected conjunctivae (Fig. 13.20)

Fig. 13.20 Louse-borne relapsing fever. Injected conjunctivae.

and, frequently, a petechial rash, epistaxis and herpes labialis. As the disease progresses, the liver and spleen frequently become tender and palpable, and jaundice is common. There may be severe serosal and intestinal haemorrhage, mental confusion and meningism. The fever ends in crisis between the 4th and 10th days, often associated with profuse sweating, hypotension, and circulatory and cardiac failure. There may be no further fever but, in a proportion of patients, after an afebrile period of about 7 days, there are one or more relapses, which are usually milder and less prolonged. In the absence of specific treatment, the mortality rate is up to 40%, especially among the elderly and malnourished.

Investigations and management

The organisms are demonstrated in the blood during fever either by dark ground microscopy of a wet film or by staining thick and thin films.

The problems of treatment are to eradicate the organism, to minimise the severe Jarisch-Herxheimer reaction which inevitably follows successful chemotherapy, and to prevent relapses. The safest treatment is procaine penicillin 300 mg i.m., followed the next day by 0.5 g tetracycline. Tetracycline alone is effective and prevents relapse, but may give rise to a worse reaction. Doxycycline 200 mg once by mouth in place of tetracycline has the advantage of also being curative for typhus, which often accompanies epidemics of relapsing fever. JHR is best managed in a high-dependency unit with expert nursing and medical care.

The patient, clothing and all contacts must be freed from lice as in epidemic typhus.

Tick-borne relapsing fever

Soft ticks (*Ornithodoros* spp.) transmit *B. duttoni* (and several other borrelia species) through saliva while feeding on their host. Those sleeping in mud houses are at risk, as the tick hides in crevices during the day and feeds on humans during the night. Rodents are the reservoir in all parts of the world except East Africa, where humans are the reservoir. Clinical manifestations are similar to the louse-borne disease but spirochaetes are detected in fewer patients on dark field microscopy. A 7-day course (due to a higher relapse rate than louse-borne relapsing fever) of treatment with either tetracycline (500 mg 6-hourly) or erythromycin (500 mg 6-hourly) is needed.

Leptospirosis

Microbiology and epidemiology

Leptospirosis is one of the most common zoonotic diseases, favoured by a tropical climate and flooding during the monsoon but occurring world-wide. Leptospirae are tightly coiled, thread-like organisms about 5–7 μ m in length which are actively motile; each end is bent into a hook. *Leptospira interrogans* is pathogenic for humans. The genus can be separated into more than 200 serovars (subtypes) belonging to 23 serogroups.

Leptospirosis appears to be ubiquitous in wildlife and in many domestic animals. The organisms persist indefinitely in the convoluted tubules of the kidney and are shed into the urine in massive numbers, but infection is asymptomatic in the host. The most frequent hosts are rodents, especially the common rat (*Rattus norvegicus*). Particular leptospiral serogroups are associated with characteristic animal hosts; *L. ictero-haemorrhagiae* is the

classical parasite of rats, *L. canicola* of dogs, *L. hebdomadis* of cattle, and *L. pomona* of pigs. There is nevertheless considerable overlap in host-serogroup associations.

Leptospire can enter their human hosts through intact skin or mucous membranes, but entry is facilitated by cuts and abrasions. Prolonged immersion in contaminated water will also favour invasion, as the spirochaete can survive in water for months. Leptospirosis is common in the tropics and also in freshwater sports enthusiasts.

Clinical features

After a relatively brief bacteraemia, invading organisms are distributed throughout the body, mainly in kidneys, liver, meninges and brain. The incubation period averages 1–2 weeks. Four main clinical syndromes can be discerned.

Bacteraemic leptospirosis

Bacteraemia with any serogroup can produce a non-specific illness with high fever, weakness, muscle pain and tenderness (especially of the calf and back), intense headache and photophobia, and sometimes diarrhoea and vomiting. Conjunctival congestion is the only notable physical sign. The illness comes to an end after about 1 week, or else merges into one of the other forms of infection.

Aseptic meningitis

Classically associated with *L. canicola* infection, this illness is very difficult to distinguish from viral meningitis. The conjunctivae may be congested but there are no other differentiating signs. Laboratory clues include a neutrophil leucocytosis, abnormal LFTs, and the occasional presence of albumin and casts in the urine.

Icteric leptospirosis (Weil's disease)

Less than 10% of symptomatic infections result in severe icteric illness. Weil's disease is a dramatic life-threatening event, characterised by fever, haemorrhages, jaundice and renal impairment. Conjunctival hyperaemia is a frequent feature. The patient may have a transient macular erythematous rash, but the characteristic skin changes are purpura and large areas of bruising. In severe cases there may be epistaxis, haematemesis and melaena, or bleeding into the pleural, pericardial or subarachnoid spaces. Thrombocytopenia, probably related to activation of endothelial cells with platelet adhesion and aggregation, is present in 50% of cases. Jaundice is deep and the liver is enlarged, but there is usually little evidence of hepatic failure or encephalopathy. Renal failure, primarily caused by impaired renal perfusion and acute tubular necrosis, manifests as oliguria or anuria, with the presence of albumin, blood and casts in the urine.

Weil's disease may also be associated with myocarditis, encephalitis and aseptic meningitis. Uveitis and iritis may appear months after apparent clinical recovery.

Pulmonary syndrome

This syndrome has long been recognised in the Far East, and has been described during an outbreak of leptospirosis in Nicaragua. It is characterised by haemoptysis, patchy lung infiltrates on chest X-ray, and respiratory failure. Total bilateral lung consolidation and ARDS (p. 187) with multi-organ dysfunction may develop, with a high mortality (> 50%).

Diagnosis

A polymorphonuclear leucocytosis is accompanied in severe infection by thrombocytopenia and elevated blood levels of creatine kinase. In jaundiced patients there is mild hepatitis and the prothrombin time may be a little prolonged. The CSF in leptospiral meningitis shows a variable cellular response, a moderately elevated protein level and normal glucose content.

In the tropics, dengue, malaria, typhoid fever, scrub typhus and hantavirus infection are important differential diagnoses.

Definitive diagnosis of leptospirosis depends upon isolation of the organism, serological tests or the detection of specific DNA.

- Blood cultures are most likely to be positive if taken before the 10th day of illness. Special media are required and cultures may have to be incubated for several weeks.
- Leptospire appear in the urine during the 2nd week of illness, and in untreated patients may be recovered on culture for several months.
- Serological tests are diagnostic if seroconversion or a fourfold increase in titre is demonstrated. The microscopic agglutination test (MAT) is the test of choice and can become positive by the end of the first week. IgM ELISA and immunofluorescent techniques are, however, easier to perform, while rapid immunochromatographic tests are specific but of only moderate sensitivity in the 1st week of illness.
- Detection of leptospiral DNA by PCR is possible in blood in early symptomatic disease, and in urine from the 8th day of illness and for many months thereafter.

Management and prevention

The general care of the patient is critically important. Blood transfusion for haemorrhage and careful attention to renal failure, the usual cause of death, are especially important. Renal failure is potentially reversible with adequate support such as dialysis. The optimal antimicrobial regimen has not been established. Most infections are self-limiting. Therapy with either oral doxycycline (100 mg 12-hourly for 1 week) or intravenous penicillin (900 mg 6-hourly for 1 week) is effective but may not prevent the development of renal failure. Parenteral ceftriaxone (1 g daily) is as effective as penicillin. A Jarisch-Herxheimer reaction may occur during treatment but is usually mild. Uveitis is treated with a combination of systemic antibiotics and local corticosteroids.

Trials in military personnel have shown that infection with *L. interrogans* can be prevented by taking prophylactic doxycycline 200 mg weekly.

Plague

Plague is caused by *Yersinia pestis*, a small Gram-negative bacillus that is spread between rodents by their fleas. If domestic rats become infected, infected fleas may bite humans. Hunters and trappers can contract plague from handling rodents. In the late stages of human plague, *Y. pestis* may be expectorated and spread between humans by droplets, causing 'pneumonic plague'.

Epidemics of plague, such as the 'Black Death', have occurred since ancient times. It is often said that the first sign of plague is the appearance of dead rats. Plague foci are widely distributed throughout the world, including

the USA; human cases are reported from about ten countries per year (Fig. 13.21).

Y. pestis is a potential bioweapon because of its capacity for mass production and aerosol transmission, and the high fatality rate associated with pneumonic plague.

Clinical features

Organisms inoculated through the skin are taken rapidly to the draining lymph nodes, where they elicit a severe inflammatory response that may be haemorrhagic. If the infection is not contained, septicaemia ensues and necrotic, purulent or haemorrhagic lesions develop in many organs. Oliguria and shock follow, and disseminated intravascular coagulation may result in widespread haemorrhage. Inhalation of *Y. pestis* causes alveolitis. The incubation period is 3–6 days, but shorter in pneumonic plague.

Bubonic plague

In this, the most common form of the disease, onset is usually sudden, with a rigor, high fever, dry skin and severe headache. Soon, aching and swelling at the site of the affected lymph nodes begin. The groin is the most common site of this 'bubo', made up of the swollen lymph nodes and surrounding tissue. Some infections are relatively mild but in the majority of patients toxæmia quickly increases, with a rapid pulse, hypotension and mental confusion. The spleen is usually palpable.

Septicaemic plague

Those not exhibiting a bubo usually deteriorate rapidly and have a high mortality. The elderly are more prone to this form of illness. The patient is toxic and may have gastrointestinal symptoms such as nausea, vomiting, abdominal pain and diarrhoea. DIC may occur, manifested by bleeding from various orifices or puncture sites, along with ecchymoses. Hypotension, shock, renal failure and ARDS may lead to further deterioration. Meningitis, pneumonia and expectoration of blood-stained sputum containing *Y. pestis* may complicate septicaemic, or occasionally bubonic, plague.

Pneumonic plague

Following primary infection in the lung, the onset of disease is very sudden, with cough and dyspnoea. The

patient soon expectorates copious blood-stained, frothy, highly infective sputum, becomes cyanosed and dies. Chest radiology reveals bilateral infiltrates which may be nodular and progress to an ARDS-like picture.

Investigations

The organism may be cultured from blood, sputum and bubo aspirates. For rapid diagnosis Gram, Giemsa and Wayson's stains (the latter containing methylene blue) are applied to smears from these sites. *Y. pestis* is seen as bipolar staining coccobacilli, sometimes referred to as having a 'safety pin' appearance. Smears are also subjected to antigen detection by immunofluorescence, using *Y. pestis* F1 antigen-specific antibodies. The diagnosis may be confirmed by seroconversion or a single high titre (> 128) of anti-F1 antibodies in serum. DNA detection by PCR is under evaluation.

Plague is a notifiable disease under international health regulations (Box 6.13, p. 147).

Management

If the diagnosis is suspected on clinical and epidemiological grounds, treatment must be started as soon as, or even before, samples have been collected for laboratory diagnosis. Streptomycin (1 g 12-hourly) or gentamicin (1 mg/kg 8-hourly) is the drug of choice. Tetracycline (500 mg 6-hourly) and chloramphenicol (12.5 mg/kg 6-hourly) are alternatives. Fluoroquinolones (ciprofloxacin and levofloxacin) may be as effective, but there is less clinical experience. Treatment may also be needed for acute circulatory failure, DIC and hypoxia.

Prevention and infection control

Rats and fleas should be controlled. In endemic areas, people should avoid handling and skinning wild animals. The patient should be isolated for the first 48 hours or until clinical improvement begins. Attendants must wear gowns, masks and gloves. Exposed symptomatic or asymptomatic people who have been in close contact with a patient with pneumonic plague should receive post-exposure antibiotic prophylaxis (doxycycline 100 mg or ciprofloxacin 500 mg 12-hourly) for 7 days.

A formalin-killed vaccine is available for those at occupational risk but offers little protection against

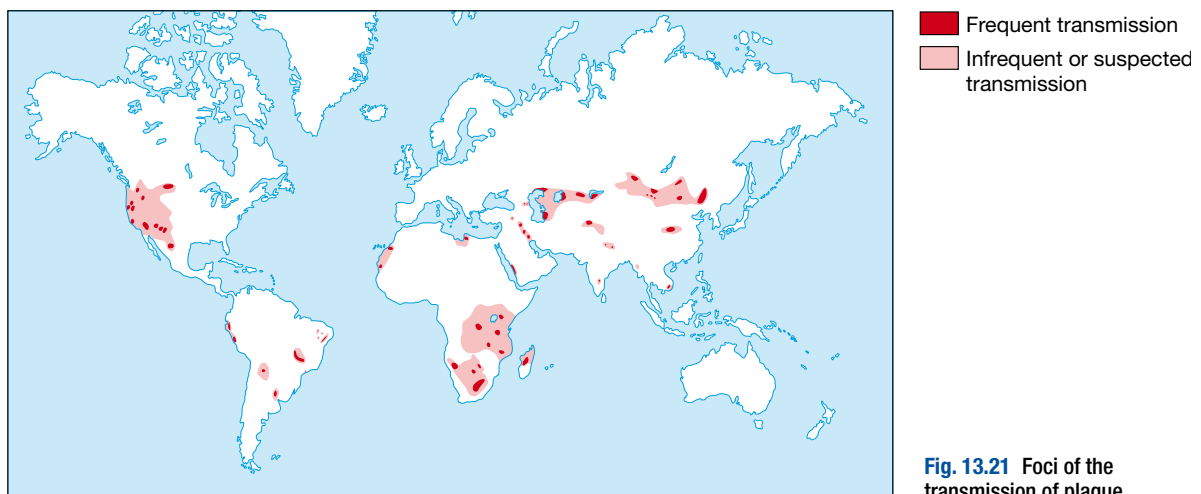

Fig. 13.21 Foci of the transmission of plague.

pneumonic plague. A recombinant subunit vaccine (protein antigens F1 + V) is in development.

Listeriosis

Listeria monocytogenes is an environmental Gram-positive bacillus which can contaminate food. Outbreaks have been associated with raw vegetables, soft cheeses, undercooked chicken, fish, meat and pâtés. The bacterium demonstrates 'cold enrichment', outgrowing other contaminating bacteria during refrigeration. Although food-borne outbreaks of gastroenteritis have been reported in immunocompetent individuals, *Listeria* causes more significant invasive infection especially in pregnancy, the elderly and the immunocompromised.

In pregnancy, in addition to systemic symptoms of fever and myalgia, listeriosis causes chorioamnionitis, fetal deaths, abortions and neonatal infection. In other susceptible individuals, it causes systemic illness due to bacteraemia without focal symptoms. Meningitis, similar to other bacterial meningitis but with normal CSF glucose, is the next most common presentation; CSF usually shows increased neutrophils but occasionally only the mononuclear cells are increased (p. 1205).

Investigations and management

Diagnosis is made by blood and CSF culture. The organism grows readily in culture media.

The most effective regimen consists of a combination of an intravenous aminopenicillin (amoxicillin or ampicillin) plus an aminoglycoside. A sulfamethoxazole/trimethoprim combination can be used in those with penicillin allergy. Cephalosporins are of no use in this infection, as the organism is inherently resistant, an important consideration when empirically treating meningitis.

Proper treatment of foods before eating is the key to preventing listeriosis. Pregnant women are advised to avoid high-risk products, including soft cheeses.

Typhoid and paratyphoid (enteric) fevers

Typhoid and paratyphoid fevers, which are transmitted by the faecal-oral route, are important causes of fever in India, sub-Saharan Africa and Latin America. Elsewhere they are relatively rare. Enteric fevers are caused by infection with *Salmonella typhi* and *S. paratyphi* A and B. After a few days of bacteraemia, the bacilli localise, mainly in the lymphoid tissue of the small intestine, resulting in typical lesions in the Peyer's patches and follicles. These swell at first, then ulcerate and usually heal. After clinical recovery, about 5% of patients become chronic carriers; the bacilli may live in the gallbladder for months or years and pass intermittently in the stool and less commonly in the urine.

Clinical features

Typhoid fever

Clinical features are outlined in Box 13.44. The incubation period is about 10–14 days and the onset may be insidious. The temperature rises in a step-ladder fashion for 4 or 5 days with malaise, increasing headache, drowsiness and aching in the limbs. Constipation may be present, although in children diarrhoea and vomiting may be prominent early in the illness. The pulse is often

13.44 Clinical features of typhoid fever

• Splenomegaly	• Diarrhoea
• Cough	
End of 2nd week	
• Delirium, complications, then coma and death (if untreated)	

slower than would be expected from the height of the temperature, i.e. a relative bradycardia.

At the end of the first week, a rash may appear on the upper abdomen and on the back as sparse, slightly raised, rose-red spots, which fade on pressure. It is usually visible only on white skin. Cough and epistaxis occur. Around the 7th–10th day the spleen becomes palpable. Constipation is then succeeded by diarrhoea and abdominal distension with tenderness. Bronchitis and delirium may develop. If untreated, by the end of the 2nd week the patient may be profoundly ill.

Paratyphoid fever

The course tends to be shorter and milder than that of typhoid fever and the onset is often more abrupt with acute enteritis. The rash may be more abundant and the intestinal complications less frequent.

Complications

These are given in Box 13.45. Haemorrhage from, or a perforation of, the ulcerated Peyer's patches may occur at the end of the 2nd week or during the 3rd week of the illness. A drop in temperature to normal or subnormal levels may be falsely reassuring in patients with intestinal haemorrhage. Additional complications may involve almost any viscus or system because of the septicaemia present during the 1st week. Bone and joint infection is common in children with sickle-cell disease.

Investigations

In the first week the diagnosis may be difficult because in this invasive stage with bacteraemia the symptoms are

those of a generalised infection without localising features. A white blood count may be helpful, as there is typically a leucopenia. Blood culture is the most important diagnostic method. The faeces will contain the organism more frequently during the 2nd and 3rd weeks.

Management

Antibiotic therapy must be guided by in vitro sensitivity testing. Chloramphenicol (500 mg 6-hourly), ampicillin (750 mg 6-hourly) and co-trimoxazole (2 tablets or i.v. equivalent 12-hourly) are losing their effect due to resistance in many areas of the world, especially India and South-east Asia. The fluoroquinolones are the drugs of choice (e.g. ciprofloxacin 500 mg 12-hourly) if the organism is susceptible, but resistance is common, especially in the Indian subcontinent; 40% of cases in the UK are now resistant. Extended-spectrum cephalosporins (ceftriaxone and cefotaxime) are useful alternatives but have a slightly increased treatment failure rate. Azithromycin (500 mg once daily) is an alternative where fluoroquinolone resistance is present but has not been validated in severe disease. Treatment should be continued for 14 days. Pyrexia may persist for up to 5 days after the start of specific therapy. Even with effective chemotherapy there is still a danger of complications, recrudescence of the disease and the development of a carrier state.

Chronic carriers are treated for 4 weeks with ciprofloxacin; cholecystectomy may be necessary.

Prevention

Improved sanitation and living conditions reduce the incidence of typhoid. Travellers to countries where enteric infections are endemic should be inoculated with one of the three available typhoid vaccines (two inactivated injectable and one oral live attenuated).

Tularaemia

Tularaemia is primarily a zoonotic disease of the northern hemisphere. It is caused by a highly infectious Gram-negative bacillus, *Francisella tularensis*. *F. tularensis* is passed transovarially (ensuring transmission from parent to progeny) in ticks, which allows persistence in nature without the absolute requirement for an infected animal reservoir. It is a potential weapon for bioterrorism. Wild rabbits, rodents, and domestic dogs or cats are some of the many potential reservoirs, and ticks, mosquitoes or other biting flies are the vectors.

Infection is introduced either through an arthropod or animal bite or via contact with infected animals, soil or water through skin abrasions. This results in the most common 'ulceroglandular' variety of the disease (70–80%), characterised by skin ulceration with regional lymphadenopathy. There is also a purely 'glandular' form. Alternatively, inhalation of the infected aerosols may result in pulmonary tularaemia, presenting as pneumonia. Rarely, the portal of entry of infection may be the conjunctiva, leading to a nodular, ulcerated conjunctivitis with regional lymphadenopathy (an 'oculoglandular' form).

Investigations and management

Demonstration of a single high titre ($\geq 1:160$) or a four-fold rise in 2–3 weeks in the tularaemia tube agglutination test confirms the diagnosis. Bacterial yield from the

lesions is extremely poor. DNA detection methods to enable rapid diagnosis are in development.

Treatment consists of a 7–10-day course of parenteral aminoglycosides, streptomycin (7.5–10 mg/kg 12-hourly) or gentamicin (1.7 mg/kg 8-hourly). *F. tularensis* is not susceptible to most other antibiotics.

Melioidosis

Melioidosis is caused by *Burkholderia pseudomallei*, a saprophyte found in soil and water (rice paddy fields). Infection is by inoculation or inhalation leading to bacteraemia, which is followed by the formation of abscesses in the lungs, liver and spleen. Patients with diabetes, renal stones, thalassaemia or severe burns are particularly susceptible. The disease is most common in South India, East Asia and northern Australia, and carries a significant mortality. Disease may present many years or decades after the initial exposure.

Clinical features

There is high fever, prostration and sometimes diarrhoea, with signs of pneumonia and enlargement of the liver and spleen. The chest X-ray resembles that of acute caseous tuberculosis. In more chronic forms multiple abscesses occur in subcutaneous tissue and bone, and profound wasting is a major problem.

Investigations and management

Culture of blood, sputum or pus may yield *B. pseudomallei*. Indirect haemagglutination testing can be helpful in travellers; however, most people in endemic areas are seropositive.

In the acute illness prompt treatment, without waiting for confirmation by culture, may be life-saving. Ceftazidime 100 mg/kg (2 g 8-hourly), imipenem 50 mg/kg (1 g 6-hourly) or meropenem (0.5–1 g 8-hourly) is given for 2–3 weeks. This is followed by maintenance therapy of doxycycline 200 mg daily, plus co-trimoxazole (sulfamethoxazole 1600 mg plus trimethoprim 320 mg 12-hourly) for a minimum of 12 weeks. Abscesses should be drained surgically.

Actinomycete infections

Nocardiosis

Nocardiosis is an uncommon Gram-positive bacterial infection caused by aerobic actinomycetes of the genus *Nocardia*. They can cause localised or systemic suppurative disease in immunocompromised humans and animals, especially lung and brain abscesses. On microscopy, nocardia appear as long filamentous branching Gram-positive rods which are also weakly acid-fast. They are easily grown in culture but require prolonged incubation.

Co-trimoxazole is the treatment of choice but third-generation cephalosporins and carbapenems have also been used successfully. For severe infections an aminoglycoside such as amikacin is usually added. Surgical drainage of large abscesses may be necessary. Oral treatment is usually continued for a year if there is CNS involvement.

Actinomyces israelii

Actinomyces israelii can cause deep infection in the head and neck, and also suppurating disease in the pelvis associated with intrauterine contraceptive devices (IUCDs). Treatment is usually with penicillin or doxycycline.

Gastrointestinal bacterial infections

The differential diagnosis and approach to patients presenting with acute gastroenteritis is described on pages 302–303.

Staphylococcal food poisoning

Staph. aureus transmission takes place via the hands of food handlers to foodstuffs such as dairy products, including cheese, and cooked meats. Inappropriate storage of these foods allows growth of the organism and production of one or more heat-stable enterotoxins which cause the symptoms.

Nausea and profuse vomiting develop within 1–6 hours. Diarrhoea may not be marked. The toxins which cause the syndrome act as 'super-antigens', inducing a significant neutrophil leucocytosis which may be clinically misleading. Super-antigens are secreted proteins (exotoxins) that exhibit highly potent lymphocyte-transforming (mitogenic) activity directed towards T lymphocytes. Most cases settle rapidly but severe dehydration can occasionally be life-threatening.

Antiemetics and appropriate fluid replacement are the mainstays of treatment. Suspect food should be cultured for staphylococci and demonstration of toxin production. The public health authorities should be notified if food vending is involved.

Bacillus cereus food poisoning

Ingestion of the pre-formed heat-stable exotoxins of *B. cereus* causes rapid onset of vomiting and some diarrhoea within hours of food consumption, which resolves within 24 hours. Fried rice and freshly made vanilla sauces are frequent sources; the organism grows and produces enterotoxin during storage (Fig. 13.22). If viable bacteria are ingested and toxin formation takes place within the gut lumen, then the incubation period is longer (12–24 hours) and watery diarrhoea and cramps are the predominant symptoms. The disease is self-limiting but can be quite severe.

Rapid and judicious fluid replacement and appropriate notification of the public health authorities are all that is required.

Clostridium perfringens food poisoning

Spores of *C. perfringens* are widespread in the guts of large animals and in soil. If contaminated meat products are incompletely cooked and stored in anaerobic conditions, *C. perfringens* spores germinate and viable organisms multiply to give large numbers. Subsequent reheating of the food causes heat-shock sporulation of the organisms, during which they release an enterotoxin. Symptoms (diarrhoea and cramps) occur some 6–12 hours following ingestion. The illness is usually self-limiting.

Clostridial enterotoxins are potent and most people who ingest them will be symptomatic. 'Point source' outbreaks, in which a number of cases all become symptomatic following ingestion, classically occur after school or canteen lunches where meat stews are served.

Clostridial necrotising enteritis (CNE) or pigbel is an often fatal type of food poisoning caused by a β -toxin of *C. perfringens*, type C. It occurs in association with protein malnutrition or food containing trypsinases

Fig. 13.22 *Bacillus cereus* food poisoning.

such as sweet potatoes. The toxin is normally inactivated by proteolytic enzymes and by normal cooking, but when these protections are impeded, the disease emerges.

Campylobacter jejuni infection

This infection is essentially a zoonosis, although contaminated water may be implicated, as the organism can survive for many weeks in fresh water. The most common sources of the infection are chicken, beef and contaminated milk products. There has been an association with pet puppies. *Campylobacter* infection is now the most common cause of bacterial gastroenteritis in the UK, accounting for some 100 000 cases per annum, most of which are sporadic.

The incubation period is 2–5 days. Colicky abdominal pain, which may be quite severe and mimic surgical pathology, occurs with nausea, vomiting and significant diarrhoea, frequently containing blood. The majority of *Campylobacter* infections affect fit young adults and are self-limiting after 5–7 days. About 10–20% will have

prolonged symptomatology, occasionally meriting treatment with antibiotics such as ciprofloxacin.

Approximately 1% of cases will develop bacteraemia and possible distant foci of infection. *Campylobacter* species have been linked to Guillain-Barré syndrome and post-infectious reactive arthritis (pp. 1229 and 1094).

Salmonella spp. infection

Salmonella serotypes other than *S. typhi* and *S. paratyphi* (see p. 334), of which there are more than 2000, are subdivided into five distinct subgroups which produce gastroenteritis. They are widely distributed throughout the animal kingdom. Two serotypes are most important world-wide: *S. enteritidis* phage type 4 and *S. typhimurium* dt.104. The latter may be resistant to commonly used antibiotics such as ciprofloxacin. Some strains have a clear relationship to particular animal species, e.g. *S. arizonae* and pet reptiles. Transmission is by contaminated water or food, particularly poultry, egg products and related fast foods, direct person-to-person spread or the handling of exotic pets such as salamanders, lizards or turtles. The incidence of *Salmonella* enteritis is falling in the UK due to an aggressive culling policy in broiler chicken stocks, coupled with vaccination.

The incubation period of *Salmonella* gastroenteritis is 12–72 hours and the predominant feature is diarrhoea. Vomiting may be present at the outset and blood is quite frequently noted in the stool. Approximately 5% of cases are bacteraemic. Reactive (post-infective) arthritis occurs in approximately 2%.

Antibiotics are not indicated for uncomplicated *Salmonella* gastroenteritis (Box 13.46). However, evidence of bacteraemia is a clear indication for antibiotic therapy, as salmonellae are notorious for persistent infection and often colonise endothelial surfaces such as an atherosclerotic aorta or a major blood vessel. Mortality, as with other forms of gastroenteritis, is higher in the elderly (see Box 13.13, p. 302).

EBM 13.46 Antibiotics in *Salmonella* gastroenteritis

'In otherwise healthy adults or children with non-severe *Salmonella* diarrhoea, antibiotics have no clinical benefit over placebo, increase side-effects and prolong *Salmonella* detection.'

• Sirinavin S, Garner P (Cochrane Review). Cochrane Library, issue 1, 2001. Oxford: Update Software.

Escherichia coli infection

Many serotypes of *E. coli* are present in the human gut at any given time. Production of disease depends on either colonisation with a new or previously unrecognised strain, or the acquisition by current colonising bacteria of a particular pathogenicity factor for mucosal attachment or toxin production. Travel to unfamiliar areas of the world allows contact with different strains of endemic *E. coli* and the development of travellers' diarrhoea. Enteropathogenic strains may be found in the gut of healthy individuals and, if these people move to a new environment, close contacts may develop symptoms.

At least five different clinico-pathological patterns of diarrhoea are associated with specific strains of *E. coli* with characteristic virulence factors.

Enterotoxigenic *E. coli* (ETEC)

These cause the majority of cases of travellers' diarrhoea in developing countries, although there are other causes (see Box 13.21, p. 307). The organisms produce either a heat-labile or a heat-stable enterotoxin, causing marked secretory diarrhoea and vomiting after 1–2 days' incubation. The illness is usually mild and self-limiting after 3–4 days. Antibiotics, such as ciprofloxacin, have been used to limit the duration of symptoms (see Box 13.22, p. 307) but are of questionable value.

Entero-invasive *E. coli* (EIEC)

This illness is very similar to *Shigella* dysentery (see p. 339) and is caused by invasion and destruction of colonic mucosal cells. No enterotoxin is produced. Acute watery diarrhoea, abdominal cramps and some scanty blood-staining of the stool are common. The symptoms are rarely severe and are usually self-limiting.

Enteropathogenic *E. coli* (EPEC)

These organisms are very important in infant diarrhoea. They are able to attach to the gut mucosa, inducing a specific 'attachment and effacement' lesion, and causing destruction of microvilli and disruption of normal absorptive capacity. The symptoms vary from mild non-bloody diarrhoea to quite severe illness, but without bacteraemia.

Entero-aggregative *E. coli* (EAEC)

These strains adhere to the mucosa but also produce a locally active enterotoxin and demonstrate a particular 'stacked brick' aggregation to tissue culture cells when viewed by microscopy. They have been associated with prolonged diarrhoea in children in South America, South-east Asia and India.

Enterohaemorrhagic *E. coli* (EHEC)

A number of distinct 'O' serotypes of *E. coli* possess both the genes necessary for adherence (see 'EPEC' above) and plasmids encoding for two distinct enterotoxins (verotoxins) which are identical to the toxins produced by *Shigella* ('shiga-toxins 1 and 2'). *E. coli* O157:H7 is perhaps the best known of these verotoxin-producing *E. coli* (VTEC), but others, including types O126 and O11, are also implicated. Although the incidence is considerably lower than *Campylobacter* and *Salmonella* infection, it is increasing in the developing world.

The reservoir of infection is in the gut of herbivores. The organism has an extremely low infecting dose (10–100 organisms). Runoff water from pasture lands where cattle have grazed which is used to irrigate vegetable crops, as well as contaminated milk, meat products (especially hamburgers which have been incompletely cooked), lettuce, radish shoots and apple juice, have all been implicated as sources (Fig. 13.23).

The incubation period is between 1 and 7 days. Initial watery diarrhoea becomes frankly and uniformly blood-stained in 70% of cases and is associated with severe and often constant abdominal pain. There is little systemic upset, vomiting or fever.

Enterotoxins have both a local effect on the bowel and a distant effect on particular body tissues such as glomerular apparatus, heart and brain. The potentially life-threatening haemolytic uraemic syndrome (HUS, p. 498) occurs in 10–15% of sufferers from this infection, arising

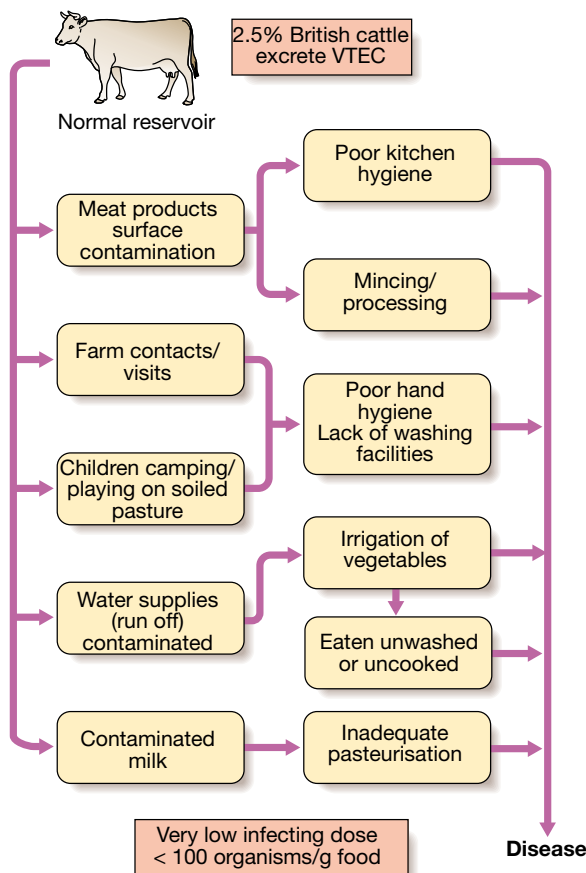

Fig. 13.23 Verocytotoxinogenic *E. coli* (VTEC) infections.

5–7 days after the onset of symptoms. It is most likely at the extremes of age, is heralded by a high peripheral leucocyte count and may be induced, particularly in children, by antibiotic therapy.

HUS is treated by dialysis if necessary and may be averted by plasma exchange. Antibiotics should be avoided since they can stimulate toxin release.

***Clostridium difficile* infection**

C. difficile is the most commonly diagnosed cause of antibiotic-associated diarrhoea (p. 304), and is an occasional constituent of the normal intestinal flora. *C. difficile* is capable of producing two toxins (A and B). *C. difficile* infection (CDI) usually follows antimicrobial therapy. It has been assumed that disease results from abolition of colonisation resistance following broad-spectrum antibiotic therapy. However, antibiotic exposure itself can also stimulate toxin production. The combination of toxin production and the ability to produce environmentally stable spores accounts for the clinical features and transmissibility of CDI. A hypervirulent strain of *C. difficile*, ribotype 027, has emerged, which produces more toxin than other *C. difficile* strains and thus more severe disease.

Clinical features

Disease manifestations range from diarrhoea to life-threatening pseudomembranous colitis. Around 80% of cases occur in people over 65 years of age, many of

whom are frail with comorbid diseases. Symptoms usually begin in the first week of antibiotic therapy but can occur at any time up to 6 weeks after treatment has finished. The onset is often insidious, with lower abdominal pain and diarrhoea which may become profuse and watery. The presentation may resemble acute ulcerative colitis with bloody diarrhoea, fever and even toxic dilatation and perforation. Ileus is also seen in pseudomembranous colitis.

Investigations

C. difficile can be isolated from stool culture in 30% of patients with antibiotic-associated diarrhoea and over 90% of those with pseudomembranous colitis, but also from 5% of healthy adults and up to 20% of elderly patients in residential care. The diagnosis of CDI therefore rests on detection of toxins A or B in the stool using ELISA or tissue culture cytotoxicity assays.

The rectal appearances at sigmoidoscopy may be characteristic, with erythema, white plaques or an adherent pseudomembrane (Fig. 13.24). Appearances may also resemble those of ulcerative colitis. In some cases, the rectum is spared and abnormalities are observed in the proximal colon. Patients who are ill may require abdominal and erect chest X-rays to exclude perforation or toxic dilatation, respectively. CT may be useful when the diagnosis is in doubt.

Management

The precipitating antibiotic should be stopped and the patient should be isolated. Supportive therapy with intravenous fluids and resting of the bowel is often needed. CDI is treated with antibiotics. Traditionally, metronidazole (500 mg orally 8-hourly for 10 days) was used as first-line therapy, with a switch to vancomycin (125 mg orally 6-hourly for 7–10 days) if there was a relapse (15–30% of patients), failure of initial response or evidence of more fulminant infection. However, some authorities now recommend vancomycin as initial therapy, in view of reports of metronidazole resistance and better efficacy of vancomycin against hypervirulent *C. difficile* strains. Fusidic acid, nitazoxanide and rifaximin have been used successfully in some studies, while intravenous immunoglobulin is sometimes given in the most severe cases.

Fig. 13.24 *Clostridium difficile* infection. Colonoscopic view showing numerous adherent 'pseudomembranes' on the mucosa.

***Yersinia enterocolitica* infection**

This organism, commonly found in pork, causes mild to moderate gastroenteritis and can produce significant mesenteric adenitis after an incubation period of 3–7 days. It predominantly causes disease in children but adults may also be affected. The illness resolves slowly, with 10–30% of cases complicated by persistent arthritis or Reiter's syndrome (p. 1094).

Cholera

Cholera, caused by *Vibrio cholerae* serotype 01, is the archetypal toxin-mediated bacterial cause of acute watery diarrhoea. The enterotoxin activates adenylate cyclase in the intestinal epithelium, inducing net secretion of chloride and water. Following its origin in the Ganges valley, devastating epidemics have occurred, often in association with large religious festivals, and pandemics have spread world-wide. The seventh pandemic, due to the El Tor biotype, began in 1961 and spread via the Middle East to become endemic in Africa. In 1990 it reached Peru and spread throughout South and Central America. Since 2005 numbers of cases of cholera have been increasing. There are recurrent outbreaks and epidemics in Africa, often related to flooding. El Tor is more resistant to commonly used antimicrobials than classical *Vibrio*, and causes prolonged carriage in 5% of infections. A new classical toxigenic strain, serotype 0139, established itself in Bangladesh in 1992 and started a new pandemic.

Infection spreads via the stools or vomit of symptomatic patients or of the much larger number of sub-clinical cases. Organisms survive for up to 2 weeks in fresh water and 8 weeks in salt water. Transmission is normally through infected drinking water, shellfish and food contaminated by flies, or on the hands of carriers.

Clinical features

Severe diarrhoea without pain or colic begins suddenly and is followed by vomiting. Following the evacuation of normal gut faecal contents, typical 'rice-water' material is passed, consisting of clear fluid with flecks of mucus. Classical cholera produces enormous loss of fluid and electrolytes, leading to intense dehydration with muscular cramps. Shock and oliguria develop but mental clarity remains. Death from acute circulatory failure may occur rapidly unless fluid and electrolytes are replaced. Improvement is rapid with proper treatment.

The majority of infections, however, cause mild illness with slight diarrhoea. Occasionally, a very intense illness, 'cholera sicca', occurs, with loss of fluid into dilated bowel, killing the patient before typical gastrointestinal symptoms appear. The disease is more dangerous in children.

Diagnosis and management

Clinical diagnosis is easy during an epidemic. Otherwise the diagnosis should be confirmed bacteriologically. Stool dark-field microscopy shows the typical 'shooting star' motility of *V. cholerae*. Rectal swab or stool cultures allow identification. Cholera is notifiable under international health regulations.

Maintenance of circulation by replacement of water and electrolytes is paramount (p. 303). Ringer-Lactate is the best fluid for intravenous replacement. Vomiting usually stops once the patient is rehydrated, and fluid should then be given orally up to 500 mL hourly. Early

intervention with oral rehydration solutions that include resistant starch shortens the duration of diarrhoea and improves prognosis. Total fluid requirements may exceed 50 L over a period of 2–5 days. Accurate records are greatly facilitated by the use of a 'cholera cot', which has a reinforced hole under the patient's buttocks beneath which a graded bucket is placed.

Three days' treatment with tetracycline 250 mg 6-hourly, a single dose of doxycycline 300 mg or ciprofloxacin 1 g in adults reduces the duration of excretion of *V. cholerae* and the total volume of fluid needed for replacement.

Prevention

Strict personal hygiene is vital and drinking water should come from a clean piped supply or be boiled. Flies must be denied access to food. Parenteral vaccination with a killed suspension of *V. cholerae* provides some protection. Oral vaccines containing killed *V. cholerae* and the B subunit of cholera toxin are available but are of limited efficacy.

In epidemics, public education and control of water sources and population movement are vital. Mass single-dose vaccination and treatment with tetracycline are valuable. Disinfection of discharges and soiled clothing, and scrupulous hand-washing by medical attendants reduce the danger of spread.

***Vibrio parahaemolyticus* infection**

This marine organism produces a disease similar to enterotoxigenic *E. coli* (see above). It is acquired from raw seafood and is very common where ingestion of such food is widespread (e.g. Japan). After an incubation period of approximately 20 hours, explosive diarrhoea, abdominal cramps and vomiting occur. Systemic symptoms of headache and fever are frequent but the illness is self-limiting after 4–7 days. Rarely, a severe septicaemic illness arises; in this case *V. parahaemolyticus* can be isolated using specific halophilic culture.

Bacillary dysentery (shigellosis)

Shigellae are Gram-negative rods, closely related to *E. coli*, that invade the colonic mucosa. There are four main groups: *Sh. dysenteriae*, *flexneri*, *boydii* and *sonnei*. In the tropics bacillary dysentery is usually caused by *Sh. flexneri*, whilst in the UK most cases are caused by *Sh. sonnei*. Shigellae are often resistant to multiple antibiotics, especially in tropical countries. The organism only infects humans and its spread is facilitated by its low infecting dose of around 10 organisms.

Spread may occur via contaminated food or flies, but transmission by unwashed hands after defecation is by far the most important factor. Outbreaks occur in mental hospitals, residential schools and other closed institutions, and dysentery is a constant accompaniment of wars and natural catastrophes, which bring crowding and poor sanitation in their wake. *Shigella* infection may spread rapidly amongst men who have sex with men.

Clinical features

Disease severity varies from mild *Sh. sonnei* infections that may escape detection to more severe *Sh. flexneri* infections, while those due to *Sh. dysenteriae* may be fulminating and cause death within 48 hours.

In a moderately severe illness, the patient complains of diarrhoea, colicky abdominal pain and tenesmus. Stools are small, and after a few evacuations contain blood and purulent exudate with little faecal material. Fever, dehydration and weakness occur, with tenderness over the colon. Arthritis or iritis may occasionally complicate bacillary dysentery (Reiter's syndrome, p. 1094), associated with HLA-B27.

Management and prevention

Oral rehydration therapy or, if diarrhoea is severe, intravenous replacement of water and electrolyte loss is necessary. Antibiotic therapy with ciprofloxacin (500 mg 12-hourly for 3 days) is effective in known shigellosis and appropriate in epidemics. The use of antidiarrhoeal medication should be avoided.

The prevention of faecal contamination of food and milk and the isolation of cases may be difficult, except in limited outbreaks. Hand-washing is very important.

Respiratory bacterial infections

Most of these infections are described in Chapter 19.

Diphtheria

Infection with *Corynebacterium diphtheriae* occurs most commonly in the upper respiratory tract and is usually spread by droplet infection from cases or carriers. Infection may also complicate skin lesions, especially in those who misuse alcohol. The organisms remain localised at the site of infection but serious consequences result from the absorption of a soluble exotoxin which damages the heart muscle and the nervous system.

Diphtheria has been eradicated from many parts of the world by mass vaccination using a modified exotoxin but remains important in areas where vaccination has been incomplete, e.g. in Russia and South-east Asia. The disease is notifiable in all countries of Europe and North America and international guidelines have been issued by the WHO for the management of infection.

Clinical features

The average incubation period is 2–4 days. The disease begins insidiously with a sore throat (Box 13.47). Despite modest fever there is usually marked tachycardia. The diagnostic feature is the 'wash-leather' elevated greyish-green membrane on the tonsils. It has a well-defined edge, is firm and adherent, and is surrounded by a zone of inflammation. There may be swelling of the neck ('bull-neck') and tender enlargement of the lymph nodes.

13.47 Clinical features of diphtheria

Acute infection

- Membranous tonsillitis
- or Nasal infection
- or Laryngeal infection
- or Skin/wound/conjunctival infection (rare)

Complications

- Laryngeal obstruction or paralysis
- Myocarditis
- Peripheral neuropathy

In the mildest infections, especially in the presence of a high degree of immunity, a membrane may never appear and the throat is merely slightly inflamed.

With anterior nasal infection there is nasal discharge, frequently blood-stained. In laryngeal diphtheria a husky voice and high-pitched cough signal potential respiratory obstruction requiring urgent tracheostomy. If infection spreads to the uvula, fauces and nasopharynx, the patient is gravely ill.

Death from acute circulatory failure may occur within the first 10 days. Late complications occur as a result of toxin action on the heart or nervous system. About 25% of survivors of the early toxæmia may later develop myocarditis with arrhythmias or cardiac failure. These are usually reversible with no permanent damage other than heart block in survivors.

Neurological involvement occurs in 75% of cases. After tonsillar or pharyngeal diphtheria it usually starts after 10 days with palatal palsy. Paralysis of accommodation often follows, manifest by difficulty in reading small print. Generalised polyneuritis with weakness and paraesthesia may follow in the next 10–14 days. Recovery from such neuritis is always ultimately complete.

Management

A clinical diagnosis of diphtheria must be notified to the public health authorities and the patient sent urgently to a specialist infectious diseases unit. Treatment should begin once appropriate swabs have been taken before waiting for microbiological confirmation.

Diphtheria antitoxin is produced from hyperimmune horse serum. It neutralises circulating toxin, but has no effect on toxin already fixed to tissues, so it must be injected intramuscularly without awaiting the result of a throat swab. However, reactions to this foreign protein include a potentially lethal immediate anaphylactic reaction (p. 89) and a 'serum sickness' with fever, urticaria and joint pains, which occurs 7–12 days after injection. A careful history of previous horse serum injections or allergic reactions should be taken and a small test injection of serum should be given half an hour before the full dose in every patient. Adrenaline (epinephrine) solution must be available to deal with any immediate type of reaction (0.5–1.0 mL of 1/1000 solution i.m.). An antihistamine is also given. In a severely ill patient the risk of anaphylactic shock is outweighed by the mortal danger of diphtheritic toxæmia, and up to 100 000 U of antitoxin are injected intravenously if the test dose has not given rise to symptoms. For disease of moderate severity, 16 000–40 000 U i.m. will suffice, and for mild cases 4000–8000 U.

Penicillin (1200 mg 6-hourly i.v.) or amoxicillin (500 mg 8-hourly) should be administered for 2 weeks to eliminate *C. diphtheriae*. Patients allergic to penicillin can be given erythromycin. Due to poor immunogenicity of primary infection all sufferers should be immunised with diphtheria toxoid following recovery.

Patients must be managed in strict isolation attended by staff with a clearly documented immunisation history until three swabs 24 hours apart are culture-negative.

Prevention

Active immunisation should be given to all children. If diphtheria occurs in a closed community, contacts should be given erythromycin, which is more effective than penicillin in eradicating the organism in carriers.

All contacts should also be immunised or given a booster dose of toxoid. Booster doses are required every 10 years to maintain immunity.

Pneumococcal infection

Strep. pneumoniae (the pneumococcus) is the leading cause of community-acquired pneumonia globally (p. 670) and one of the leading causes of infection-related mortality. Otitis media, meningitis and sinusitis are also frequently due to *Strep. pneumoniae*. Occasional patients present with bacteraemia without obvious focus. Asplenic individuals are at risk of fulminant pneumococcal disease with purpuric rash.

Increasing rates of penicillin resistance have been reported for *Strep. pneumoniae*, and strains with high-level resistance require treatment with glycopeptides rather than with penicillins or cephalosporins. Newer quinolones are also used but rates of resistance are rising.

Vaccination of infants with the protein conjugate pneumococcal vaccine decreases *Strep. pneumoniae* infection in infants and in their relatives. The polysaccharide pneumococcal vaccine is used in individuals predisposed to *Strep. pneumoniae* infection and the elderly, but only modestly reduces pneumococcal bacteraemia and does not prevent pneumonia. All asplenic individuals should receive vaccination against *Strep. pneumoniae*.

Anthrax

Anthrax is an endemic zoonosis in many countries; it causes human disease following inoculation of the spores of *Bacillus anthracis*. *B. anthracis* was the first recognised bacterial pathogen described by Koch and became the model pathogen for 'Koch's postulates' (see Box 6.1, p. 132). It is a Gram-positive organism with a central spore. The spores can survive for years in soil. Infection is commonly acquired from contact with animals, particularly herbivores. The ease of production of *B. anthracis* spores makes this infection a candidate for biological warfare or bioterrorism. *B. anthracis* produces a number of toxins which mediate the clinical features of disease.

Clinical features

These depend on the route of entry of the anthrax spores.

Cutaneous anthrax

This skin lesion is associated with occupational exposure to anthrax spores during processing of hides and bone products, or with bioterrorism. It accounts for the vast majority of clinical cases. Animal infection is a serious problem in Africa, India, Pakistan and the Middle East.

Spores are inoculated into exposed skin. A single lesion develops as an irritable papule on an oedematous haemorrhagic base. This progresses to a depressed black eschar. Despite extensive oedema, pain is infrequent.

Gastrointestinal anthrax

This is associated with the ingestion of meat products that have been contaminated or incompletely cooked. The caecum is the seat of the infection, which produces nausea, vomiting, anorexia and fever, followed in 2–3 days by severe abdominal pain and bloody diarrhoea. Toxaemia and death can develop rapidly thereafter.

Inhalational anthrax

This form of the disease is extremely rare, unless associated with bioterrorism. Without rapid and aggressive therapy at the onset of symptoms, the mortality is 50–90%. Fever, dyspnoea, cough, headache and symptoms of septicaemia develop 3–14 days following exposure. Typically, the chest X-ray shows only widening of the mediastinum and pleural effusions which are haemorrhagic. Meningitis may occur.

Management

B. anthracis can be cultured from skin swabs from lesions. Skin lesions are readily curable with early antibiotic therapy. Treatment is with ciprofloxacin (500 mg 12-hourly) until penicillin susceptibility is confirmed; the regimen can then be changed to benzylpenicillin with doses up to 2.4 g i.v. given 4-hourly or phenoxymethylpenicillin 500–1000 mg 6-hourly administered for 10 days. The addition of an aminoglycoside may improve the outlook in severe disease. In view of concerns about concomitant inhalational exposure, particularly in the era of bioterrorism, a further 2-month course of ciprofloxacin 500 mg 12-hourly or doxycycline 100 mg 12-hourly orally is added. Prophylaxis with ciprofloxacin (500 mg 12-hourly) is recommended for anyone at high risk of exposure to anthrax spores.

Bacterial infections with neurological involvement

Infections affecting the CNS, including bacterial meningitis, botulism and tetanus, are described on pages 1205–1214.

Mycobacterial infections

Tuberculosis is predominantly, although by no means exclusively, a respiratory disease and is described on page 688.

Leprosy

Leprosy (Hansen's disease) is a chronic granulomatous disease affecting skin and nerves, caused by *Mycobacterium leprae*, a slow-growing mycobacterium which cannot be cultured in vitro. The clinical manifestations are determined by the degree of the patient's cell-mediated immunity (CMI, p. 76) towards *M. leprae* (Fig. 13.25). High levels of CMI with elimination of leprosy bacilli produce tuberculoid leprosy, whereas absent CMI results in lepromatous leprosy. The complications of leprosy are due to nerve damage, immunological reactions and bacillary infiltration. Leprosy patients are frequently stigmatised and using the word 'leper' is inappropriate.

Epidemiology and transmission

Some 4 million people have leprosy and around 750 000 new cases are detected annually. About 70% of the world's leprosy patients live in India, with the disease endemic in Brazil, Indonesia, Mozambique, Madagascar, Tanzania and Nepal.

Untreated lepromatous patients discharge bacilli from the nose. Infection occurs through the nose, followed by haematogenous spread to skin and nerve. The

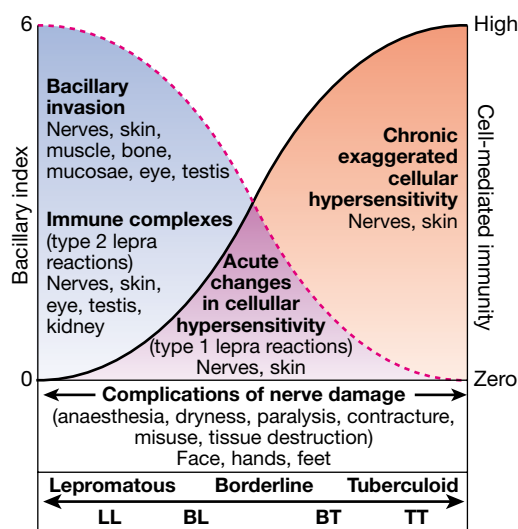

Fig. 13.25 Leprosy: mechanisms of damage and tissue affected.

Mechanisms under the broken line are characteristic of disease near the lepromatous end of the spectrum, and those under the solid line are characteristic of the tuberculoid end. They overlap in the centre where, in addition, instability predisposes to type 1 lepra reactions. At the peak in the centre neither bacillary growth nor cell-mediated immunity has the upper hand. (BL = borderline lepromatous; BT = borderline tuberculoid)

incubation period is 2–5 years for tuberculoid cases and 8–12 years for lepromatous cases. Leprosy incidence peaks at 10–14 years, and is more common in males and in those with close household exposure to leprosy cases.

Pathogenesis

M. leprae has a predilection for infecting Schwann cells and skin macrophages. In tuberculoid leprosy, effective CMI controls bacillary multiplication ('paucibacillary') but organised epithelioid granulomas are formed. In lepromatous leprosy, there is abundant bacillary multiplication ('multibacillary'), e.g. in Schwann cells and perineurium. Between these two extremes is a continuum, varying from patients with moderate CMI (borderline tuberculoid) to patients with little cellular response (borderline lepromatous).

In addition, immunological reactions to the infection occur as the immune response develops and the antigenic stimulus from the bacilli varies, particularly in borderline patients. Delayed hypersensitivity reactions produce type 1 (reversal) reactions, while immune complexes contribute to type 2 (erythema nodosum leprosum) reactions.

HIV/leprosy co-infected patients have typical lepromatous and tuberculoid leprosy skin lesions and typical leprosy histology and granuloma formation. Surprisingly, even with low circulating CD4 counts, tuberculoid leprosy may be observed and there is not an obvious shift to lepromatous leprosy.

Clinical features

Box 13.48 gives the cardinal features of leprosy. Types of leprosy are compared in Box 13.49.

- **Skin.** The most common skin lesions are macules or plaques. Tuberculoid patients have few, hypopigmented lesions. In lepromatous leprosy,

i

13.48 Cardinal features of leprosy

- Skin lesions, typically anaesthetic at tuberculoid end of spectrum
- Thickened peripheral nerves
- Acid-fast bacilli on skin smears or biopsy

13.49 Clinical characteristics of the polar forms of leprosy

Clinical and tissue-specific features	Lepromatous	Tuberculoid
Skin and nerves		
Number and distribution	Widely disseminated	One or a few sites, asymmetrical
Skin lesions		
Definition		
Clarity of margin	Poor	Good
Elevation of margin	Never	Common
Colour		
Dark skin	Slight hypopigmentation	Marked hypopigmentation
Light skin	Slight erythema	Coppery or red
Surface	Smooth, shiny	Dry, scaly
Central healing	None	Common
Sweat and hair growth	Impaired late	Impaired early
Loss of sensation	Late	Early and marked
Nerve enlargement and damage	Late	Early and marked
Bacilli (bacterial index)	Many (5 or 6+)	Absent (0)
Natural history	Progressive	Self-healing
Other tissues	Upper respiratory mucosa, eye, testes, bones, muscle	None
Reactions	Immune complexes (type 2)	Cell-mediated (type 1)

papules, nodules or diffuse infiltration of the skin occur. The earliest lesions are ill defined; gradually, the skin becomes infiltrated and thickened. Facial skin thickening leads to the characteristic leonine facies (Fig. 13.26B).

- **Anaesthesia.** In skin lesions the small dermal sensory and autonomic nerve fibres are damaged, causing local sensory loss and loss of sweating within that area. Anaesthesia may also occur in the distribution of a damaged large peripheral nerve. A 'glove and stocking' sensory neuropathy is also common in lepromatous leprosy.
- **Nerve damage.** Peripheral nerve trunks are affected at 'sites of predilection'. These are the ulnar (elbow), median (wrist), radial (humerus), radial cutaneous (wrist), common peroneal (knee), posterior tibial and sural nerves (ankle), facial nerve (zygomatic arch) and great auricular nerve (posterior triangle

Fig. 13.26 Clinical features of leprosy. **A** Tuberculoid leprosy. Single lesion with a well-defined active edge and anaesthesia within the lesion. **B** Lepromatous leprosy. Widespread nodules and infiltration, with loss of the eyebrows. This man also has early collapse of the nose. **C** Borderline tuberculoid leprosy with severe nerve damage. This boy has several well-defined, hypopigmented, macular, anaesthetic lesions. He has severe nerve damage affecting both ulnar and median nerves bilaterally and has sustained severe burns to his hands. **D** Reversal (type 1) reactions. Erythematous, oedematous lesions.

of the neck). Damage to peripheral nerve trunks produces characteristic signs with regional sensory loss and muscle dysfunction (Fig. 13.26C). All these nerves should be examined for enlargement and tenderness and tested for motor and sensory function. The CNS is not affected.

- **Eye involvement.** Blindness is a devastating complication for a patient with anaesthetic hands and feet. Eyelid closure is impaired when the facial nerve is affected. Damage to the trigeminal nerve causes anaesthesia of the cornea and conjunctiva. The cornea is then susceptible to trauma and ulceration.
- **Other features.** Many organs can be affected. Nasal collapse occurs secondary to bacillary destruction of the bony nasal spine. Diffuse infiltration of the testes causes testicular atrophy and the acute orchitis that occurs with type 2 reactions. This results in azoospermia and hypogonadism.

Leprosy reactions

Leprosy reactions (Box 13.50) are events superimposed on the cardinal features shown in Box 13.48.

- **Type 1 (reversal) reactions:** These occur in 30% of borderline patients (BT, BB or BL) and are delayed hypersensitivity reactions. Skin lesions become erythematous (Fig. 13.26D). Peripheral nerves become tender and painful, with sudden loss of nerve function. These reactions may occur spontaneously, after starting treatment and also after completion of multidrug therapy.
- **Type 2 (erythema nodosum leprosum – ENL) reactions:** These are partly due to immune complex deposition

and occur in BL and LL patients who produce antibodies and have a high antigen load. They manifest with malaise, fever and crops of small pink nodules on the face and limbs. Iritis and episcleritis

13.50 Reactions in leprosy

	Lepra reaction type 1 (reversal)	Lepra reaction type 2 (erythema nodosum leprosum, ENL)
Mechanism	Cell-mediated hypersensitivity	Immune complexes
Clinical features	Painful tender nerves, loss of function Swollen skin lesions New skin lesions	Tender papules and nodules; may ulcerate Painful tender nerves, loss of function Iritis, orchitis, myositis, lymphadenitis Fever, oedema
Management	Prednisolone 40 mg, reducing over 3–6 months ¹	Moderate: prednisolone 40 mg daily Severe: thalidomide ² or prednisolone 40–80 mg daily, reducing over 1–6 months; local if eye involved ³
¹ Indicated for any new impairment of nerve or eye function. ² Contraindicated in fertile women. ³ 1% hydrocortisone drops or ointment and 1% atropine drops.		

are common. Other signs are acute neuritis, lymphadenitis, orchitis, bone pain, dactylitis, arthritis and proteinuria. ENL may continue intermittently for several years.

Borderline cases

In borderline tuberculoid (BT) cases, skin lesions are more numerous than in tuberculoid (TT) cases, and there is more severe nerve damage and a risk of type 1 reactions. In borderline leprosy (BB) cases, skin lesions are numerous and vary in size, shape and distribution; annular lesions are characteristic and nerve damage is variable. In borderline lepromatous (BL) cases, there are widespread small macules in the skin and widespread nerve involvement; both type 1 and type 2 reactions occur.

Pure neural leprosy (i.e. without skin lesions) occurs principally in India and accounts for 10% of patients. There is asymmetrical involvement of peripheral nerve trunks and no visible skin lesions. On nerve biopsy all types of leprosy have been found.

Investigations

The diagnosis is clinical, made by finding a cardinal sign of leprosy and supported by finding acid-fast bacilli in slit-skin smears or typical histology in a skin biopsy. Slit-skin smears are obtained by scraping dermal material on to a glass slide. The smears are then stained for acid-fast bacilli, the number counted per high-power field and a score derived on a logarithmic scale (0–6): the bacterial index (BI). Smears are useful for confirming the diagnosis and monitoring response to treatment. Neither serology nor PCR testing for *M. leprae* DNA is sensitive or specific enough for diagnosis.

Management

The principles of treatment are outlined in Box 13.51. All leprosy patients should be given multidrug treatment (MDT) with an approved first-line regimen (Box 13.52).

Rifampicin is a potent bactericidal for *M. leprae* but should always be given in combination with other anti-leprotics since a single-step mutation can confer resistance. Dapsone is bacteriostatic. It commonly causes mild haemolysis but rarely anaemia. Clofazimine is a red, fat-soluble crystalline dye, weakly bactericidal for *M. leprae*. Skin discoloration (red to purple-black) and ichthyosis are troublesome side-effects, particularly on pale skins. New drugs that are bactericidal for *M. leprae* have been identified, notably the fluoroquinolones pefloxacin and ofloxacin, minocycline and clarithromycin. These agents are now established second-line drugs. Minocycline causes a grey pigmentation of skin lesions.

13.51 Principles of leprosy treatment

- Stop the infection with chemotherapy
- Treat reactions
- Educate the patient about leprosy
- Prevent disability
- Support the patient socially and psychologically

13.52 Modified WHO-recommended multidrug therapy (MDT) regimens in leprosy

Type of leprosy ¹	Monthly supervised treatment	Daily self-administered treatment	Duration of treatment ²
Paucibacillary	Rifampicin 600 mg	Dapsone 100 mg	6 mths
Multibacillary	Rifampicin 600 mg Clofazimine 300 mg	Clofazimine 50 mg Dapsone 100 mg	12 mths
Paucibacillary single-lesion	Ofloxacin 400 mg Rifampicin 600 mg Minocycline 100 mg		Single dose

¹Classification uses the bacillary index (BI) in slit-skin smears or, if BI is not available, the number of skin lesions:

- paucibacillary single-lesion leprosy (one skin lesion)
- paucibacillary (2–5 skin lesions)
- multibacillary (> 5 skin lesions).

²Studies from India have shown that multibacillary patients with an initial BI > 4 need longer treatment, for at least 24 months.

Although single-dose treatment is less effective than the conventional 6-month treatment for paucibacillary leprosy, it is an operationally attractive field regimen and has been recommended for use by the WHO.

Lepra reactions are treated as shown in Box 13.50. Chloroquine can also be used.

Patient education

Educating leprosy patients about their disease is vital. Patients should be reassured that after 3 days of chemotherapy they are not infectious and can lead a normal social life. It should be emphasised that gross deformities are not inevitable.

Patients with anaesthetic hands or feet need to take special care to avoid and treat burns and other minor injuries. Good footwear is important. Physiotherapy may be required to maintain range of movement of affected muscles and neighbouring joints.

Prognosis

Untreated, tuberculoid leprosy has a good prognosis; it may self-heal and peripheral nerve damage is limited. Lepromatous leprosy (LL) is a progressive condition with high morbidity if untreated.

After treatment, the majority of patients, especially those who have no nerve damage at the time of diagnosis, do well, with resolution of skin lesions. Borderline patients are at risk of developing type 1 reactions which may result in devastating nerve damage.

Prevention and control

The previous strategy of centralised leprosy control campaigns has now been superseded by integrated programmes, with primary health-care workers in many countries now responsible for case detection and provision of MDT. It is not yet clear how successful this will be, especially in the time-consuming area of disability prevention.

BCG vaccination has been shown to give good but variable protection against leprosy; adding killed *M. leprae* to BCG does not enhance protection.

Rickettsial and related intracellular bacterial infections

Rickettsial fevers

The rickettsial fevers are the most common tick-borne infections. Patients present acutely with headache, rash and sometimes neurological disturbance. It is important to ask about exposures that would put patients at risk of bites or contact with ticks, lice or fleas. There are two main groups of rickettsial fevers: spotted fevers and typhus (Box 13.53).

Pathogenesis

The rickettsiae are intracellular Gram-negative organisms which parasitise the intestinal canal of arthropods. Infection is usually conveyed to humans through

the skin from the excreta of arthropods, but the saliva of some biting vectors is infected. The organisms multiply in capillary endothelial cells, producing lesions in the skin, CNS, heart, lungs, liver, kidneys and skeletal muscles. Endothelial proliferation, associated with a perivascular reaction, may cause thrombosis and purpura. In epidemic typhus the brain is the target organ; in scrub typhus the cardiovascular system and lungs in particular are attacked. An eschar, a black necrotic crusted sore, is often found in tick- and mite-borne typhus (see Fig. 13.6C, p. 309). This is due to vasculitis following immunological recognition of the inoculated organism. Regional lymph nodes often enlarge.

Spotted fever group

Rocky Mountain spotted fever

Rickettsia rickettsii is transmitted by tick bites. It is widely distributed and increasing in western and south-eastern states of the USA and also in Central and South America. The incubation period is about 7 days. The rash appears on about the 3rd or 4th day of illness, looking at first

13.53 Features of rickettsial infections

Disease	Organism	Reservoir	Vector	Geographical area	Rash	Gangrene	Target organs	Mortality
Spotted fever group								
Rocky Mountain spotted fever	<i>R. rickettsii</i>	Rodents, dogs, ticks	<i>Ixodes</i> tick	North, Central and South America	Morbilloform Haemorrhagic	Often	Bronchi, myocardium, brain, skin	2–12% ²
Boutonneuse fever	<i>R. conorii</i>	Rodents, dogs, ticks	<i>Ixodes</i> tick	Mediterranean, Africa, South-west Asia, India	Maculopapular	—	Skin, meninges	2.5% ³
Siberian tick typhus	<i>R. siberica</i>	Rodents, birds, domestic animals, ticks	Various ticks	Siberia, Mongolia, northern China	Maculopapular	—	Skin, meninges	Rare ³
Australian tick typhus	<i>R. australis</i>	Rodents, ticks	Ticks	Australia	Maculopapular	—	Skin, meninges	Rare ³
Oriental spotted fever	<i>R. japonica</i>	Rodents, dogs, ticks	Ticks	Japan	Maculopapular	—	Skin, meninges	Rare ³
African tick bite fever ¹	<i>R. africae</i>	Cattle, game, ticks	<i>Ixodes</i> tick	South Africa	Can be spotless	—	Skin, meninges	Rare ³
Typhus group								
Scrub typhus	<i>Orientia tsutsugamushi</i>	Rodents	<i>Trombicula</i> mite	SE Asia	Maculopapular	Unusual	Bronchi, myocardium, brain, skin	Rare ³
Epidemic typhus	<i>R. prowazekii</i>	Humans	Louse	World-wide	Morbilloform Haemorrhagic	Often	Brain, skin, bronchi, myocardium	Up to 40%
Endemic typhus	<i>R. typhi</i>	Rats	Flea	World-wide	Slight	—	—	Rare ³

¹Eschar at bite site and local lymphadenopathy

²Highest in adult males.

³Except in infants, older people and the debilitated.

like measles, but in a few hours a typical maculopapular eruption develops. The rash spreads in 24–48 hours from wrists, forearms and ankles to the back, limbs and chest, and then to the abdomen, where it is least pronounced. Larger cutaneous and subcutaneous haemorrhages may appear in severe cases. The liver and spleen become palpable. At the extremes of life the mortality is 2–12%.

Other spotted fevers

R. conorii (boutonneuse fever) and *R. africae* (African tick fever) cause Mediterranean and African tick typhus, which also occurs on the Indian subcontinent. The incubation period is approximately 7 days. Infected ticks may be picked up by walking on grasslands or dogs may bring ticks into the house. Careful examination might reveal a diagnostic eschar, and the maculopapular rash on the trunk, limbs, palms and soles. There may be delirium and meningeal signs in severe infections but recovery is usual. *R. africae* can be associated with multiple eschars. Some cases, particularly those with *R. africae*, present without rash ('spotless spotted fever'). Other spotted fevers are shown in Box 13.53.

Typhus group

Scrub typhus fever

Scrub typhus is caused by *Orientia tsutsugamushi* (formerly *Rickettsia tsutsugamushi*), transmitted by mites. It occurs in the Far East, Myanmar, Pakistan, Bangladesh, India, Indonesia, the South Pacific islands and Queensland, particularly where patches of forest cleared for plantations have attracted rats and mites.

In many patients one eschar or more develops, surrounded by an area of cellulitis (see Fig. 13.6C, p. 309) and enlargement of regional lymph nodes. The incubation period is about 9 days.

Mild or subclinical cases are common. The onset of symptoms is usually sudden, with headache (often retro-orbital), fever, malaise, weakness and cough. In severe illness the general symptoms increase, with apathy and prostration. An erythematous maculopapular rash often appears on about the 5th–7th day and spreads to the trunk, face and limbs, including the palms and soles, with generalised painless lymphadenopathy. The rash fades by the 14th day. The temperature rises rapidly and continues as a remittent fever (i.e. the difference between maximum and minimum temperature exceeds 1°C) remaining above normal with sweating until it falls on the 12th–18th day. In severe infection the patient is prostrate with cough, pneumonia, confusion and deafness. Cardiac failure, renal failure and haemorrhage may develop. Convalescence is often slow and tachycardia may persist for some weeks.

Epidemic (louse-borne) typhus

Epidemic typhus is caused by *R. prowazekii* and is transmitted by infected faeces of the human body louse, usually through scratching the skin. Patients suffering from epidemic typhus infect the lice, which leave when the patient is febrile. In conditions of overcrowding the disease spreads rapidly. It is prevalent in parts of Africa, especially Ethiopia and Rwanda, and in the South American Andes and Afghanistan. Large epidemics have occurred in Europe, usually as a sequel to war. The incubation period is usually 12–14 days.

There may be a few days of malaise but the onset is more often sudden with rigors, fever, frontal headaches, pains in the back and limbs, constipation and bronchitis. The face is flushed and cyanotic, the eyes are congested and the patient becomes confused. The rash appears on the 4th–6th day. In its early stages it disappears on pressure but soon becomes petechial with subcutaneous mottling. It appears first on the anterior folds of the axillae, sides of the abdomen or backs of hands, then on the trunk and forearms. The neck and face are seldom affected. During the 2nd week symptoms increase in severity. Sores develop on the lips. The tongue becomes dry, brown, shrunk and tremulous. The spleen is palpable, the pulse feeble and the patient stuporous and delirious. The temperature falls rapidly at the end of the 2nd week and the patient recovers gradually. In fatal cases the patient usually dies in the 2nd week from toxæmia, cardiac or renal failure, or pneumonia.

Endemic (flea-borne) typhus

Flea-borne or 'endemic' typhus caused by *R. typhi* is endemic world-wide. Humans are infected when the faeces or contents of a crushed flea, which has fed on an infected rat, are introduced into the skin. The incubation period is 8–14 days. The symptoms resemble those of a mild louse-borne typhus. The rash may be scanty and transient.

Investigation of rickettsial infection

Routine blood investigations are not diagnostic but malaria must be excluded by blood film examination in most cases, and there is usually hepatitis and thrombocytopenia. Diagnosis is made on clinical grounds and response to treatment. Species-specific antibodies may be detected in specialised laboratories. Differential diagnoses include malaria, typhoid, meningococcal sepsis and leptospirosis.

Management of rickettsial fevers

The different rickettsial fevers vary greatly in severity but all respond to tetracycline 500 mg 6-hourly, doxycycline 200 mg daily or chloramphenicol 500 mg 6-hourly for 7 days. Louse-borne typhus and scrub typhus can be treated with a single dose of 200 mg doxycycline, repeated for 2–3 days to prevent relapse. Chloramphenicol and doxycycline-resistant strains of *O. tsutsugamushi* have been reported from Thailand and patients here may need treatment with rifampicin.

Nursing care is important, especially in epidemic typhus. Sedation may be required for delirium and blood transfusion for haemorrhage. Relapsing fever and typhoid are common intercurrent infections in epidemic typhus, and pneumonia in scrub typhus. They must be sought and treated. Convalescence is usually protracted, especially in older people.

To prevent rickettsial infection, lice, fleas, ticks and mites need to be controlled with insecticides.

Q fever

Q fever occurs world-wide and is caused by the rickettsia-like organism *Coxiella burnetii*, an obligate intracellular organism that can survive in the extracellular environment. Cattle, sheep and goats are important reservoirs and the organism is transmitted by inhalation of aerosolised particles. An important characteristic of

C. burnetii is its antigenic variation, called phase variation, due to a change of lipopolysaccharide (LPS). When isolated from animals or humans, *C. burnetii* express phase I antigen and are very infectious (a single bacterium is sufficient to infect a human). In culture there is an antigenic shift to the phase II form, which is not infectious. This antigenic shift can be measured and is valuable for the differentiation of acute and chronic Q fever.

Clinical features

The incubation period is 3–4 weeks. The initial symptoms are non-specific with fever, headache and chills; in 20% of cases a maculopapular rash occurs. Other presentations include pneumonia and hepatitis. Chronic Q fever may present with osteomyelitis, encephalitis and endocarditis.

Investigations and management

Diagnosis is usually serological and the stage of the infection can be distinguished by isotype tests and phase-specific antigens. Phase I and II IgM titres peak at 4–6 weeks. In chronic infections IgG titres to phase I and II antigens may be raised.

Prompt treatment of acute Q fever with doxycycline reduces fever duration. Treatment of Q fever endocarditis is problematic, requiring prolonged therapy with doxycycline and rifampicin or ciprofloxacin; even then, organisms are not always eradicated. Valve surgery is often required (p. 628).

Bartonellosis

This group of diseases are caused by intracellular Gram-negative bacilli closely related to the rickettsiae and have been found to be important causes of 'culture-negative' endocarditis. They are found in many domestic pets, such as cats, although for several the host is ill defined (Box 13.54). The principal human pathogens are *Bartonella quintana*, *B. henselae* and *B. bacilliformis*. *Bartonella* infections are associated with the following clinical conditions:

- *Trench fever*. This is a relapsing fever with severe leg pain and is due to *B. quintana*. The disease is not fatal but is very debilitating.
- *Bacteraemia and endocarditis in the homeless*. The endocarditis due to *B. quintana* or *henselae* is associated with severe damage to the heart valves.

13.54 Clinical diseases caused by bartonellosis

Reservoir	Vector	Organism	Disease
Cats	Flea	<i>B. henselae</i>	Cat scratch disease, bacillary angiomatosis, endocarditis
Undefined	Lice	<i>B. quintana</i>	Trench fever, bacillary angiomatosis, endocarditis
Undefined	Sandfly	<i>B. bacilliformis</i>	Carrion's disease: Oroya fever and verruga peruana
Undefined	Flea	<i>B. rochalimae</i>	Fever, rash, anaemia, splenomegaly

- *Cat scratch disease*. *B. henselae* causes this common benign lymphadenopathy in children and young adults. A vesicle or papule develops on the head, neck or arms after a cat scratch. The lesion resolves spontaneously but there may be regional lymphadenopathy that persists for up to 4 months before also resolving spontaneously.
- *Bacillary angiomatosis*. This is an HIV-associated disease due to *B. quintana* or *henselae* (p. 391).
- *Oroya fever and verruga peruana (Carrion's disease)*. This is endemic in areas of Peru. It is a biphasic disease caused by *B. bacilliformis* and is transmitted by sandflies of the genus *Phlebotomus*. Fever, haemolytic anaemia and microvascular thrombosis with end-organ ischaemia are features. It is frequently fatal if untreated.

Investigations and management

Bartonellae can be grown from the blood but this requires prolonged incubation using enriched media. Serum antibody detection is possible.

Bartonella species are susceptible to β -lactams, rifampicin, erythromycin and tetracyclines. Antibiotic use is guided by clinical need. Cat scratch disease usually resolves spontaneously but *Bartonella* endocarditis requires valve replacement and combination antibiotic therapy.

Chlamydial infections

These are listed in Box 13.55 and are also described in Chapters 15 and 19.

Trachoma

Trachoma is a chronic keratoconjunctivitis caused by *Chlamydia trachomatis*, and is the most common cause of avoidable blindness. The classic trachoma environment is dry and dirty, causing children to have eye and nose discharges. Transmission occurs through flies, on fingers and within families. In endemic areas the disease is most common in children.

Pathology and clinical features

The onset is usually insidious and infection may be asymptomatic. The infection lasts for years, may be latent over long periods and may recrudesce. The conjunctiva of the upper lid is first affected with vascularisation and cellular infiltration. Early symptoms include conjunctival irritation and blepharospasm. The early follicles of

13.55 Chlamydial infections

Organism	Disease caused
<i>Chlamydia trachomatis</i>	Trachoma Lymphogranuloma venereum (Box 15.11, p. 422) Cervicitis, urethritis, proctitis (pp. 421–422)
<i>Chlamydia psittaci</i>	Psittacosis (Box 19.43, p. 682)
<i>Chlamydophila (Chlamydia) pneumoniae</i>	Atypical pneumonia (Box 19.43, p. 682) Acute/chronic sinusitis

Fig. 13.27 Trachoma. Trachoma is characterised by hyperaemia and numerous pale follicles.

trachoma are characteristic (Fig. 13.27), but clinical differentiation from conjunctivitis due to other viruses may be difficult. Scarring causes inversion of the lids (entropion) so that the lashes rub against the cornea (trichiasis). The cornea becomes vascularised and opaque. The problem may not be detected until vision begins to fail.

Investigations and management

Intracellular inclusions may be demonstrated in conjunctival scrapings by staining with iodine or immunofluorescence. Chlamydia may be isolated in chick embryo or cell culture.

A single dose of azithromycin (20 mg/kg) has been shown to be superior to 6 weeks of 12-hourly tetracycline eye ointment for individuals in mass treatment programmes. Deformity and scarring of the lids, and corneal opacities, ulceration and scarring require surgical treatment after control of local infection.

Prevention

Personal and family cleanliness should be improved. Proper care of the eyes of newborn and young children is essential. Family contacts should be examined. The WHO is promoting the SAFE strategy for trachoma control (surgery, antibiotics, facial cleanliness and environmental improvement).

PROTOZOAL INFECTIONS

Protozoa are responsible for many important infectious diseases. They can be categorised according to whether they cause systemic or local infection. Trichomoniasis is described on page 415.

Systemic protozoal infections

Malaria

Malaria in humans is caused by *Plasmodium falciparum*, *P. vivax*, *P. ovale*, *P. malariae* and the predominantly simian parasite, *P. knowlesi*. It is transmitted by the bite of female anopheline mosquitoes and occurs throughout the tropics and subtropics at altitudes below 1500 metres (Fig. 13.28). Recent estimates have put the number of episodes of clinical malaria at 515 million cases per year, with two-thirds of these occurring in sub-Saharan Africa, especially amongst children and pregnant women. Following previous WHO-sponsored campaigns focusing on prevention and effective treatment, the incidence of malaria was greatly reduced between 1950 and 1960, but since 1970 there has been resurgence. Furthermore, *P. falciparum* has now become resistant to chloroquine and sulfadoxine-pyrimethamine, initially in South-east Asia and now throughout Africa. The WHO's Millennium Development Goal 6 aims to halt the spread of the disease by 2015, and its 'Roll Back Malaria' campaign is designed to halve mortality by 2010 by utilising the 'best evidence' vector and disease control methods, such as artemisinin combination therapy (ACT).

Travellers are susceptible to malaria (p. 305). Due to increased travel, over 2000 cases are imported annually into the UK. Most are due to *P. falciparum*, usually from Africa, and of these 1% die because of late diagnosis. Immigrants returning home after visiting family and friends overseas but who have long-term residence in the UK are particularly at risk. They have lost their partial immunity and do not realise that they should be taking malaria prophylaxis. A few people living near airports in Europe have acquired malaria from accidentally imported mosquitoes.

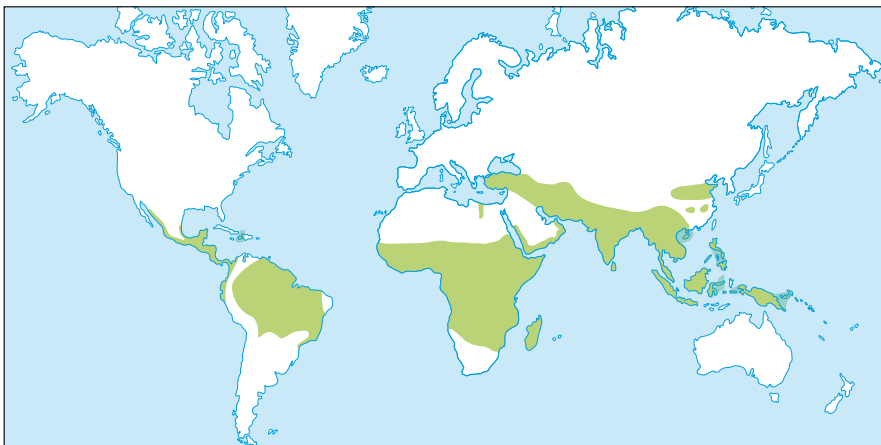

Fig. 13.28 Distribution of malaria. (For up-to-date information see the Malaria Atlas Project (MAP): www.map.ox.ac.uk).

Fig. 13.29 Scanning electron micrograph of *P. falciparum* oöcysts lining an anopheline mosquito's stomach.

Pathogenesis

Life cycle of the malarial parasite

The female anopheline mosquito becomes infected when it feeds on human blood containing gametocytes, the sexual forms of the malarial parasite (Figs 13.29 and 13.30). Development in the mosquito takes from 7 to 20 days, and results in sporozoites accumulating in the salivary glands which are inoculated into the human blood stream. Sporozoites disappear from human blood within half an hour and enter the liver. After some days merozoites leave the liver and invade red blood cells, where further asexual cycles of multi-

plication take place, producing schizonts. Rupture of the schizont releases more merozoites into the blood and causes fever, the periodicity of which depends on the species of parasite.

P. vivax and *P. ovale* may persist in liver cells as dormant forms, hypnozoites, capable of developing into merozoites months or years later. Thus the first attack of clinical malaria may occur long after the patient has left the endemic area, and the disease may relapse after treatment if drugs that kill only the erythrocytic stage of the parasite are given.

P. falciparum and *P. malariae* have no persistent exo-erythrocytic phase but recrudescence of fever may result from multiplication of parasites in red cells which have not been eliminated by treatment and immune processes (Box 13.56).

Pathology

Red cells infected with malaria are prone to haemolysis. This is most severe with *P. falciparum*, which invades red cells of all ages but especially young cells; *P. vivax* and *P. ovale* invade reticulocytes, and *P. malariae* normoblasts, so that infections remain lighter. Anaemia may be profound and is worsened by dyserythropoiesis, splenomegaly and depletion of folate stores.

In *P. falciparum* malaria, red cells containing trophozoites adhere to vascular endothelium in post-capillary venules in brain, kidney, liver, lungs and gut. The vessels become congested, resulting in widespread organ damage which is exacerbated by rupture of schizonts, liberating toxic and antigenic substances (see Fig 13.30).

P. falciparum has influenced human evolution, with the appearance of protective mutations such as sickle-cell

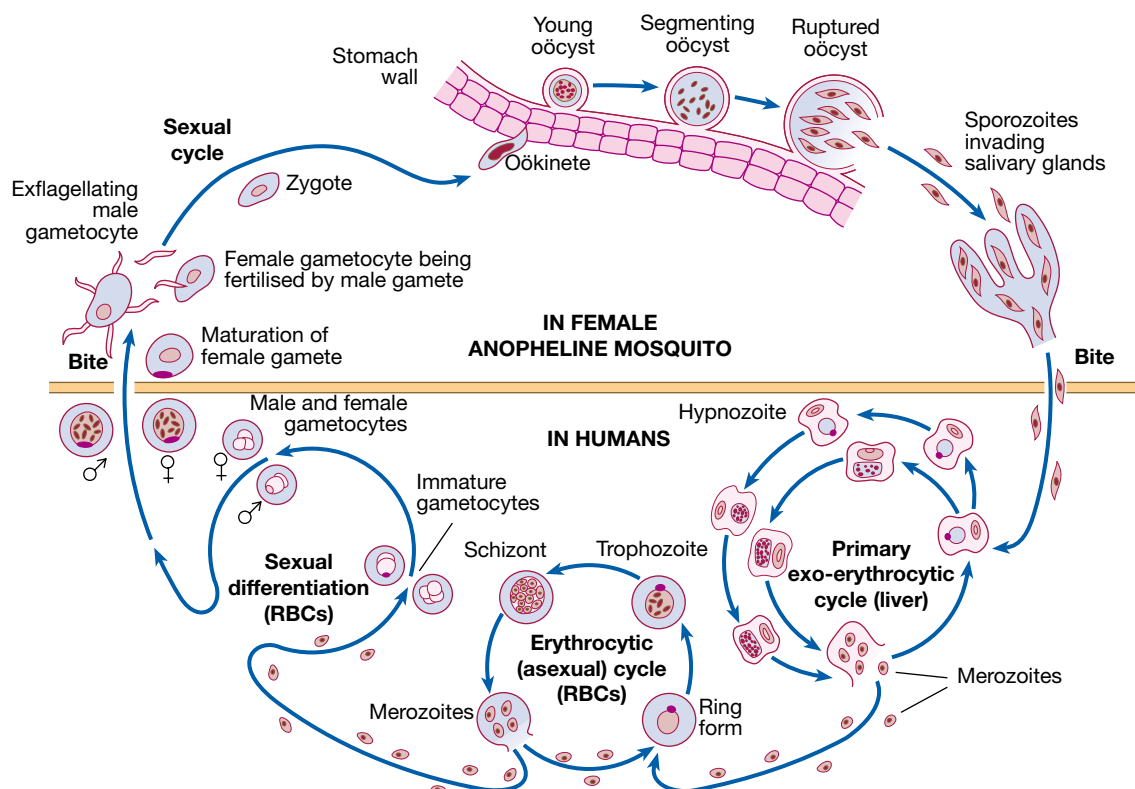

Fig. 13.30 Malarial parasites: life cycle. Hypnozoites(*) are present only in *P. vivax* and *P. ovale* infections.

13.56 Relationships between life cycle of parasite and clinical features of malaria			
Cycle/feature	<i>P. vivax</i> , <i>P. ovale</i>	<i>P. malariae</i>	<i>P. falciparum</i>
Pre-patent period (minimum incubation)	8–25 days	15–30 days	8–25 days
Exo-erythrocytic cycle	Persistent as hypnozoites	Pre-erythrocytic only	Pre-erythrocytic only
Asexual cycle	48 hrs synchronous	72 hrs synchronous	< 48 hrs asynchronous
Fever periodicity	Alternate days	Every third day	None
Delayed onset	Common	Rare	Rare
Relapses	Common up to 2 yrs	Recrudescence many years later	Recrudescence up to 1 yr

(HbS; p. 1028), thalassaemia (p. 1029), G6PD deficiency (p. 1024) and HLA-B53. *P. falciparum* does not grow well in red cells that contain haemoglobin F, C or especially S. Haemoglobin S heterozygotes (AS) are protected against the lethal complications of malaria. *P. vivax* cannot enter red cells that lack the Duffy blood group; therefore many West Africans and African-Americans are protected.

Clinical features

The clinical features of malaria are non-specific and the diagnosis must be suspected in anyone returning from an endemic area who has features of infection.

P. falciparum infection

This is the most dangerous of the malarias and patients are either 'killed or cured'. The onset is often insidious, with malaise, headache and vomiting. Cough and mild diarrhoea are also common. The fever has no particular pattern. Jaundice is common due to haemolysis and hepatic dysfunction. The liver and spleen enlarge and may become tender. Anaemia develops rapidly, as does thrombocytopenia.

A patient with *falciparum* malaria, apparently not seriously ill, may rapidly develop dangerous complications (Fig. 13.31 and Box 13.57). Cerebral malaria is manifested

13.57 Severe manifestations/complications of *falciparum* malaria and their immediate management

Coma (cerebral malaria)	Spontaneous bleeding and coagulopathy
<ul style="list-style-type: none"> • Maintain airway • Nurse on side • Exclude other treatable causes of coma (e.g. hypoglycaemia, bacterial meningitis) • Avoid harmful ancillary treatments such as corticosteroids, heparin and adrenaline (epinephrine) • Intubate if necessary 	<ul style="list-style-type: none"> • Transfuse screened fresh whole blood (cryoprecipitate/fresh frozen plasma and platelets if available) • Vitamin K injection
Hyperpyrexia	Metabolic acidosis
<ul style="list-style-type: none"> • Tepid sponging, fanning, cooling blanket • Antipyretic drug (paracetamol) 	<ul style="list-style-type: none"> • Exclude or treat hypoglycaemia, hypovolaemia and Gram-negative septicaemia • Fluid resuscitation • Give oxygen
Convulsions	Shock ('algid malaria')
<ul style="list-style-type: none"> • Maintain airway • Treat promptly with diazepam or paraldehyde injection 	<ul style="list-style-type: none"> • Suspect Gram-negative septicaemia • Take blood cultures • Give parenteral antimicrobials • Correct haemodynamic disturbances
Hypoglycaemia	Aspiration pneumonia
<ul style="list-style-type: none"> • Measure blood glucose • Give 50% dextrose injection followed by 10% dextrose infusion (glucagon may be ineffective) 	<ul style="list-style-type: none"> • Give parenteral antimicrobial drugs • Change position • Physiotherapy • Give oxygen
Severe anaemia (packed cell volume < 15%)	Hyperparasitaemia
<ul style="list-style-type: none"> • Transfuse fresh whole blood or packed cells if pathogen screening of donor blood is available 	<ul style="list-style-type: none"> • Consider exchange or partial exchange transfusion, manual or haemophoresis (e.g. > 10% of circulating erythrocytes parasitised in non-immune patient with severe disease)
Acute pulmonary oedema	Specific therapy
<ul style="list-style-type: none"> • Nurse at 45°, give oxygen, venesect 250 mL of blood, give diuretic, stop intravenous fluids • Intubate and add PEEP/CPAP (p. 195) in life-threatening hypoxaemia • Haemofilter 	<ul style="list-style-type: none"> • Intravenous artesunate • Mefloquine should be avoided due to increased risk of post-malaria neurological syndrome
Acute renal failure	
<ul style="list-style-type: none"> • Exclude pre-renal causes • Fluid resuscitation if appropriate • Peritoneal dialysis (haemofiltration or haemodialysis if available) 	

by confusion, seizures or coma, usually without localising signs. Children die rapidly without any special symptoms other than fever. Immunity is impaired in pregnancy and the parasite can preferentially bind to a placental protein known as chondroitin sulphate A. Abortion and intrauterine growth retardation from parasitisation of the maternal side of the placenta are frequent. Previous splenectomy increases the risk of severe malaria.

P. vivax and *P. ovale* infection

In many cases the illness starts with several days of continued fever before the development of classical bouts of fever on alternate days. Fever starts with a rigor. The patient feels cold and the temperature rises to about 40°C. After half an hour to an hour the hot or flush phase begins. It lasts several hours and gives way to profuse perspiration and a gradual fall in temperature. The cycle is repeated 48 hours later. Gradually the spleen and liver enlarge and may become tender. Anaemia develops slowly. Relapses are frequent in the first 2 years after leaving the malarious area and infection may be acquired from blood transfusion.

P. malariae infection

This is usually associated with mild symptoms and bouts of fever every third day. Parasitaemia may persist for many years with the occasional recrudescence of

fever, or without producing any symptoms. Chronic *P. malariae* infection causes glomerulonephritis and long-term nephrotic syndrome in children.

Investigations

Giemsa-stained thick and thin blood films should be examined whenever malaria is suspected. In the thick film erythrocytes are lysed, releasing all blood stages of the parasite. This, as well as the fact that more blood is used in thick films, facilitates the diagnosis of low-level parasitaemia. A thin film is essential to confirm the diagnosis, to identify the species of parasite and, in *P. falciparum* infections, to quantify the parasite load (by counting the percentage of infected erythrocytes). *P. falciparum* parasites may be very scanty, especially in patients who have been partially treated. With *P. falciparum*, only ring forms are normally seen in the early stages (see Fig. 13.31); with the other species all stages of the erythrocytic cycle may be found. Gametocytes appear after about 2 weeks, persist after treatment and are harmless, except that they are the source by which more mosquitoes become infected.

Immunochromatographic tests for malaria antigens, such as OptiMal® (which detects the *Plasmodium* lactate dehydrogenase of several species) and ParasightF® (which detects the *P. falciparum* histidine-rich protein 2), are extremely sensitive and specific for *falciparum*

malaria but less so for other species. They should be used in parallel with blood film examination but are especially useful where the microscopist is less experienced in examining blood films (e.g. in the UK).

DNA detection (PCR) is used mainly in research and is useful for determining whether a patient has a recrudescence of the same malaria parasite or a reinfection with a new parasite.

Management

Mild *P. falciparum* malaria

Since *P. falciparum* is now resistant to chloroquine and sulfadoxine-pyrimethamine (Fansidar) almost worldwide, an artemisinin-based treatment is recommended. Co-artemether (CoArtem® or Riamet®) contains artemether and lumefantrine and is given as 4 tablets at 0, 8, 24, 36, 48 and 60 hours. Alternatives are quinine by mouth (600 mg of quinine salt every 8 hours for 5–7 days), together with or followed by either doxycycline (200 mg once daily for 7 days) or clindamycin (450 mg every 8 hours for 7 days) or atovaquone-proguanil (Malarone®, 4 tablets once daily for 3 days). Doxycycline and artemether should be avoided in pregnancy.

WHO policy in Africa is moving towards always using artemisinin-based combination therapy (ACT), e.g. co-artemether or artesunate-amodiaquine. A combination of chlorproguanil and dapsone (Lapdap) is in clinical trials in uncomplicated malaria in sub-Saharan African children and has also been combined with artesunate. In India and other areas, artesunate (200 mg orally daily for 3 days) and mefloquine (1 g orally on day 2 and 500 mg orally on day 3) may be used.

Complicated *P. falciparum* malaria

Severe malaria should be considered in any non-immune patient with a parasite count greater than 2% and is a medical emergency (see Box 13.57). Management includes early and appropriate antimalarial chemotherapy, active treatment of complications, correction of fluid, electrolyte and acid–base balance, and avoidance of harmful ancillary treatments.

The treatment of choice is intravenous artesunate given as 2.4 mg/kg i.v. at 0, 12 and 24 hours and then once daily for 7 days. However, as soon as the patient has recovered sufficiently to swallow tablets, oral artesunate 2 mg/kg once daily is given instead of i.v. therapy,

to complete a total cumulative dose of 17–18 mg/kg. Rectal administration of artesunate is also being developed to allow administration in remote rural areas.

Quinine salt can also be used and is started with a loading dose infusion of 20 mg/kg over 4 hours up to a maximum of 1.4 g. This is followed by maintenance doses of 10 mg/kg quinine salt given as 4-hour infusions 2–3 times daily up to a maximum of 700 mg per dose, until the patient can take drugs orally. The loading dose should *not* be given if the patient has received quinine, quinidine or mefloquine during the previous 24 hours. Patients should be monitored by ECG, with special attention to QRS duration and QT interval. Mefloquine should not be used for severe malaria since no parenteral form is available.

Exchange transfusion has not been tested in randomised controlled trials but may be beneficial for non-immune patients with persisting high parasitaemias (> 10% circulating erythrocytes).

Management of non-*falciparum* malaria

P. vivax, *P. ovale* and *P. malariae* infections should be treated with oral chloroquine: 600 mg chloroquine base followed by 300 mg base in 6 hours, then 150 mg base 12-hourly for 2 more days. Some chloroquine resistance has been reported from Indonesia.

Late relapses can be prevented by prescribing anti-malarial drugs in suppressive doses. However, 'radical cure' is now achieved in most patients with *P. vivax* or *P. ovale* malaria using a course of primaquine (15 mg daily for 14 days), which destroys the hypnozoite phase in the liver. Haemolysis may develop in those who are G6PD-deficient. Cyanosis due to the formation of methaemoglobin in the red cells is more common but not dangerous.

Prevention

Clinical attacks of malaria may be preventable with chemoprophylaxis using chloroquine, atovaquone plus proguanil (Malarone), doxycycline or mefloquine. Box 13.58 gives the recommended doses for protection of the non-immune. The risk of malaria in the area to be visited and the degree of chloroquine resistance guide the recommendations for prophylaxis. Updated recommendations are summarised at www.fitfortravel.nhs.uk. Fansidar should not be used for chemoprophylaxis, as deaths have occurred from agranulocytosis or Stevens–Johnson

13.58 Chemoprophylaxis of malaria¹

Antimalarial tablets	Adult prophylactic dose	Regimen
Chloroquine resistance high		
Mefloquine ²	250 mg weekly	Started 2–3 wks before travel and continued until 4 wks after
or Doxycycline ^{3,4}	100 mg daily	Started 1 wk before and continued until 4 wks after travel
or Malarone ⁴	1 tablet daily	From 1–2 days before travel until 1 wk after return
Chloroquine resistance absent		
Chloroquine ⁵	300 mg base weekly	Started 1 wk before and continued until 4 wks after travel
and proguanil	100–200 mg daily	

¹Choice of regimen is determined by area to be visited, length of stay, level of malaria transmission, level of drug resistance, presence of underlying disease in the traveller and concomitant medication taken.

²Contraindicated in the first trimester of pregnancy, lactation, cardiac conduction disorders, epilepsy, psychiatric disorders; may cause neuropsychiatric disorders.

³Causes photosensitisation and sunburn if high-protection sunblock is not used.

⁴Avoid in pregnancy.

⁵British preparations of chloroquine usually contain 150 mg base, French preparations 100 mg base and American preparations 300 mg base.

EBM 13.59 Prevention of malaria**Insecticide-treated bed nets (ITNs)**

'Five RCTs provided strong evidence that widespread use of ITNs reduces overall mortality by about one-fifth in Africa. For every 1000 children aged 1–5 years protected, ~5.5 lives can be saved every year. In Africa, full ITN coverage could prevent 370 000 child deaths per year.'

Electronic mosquito repellents (EMRs)

'EMRs are not effective.'

Intermittent preventive treatment in pregnancy

'Antimalarial drugs reduce antenatal parasitaemia and fever in pregnant women living in areas with endemic malaria. For women in their first or second pregnancy, this reduces the instances of severe antenatal anaemia, antenatal parasitaemia and perinatal deaths, and increases birth weight.'

Intermittent preventive treatment in children

'Antimalarial drugs reduce clinical malaria, severe anaemia and hospital admissions. Effects on mortality and on health, if prophylaxis is stopped, are unknown.'

For further information:  www.cochrane.org

syndrome (p. 1285). Mefloquine is useful in areas of multiple drug resistance, such as East and Central Africa and Papua New Guinea. Experience shows it to be safe for at least 2 years, but there are several contraindications to its use (see Box 13.58).

Expert advice is required for individuals unable to tolerate the first-line agents listed, or in whom they are contraindicated. Mefloquine should be started 2–3 weeks before travel to give time for assessment of side-effects. Chloroquine should not be taken continuously as a prophylactic for more than 5 years without regular ophthalmic examination, as it may cause irreversible retinopathy. Pregnant and lactating women may take proguanil or chloroquine safely.

Prevention also involves advice about the use of high-percentage diethyltoluamide (DEET), covering up extremities when out after dark and sleeping under permethrin-impregnated mosquito nets (Box 13.59).

Malaria control in endemic areas

There are major initiatives under way to reduce malaria in endemic areas and it is estimated that these would be cost-effective, even at a cost of \$3 billion per year. Successful programmes have involved a combination of vector control, including indoor residual spraying, use of long-lasting insecticide-treated bed nets (ITNs) and intermittent preventative therapy (IPT) (repeated dose of prophylactic drugs in high-risk groups such as children and pregnant women) (see Box 13.59).

Development of a fully protective malaria vaccine is still some way off, which is not surprising considering that natural immunity is incomplete and not long-lived. There is, however, some evidence that vaccination can reduce the incidence of severe malaria in populations. Trial vaccines are being evaluated in Africa.

Babesiosis

This is caused by a tick-borne intra-erythrocytic protozoan parasite. There are more than 100 species of *Babesia*, all of which have an animal reservoir, typically either rodents or cattle, and are transmitted to humans via the tick vector *Ixodes scapularis*. Most cases of babesiosis in

Fig. 13.32 Trypanosomiasis. Scanning electron micrograph showing trypanosomes swimming among erythrocytes.

the USA are due to *B. microti* and most in Europe due to *B. divergens*. Patients present with fever and malaise 1–4 weeks after a tick bite. Illness may be complicated by haemolytic anaemia. Severe illness is seen in splenectomised patients. The diagnosis is made by blood-film examination. Treatment is with quinine and clindamycin.

African trypanosomiasis (sleeping sickness)

African sleeping sickness is caused by trypanosomes (Fig. 13.32) conveyed to humans by the bites of infected tsetse flies, and is unique to sub-Saharan Africa. *Trypanosoma brucei gambiense* trypanosomiasis has a wide distribution in West and Central Africa. *T. brucei rhodesiense* trypanosomiasis is found in parts of East and Central Africa, where it is currently on the increase (Fig. 13.33). In West Africa transmission is mainly at the riverside, where the fly rests in the shade of trees; no animal reservoir has been identified for *T. gambiense*. *T. rhodesiense* has a large reservoir in numerous wild animals and transmission takes place in the shade of woods bordering grasslands. Rural populations earning their livelihood from agriculture, fishing and animal husbandry are susceptible. Local people and tourists visiting forests infested with tsetse flies and animal reservoirs may become infected.

Clinical features

A bite by a tsetse fly is painful and commonly becomes inflamed, but if trypanosomes are introduced, the site may again become painful and swollen about 10 days

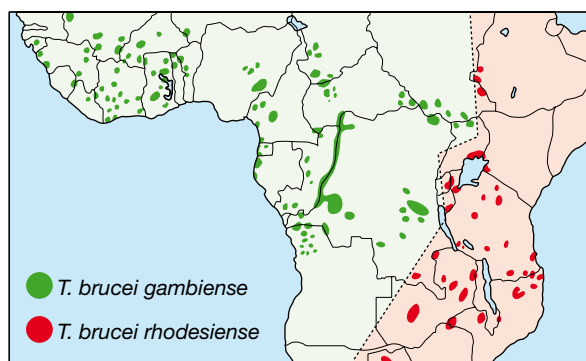

Fig. 13.33 Geographical distribution of African trypanosomiasis.

later ('trypanosomal chancre') and the regional lymph nodes enlarge ('Winterbottom's sign'). Within 2–3 weeks of infection the trypanosomes invade the blood stream. The disease is characterised by an early haematolymphatic stage and a late encephalitic stage in which the parasite crosses the blood–brain barrier and chronic encephalopathy develops.

Rhodesiense infections

In these infections the disease is more acute and severe than in *gambiense* infections, so that within days or a few weeks the patient is usually severely ill and may have developed pleural effusions and signs of myocarditis or hepatitis. There may be a petechial rash. The patient may die before there are signs of involvement of the CNS. If the illness is less acute, drowsiness, tremors and coma develop.

Gambiense infections

The distinction between early and late stages may not be apparent in *gambiense* infections. The disease usually runs a slow course over months or years, with irregular bouts of fever and enlargement of lymph nodes. These are characteristically firm, discrete, rubbery and painless, and are particularly prominent in the posterior triangle of the neck. The spleen and liver may become palpable. After some months without treatment, the CNS is invaded. This is shown clinically by headache and changed behaviour, blunting of higher mental functions, insomnia by night and sleepiness by day, mental confusion and eventually tremors, pareses, wasting, coma and death.

Investigations

Trypanosomiasis should be considered in any febrile patient from an endemic area. In *rhodesiense* infections thick and thin blood films, stained as for the detection of malaria, will reveal trypanosomes. The trypanosomes may be seen in the blood or from puncture of the primary lesion in the earliest stages of *gambiense* infections, but it is usually easier to demonstrate them by aspiration of a lymph node. Concentration methods include buffy coat microscopy and miniature anion exchange chromatography.

Due to the cyclical nature of parasitaemia, the diagnosis is often made by demonstration of antibodies using a simple, rapid card agglutination trypanosomiasis test (CATT). If the CNS is affected, the cell count ($> 20 \times 10^9$ leucocytes per litre) and protein content of the CSF are increased and the glucose is diminished. Very high levels of serum IgM or the presence of IgM in the CSF are suggestive of trypanosomiasis. Recognition of CNS involvement is critical, as failure to treat it might be fatal.

Management

Unfortunately, therapeutic options for African trypanosomiasis are limited and most of the antitrypanosomal drugs are toxic and expensive. The prognosis is good if treatment is begun early before the brain has been invaded. At this stage intravenous suramin, after a test dose of 100–200mg, should be given for *rhodesiense* infections (1g on days 1, 3, 7, 14 and 21). For *gambiense* infections, intramuscular or intravenous pentamidine 4mg/kg for 10 days is given (Box 13.60).

Once the nervous system is affected, treatment with melarsoprol (an arsenical) is effective for both East and West African diseases. It is used in a dose of 2–3.6mg/

13.60 Drugs used to treat human African trypanosomiasis

kg/day i.v. for the first course and 3.6mg/kg/day thereafter. Three 3-day treatment courses are given, separated by 7 days and by 10–21 days. Melarsoprol should be given with prednisolone 1mg/kg up to 40mg started 1–2 days before, continued during and tapered after treatment to reduce side-effects. Treatment-related mortality with melarsoprol is 4–12% due to reactive encephalopathy. For CNS infections due to *gambiense*, eflornithine (DFMO), an irreversible inhibitor of ornithine decarboxylase (100 and 150mg/kg i.v. 6-hourly for 14 days for adults and children, respectively), is considered to be a safer and cost-effective option. Combinations of either melarsoprol or eflornithine with oral nifurtimox (used for the treatment of Chagas' disease; see below) in lesser dosage and duration have been shown to decrease relapses, deaths and drug toxicity.

Prevention

In endemic *gambiense* areas, various measures may be taken against tsetse flies, and field teams help to detect and treat early human infection. In *rhodesiense* areas control is difficult.

American trypanosomiasis (Chagas' disease)

Chagas' disease occurs widely in South and Central America. The cause is *Trypanosoma cruzi*, transmitted to humans from the faeces of a reduviid (triatomine) bug in which the trypanosomes have a cycle of development before becoming infective to humans. These bugs live in wild forests in crevices, burrows and palm trees. The *Triatoma infestans* bug has become domesticated in the Southern Cone countries (Argentina, Brazil, Chile, Paraguay and Uruguay). It lives in the mud and wattle walls and thatched roofs of simple rural houses, and emerges at night to feed and defecate on the sleeping occupants. Infected faeces are rubbed in through the conjunctiva, mucosa of mouth or nose, or abrasions of the skin. Over one hundred species of mammal, domestic, peridomestic and wild, may serve as reservoirs of infection. In some areas, blood transfusion accounts for about 5% of cases. Congenital transmission occasionally occurs.

Pathology

The trypanosomes migrate via the blood stream, develop into amastigote forms in the tissues and multiply intracellularly by binary fission. In the acute phase (primarily cell-mediated), inflammation of parasitised as well as non-parasitised cardiac muscles and capillaries occurs, resulting in acute myocarditis. In the chronic phase focal myocardial atrophy, signs of chronic passive congestion and thromboembolic phenomena, cardiomegaly and apical cardiac aneurysm are salient findings. In the digestive form of disease, focal myositis and discontinuous lesions of the intramural myenteric plexus, predominantly in the oesophagus and colon, are seen.

Clinical features

Acute phase

Clinical manifestations of the acute phase are seen in only 1–2% of individuals who are infected before the age of 15 years. Young children (1–5 years) are most commonly affected. The entrance of *T. cruzi* through an abrasion produces a dusky-red firm swelling and enlargement of regional lymph nodes. A conjunctival lesion, although less common, is characteristic; the unilateral firm reddish swelling of the lids may close the eye and constitutes 'Romaña's sign'. In a few patients an acute generalised infection soon appears, with a transient morbilliform or urticarial rash, fever, lymphadenopathy and enlargement of the spleen and liver. In a small minority of patients acute myocarditis and heart failure or neurological features, including personality changes and signs of meningoencephalitis, may be seen. The acute infection may be fatal to infants.

Chronic phase

About 50–70% of infected patients become seropositive and develop an indeterminate form when no parasitaemia is detectable. They have a normal lifespan with no symptoms, but are a natural reservoir for the disease and maintain the life cycle of parasites. After a latent period of several years, 10–30% of chronic cases develop low-grade myocarditis, and damage to conducting fibres causes a cardiomyopathy characterised by cardiac dilatation, arrhythmias, partial or complete heart block and sudden death. In nearly 10% of patients, damage to Auerbach's plexus results in dilatation of various parts of the alimentary canal, especially the colon and oesophagus, so-called 'mega' disease. Dilatation of the bile ducts and bronchi is also a recognised sequela. Autoimmune processes may be responsible for much of the damage. There are geographical variations of the basic pattern of disease. Reactivation of Chagas' disease can occur in patients with HIV if the CD4 count falls lower than 200 cells/mm³ (p. 390).

Investigations

T. cruzi is easily detectable in a blood film in the acute illness. In chronic disease it may be recovered in up to 50% of cases by xenodiagnosis, in which infection-free, laboratory-bred reduviid bugs are allowed to feed on the patient; subsequently, the hind gut or faeces of the bug are examined for parasites. Parasite DNA detection by PCR in the patient's blood is a highly sensitive method for documentation of infection and, in addition, can be employed in faeces of bugs used in xenodiagnosis tests to improve sensitivity. Antibody detection is also highly sensitive (99%).

Management and prevention

Parasiticidal agents are used to treat the acute phase, congenital disease and early chronic phase (within 10 years of infection). Nifurtimox is given orally. The dose, which has to be carefully supervised to minimise toxicity while preserving parasiticidal activity, is 10 mg/kg divided into three equal doses, daily by mouth for 60–90 days. The paediatric dose is 15 mg/kg daily. Cure rates of 80% in acute disease are obtained. Benznidazole is an alternative, given at a dose of 5–10 mg/kg daily by mouth, in two divided doses for 60 days; children receive 10 mg/kg daily. Both nifurtimox and benznidazole are toxic, with adverse reaction rates of 30–55%. Specific drug treatment of the chronic form is now increasingly favoured, but in the cardiac or digestive 'mega' diseases it does not reverse established tissue damage. Surgery may be needed.

Preventative measures include improving housing and destruction of reduviid bugs by spraying of houses with insecticides. Blood donors should be screened.

Toxoplasmosis

Toxoplasma gondii is an intracellular parasite. The sexual phase of the parasite's life cycle (Fig. 13.34) occurs in the small intestinal epithelium of the domestic cat. Oöcysts are shed in cat faeces and are spread to intermediate hosts (pigs, sheep and also humans) through widespread contamination of soil. Oöcysts may survive in moist conditions for weeks or months. Once they are ingested, the parasite transforms into rapidly dividing tachyzoites through cycles of asexual multiplication.

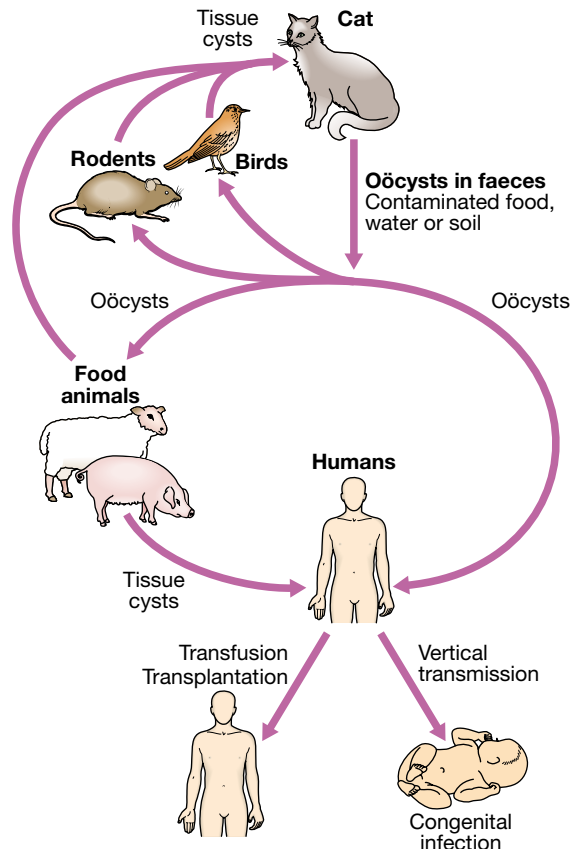

Fig. 13.34 Life cycle of *Toxoplasma gondii*.

This leads to the formation of microscopic tissue cysts containing bradyzoites, which persist for the lifetime of the host. Cats become infected or reinfected by ingesting tissue cysts in prey such as rodents and birds.

Human acquisition of infection occurs via oöcyst-contaminated soil, salads and vegetables, or by the ingestion or tasting of raw or undercooked meats containing tissue cysts. Sheep, pigs and rabbits are the most common meat sources. Outbreaks of toxoplasmosis have been linked to the consumption of unfiltered water. In developed countries, toxoplasmosis is the most common protozoal infection; around 22% of adults in the UK are seropositive. Most primary infections are subclinical; however, toxoplasmosis is thought to account for about 15% of heterophile antibody-negative glandular fever (p. 316). In India or Brazil, approximately 40–60% of pregnant females are seropositive for *Toxoplasma*. In HIV infection (p. 397), toxoplasmosis is an important opportunistic infection with considerable morbidity and mortality. Generalised toxoplasmosis has been described after accidental laboratory infection with highly virulent strains.

Clinical features

In most immunocompetent individuals, including children and pregnant women, the infection goes unnoticed. In approximately 10% of patients it causes a self-limiting illness, most common in adults aged 25–35 years. The most common presenting feature is painless lymphadenopathy, either local or generalised. In particular, the cervical nodes are involved, but mediastinal, mesenteric or retroperitoneal groups may be affected. The spleen is seldom palpable. Most patients have no systemic symptoms, but some complain of malaise, fever, fatigue, muscle pain, sore throat and headache. Complete resolution usually occurs within a few months, although symptoms and lymphadenopathy tend to fluctuate unpredictably and some patients do not recover completely for a year or more. Very infrequently, patients may develop encephalitis, myocarditis, polymyositis, pneumonitis or hepatitis. Retinochoroiditis (Fig. 13.35) is nearly always the result of congenital infection but has also been reported in acquired disease.

Congenital toxoplasmosis

Acute toxoplasmosis, mostly subclinical, affects 0.3–1% of pregnant women, with an approximately 60%

Fig. 13.35 Retinochoroiditis due to toxoplasmosis.

transmission rate to the fetus which increases with increasing gestation. Seropositive females infected 6 months before conception have no risk of fetal transmission. Congenital disease affects approximately 40% of infected fetuses, and is more likely and more severe with infection early in gestation (see Box 13.27, p. 310). Many fetal infections are subclinical at birth but long-term sequelae include retinochoroiditis, microcephaly and hydrocephalus.

Investigations

In contrast to immunocompromised patients, in whom the diagnosis often requires direct detection of parasites, serology is often used in immunocompetent individuals. The Sabin–Feldman dye test (indirect fluorescent antibody test), which detects IgG antibody. Recent infection is indicated by a fourfold or greater increase in titre when paired sera are tested in parallel. Peak titres of 1/1000 or more are reached within 1–2 months of the onset of infection, and the dye test then becomes an unreliable indicator of recent infection. The detection of significant levels of *Toxoplasma*-specific IgM antibody may be useful in confirming acute infection. False positives or persistence of IgM antibodies for years after infection make interpretation difficult; however, negative IgM antibodies virtually rule out acute infection.

During pregnancy it is critical to differentiate between recent and past infection; the presence of high-avidity IgG antibodies excludes infection acquired in the preceding 3–4 months.

If necessary, the presence of *Toxoplasma* organisms in a lymph node biopsy can be sought by staining sections histochemically with *T. gondii* antiserum, or by the use of PCR to detect *Toxoplasma*-specific DNA.

Management

In immunocompetent subjects uncomplicated toxoplasmosis is self-limiting and responds poorly to antimicrobial therapy. Treatment with pyrimethamine, sulfadiazine and folinic acid is therefore usually reserved for rare cases of severe or progressive disease, and for infection in immunocompromised patients.

In a pregnant woman with an established recent infection, spiramycin (3 g daily in divided doses) should be given until term. Once fetal infection is established, treatment with sulfadiazine and pyrimethamine plus calcium folinate is recommended (spiramycin does not cross the placental barrier). The cost/benefit of routine *Toxoplasma* screening and treatment in pregnancy is being debated in many countries. There is insufficient evidence to determine the effects on mother or baby of current antiparasitic treatment for women who seroconvert in pregnancy.

Leishmaniasis

Leishmaniasis is caused by unicellular flagellate intracellular protozoa belonging to the genus *Leishmania* (order Kinetoplastidae). There are 21 leishmanial species which cause several diverse clinical syndromes, which can be placed into three broad groups:

- visceral leishmaniasis (VL, kala-azar)
- cutaneous leishmaniasis (CL)
- mucosal leishmaniasis (ML).

Epidemiology and transmission

Although most clinical syndromes are caused by zoonotic transmission of parasites from animals (chiefly canine and rodent reservoirs) to humans through phlebotomine sandfly vectors (Fig. 13.36A), humans are the only known reservoir (anthroponotic) in major VL foci in India and for transmission of leishmaniasis between injection drug-users (Fig. 13.36B and C). Leishmaniasis occurs in 88 countries around the world, with an estimated annual incidence of 2 million new cases (500 000 for VL, and 1.5 million for CL).

The life cycle of *Leishmania* is shown in Figure 13.37. Flagellar promastigotes (10–20 µm) are introduced by the feeding female sandfly. The promastigotes are taken up by macrophages, in which they lose their flagellae and transform into amastigotes (2–4 µm; Leishman–Donovan body). These multiply, ultimately causing lysis of the macrophages and infection of other cells. Sandflies pick up amastigotes when feeding on infected patients or animal reservoirs. In the sandfly, the parasite transforms into a flagellar promastigote, which multiplies by binary fission in the gut of the vector and migrates to the proboscis to infect a new host.

Sandflies live in hot and humid climates in the cracks and crevices of mud or straw houses and lay eggs in

Fig. 13.37 Life cycle of *Leishmania*.

organic matter. People living in such conditions are more prone to acquire the disease. Female sandflies bite during the night and preferentially feed on animals; humans are incidental hosts.

Visceral leishmaniasis (VL, kala-azar)

VL is caused by the protozoan *Leishmania donovani* complex (comprising *L. donovani*, *L. infantum* and *L. chagasi*). India, Sudan, Bangladesh and Brazil account for 90% of cases of VL, while other affected regions include the Mediterranean, East Africa, China, Arabia, Israel and other South American countries (Fig. 13.38). In addition to sandfly transmission, VL has also been reported to follow blood transfusion and disease can present unexpectedly in immunosuppressed patients—for example, after renal transplantation and in HIV infection.

The great majority of people infected remain asymptomatic. In visceral diseases the spleen, liver, bone marrow and lymph nodes are primarily involved.

Clinical features

On the Indian subcontinent adults and children are equally affected; on other continents VL is predominantly a disease of small children and infants, except in adults with HIV co-infection. The incubation period ranges from weeks to months (occasionally several years).

The first sign of infection is high fever, usually accompanied by rigor and chills. Fever intensity decreases over time and patients may become afebrile for intervening periods ranging from weeks to months. This is followed by a relapse of fever, often of lesser intensity. Splenomegaly develops quickly in the first few weeks and becomes massive as the disease progresses. Moderate hepatomegaly occurs later. Lymphadenopathy is seen in the majority of

Fig. 13.36 Transmission of leishmaniasis. **A** Zoonotic transmission. **B** Anthroponotic transmission. **C** Anthroponotic transmission in the injection drug-user.

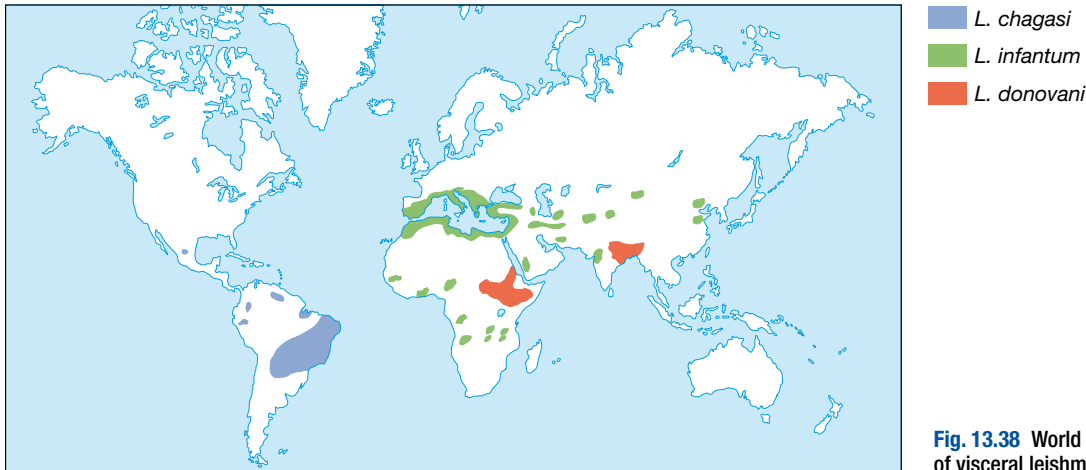

Fig. 13.38 World distribution of visceral leishmaniasis.

cases in Africa, the Mediterranean and South America, but is rare on the Indian subcontinent. Blackish discoloration of the skin, from which the disease derived its name, kala-azar (the Hindi word for 'black fever'), is a feature of advanced illness and is now rarely seen. Pancytopenia is a common feature. Moderate to severe anaemia develops rapidly, and can result in congestive cardiac failure and associated clinical features. Thrombocytopenia, often compounded by hepatic dysfunction, may result in bleeding from the retina, gastrointestinal tract and nose. In advanced illness, hypoalbuminaemia may manifest as pedal oedema, ascites and anasarca (gross generalised oedema and swelling).

As the disease advances, there is profound immunosuppression and secondary infections are very common. These include tuberculosis, pneumonia, severe amoebic or bacillary dysentery, gastroenteritis, herpes zoster and chickenpox. Skin infections, boils, cellulitis and scabies are common. Without adequate treatment most patients with clinical VL die.

Investigations

Pancytopenia is the most dominant feature, with granulocytopenia and monocytosis. Polyclonal hypergammaglobulinaemia, chiefly IgG followed by IgM, and hypoalbuminaemia are seen later.

Demonstration of amastigotes (Leishman-Donovan bodies) in splenic smears is the most efficient means of

Fig. 13.39 Splenic smear showing numerous intracellular, and a few extracellular, amastigotes.

diagnosis, with 98% sensitivity (Fig. 13.39); however, it carries a risk of serious haemorrhage in inexperienced hands. Safer methods, such as bone marrow or lymph node smears, are not as sensitive. Parasites may be demonstrated in buffy coat smears, especially in immunosuppressed patients. Sensitivity can be improved by culturing the aspirate material or by PCR for DNA detection and species identification, but these tests can only be performed in specialised laboratories.

Serodiagnosis, by ELISA or immunofluorescence antibody test, is employed in developed countries. In endemic regions, a highly sensitive and specific direct agglutination test using stained promastigotes and an equally efficient rapid immunochromatographic k39 strip test have become popular. These tests remain positive for several months after cure has been achieved, so do not predict response to treatment or relapse. A significant proportion of the healthy population in an endemic region will be positive for these tests due to past exposure. Formal gel (aldehyde) or other similar tests based on the detection of raised globulin have limited value and should not be employed for the diagnosis of VL.

Differential diagnosis

This includes malaria, typhoid, tuberculosis, schistosomiasis and many other infectious and neoplastic conditions, some of which may coexist with VL. Fever, splenomegaly, pancytopenia and non-response to antimalarial therapy may provide clues before specific laboratory diagnosis is made.

Management

Pentavalent antimonials

Antimony (Sb) compounds were the first drugs to be used for the treatment of leishmaniasis and remain the mainstay of treatment in most parts of the world. The exception is the Indian subcontinent, especially Bihar state, where almost two-thirds of cases are refractory to Sb treatment. Traditionally, pentavalent antimony is available as sodium stibogluconate (100 mg/mL) in English-speaking countries and meglumine antimoniate (85 mg/mL) in French-speaking ones. The daily dose is 20 mg/kg body weight, given either intravenously or intramuscularly for 28–30 days. Side-effects are common and include arthralgias, myalgias, raised hepatic

transaminases, pancreatitis (especially in patients co-infected with HIV) and ECG changes (T wave inversion and reduced amplitude). Severe cardiotoxicity, manifest by concave ST segment elevation, prolongation of QT_c > 0.5 msec, and ventricular dysrhythmias, is not uncommon. The incidence of cardiotoxicity and death can be very high with improperly manufactured Sb.

Amphotericin B

The antifungal drug, amphotericin B deoxycholate, given once daily or on alternate days at a dose of 0.75–1.00 mg/kg for 15–20 doses, is used as a first-line drug in many regions with a significant level of Sb unresponsiveness. It has a cure rate of nearly 100%. Infusion-related side-effects, e.g. high fever with rigor, thrombophlebitis, diarrhoea and vomiting, are extremely common. Serious adverse events, such as renal or hepatic toxicity, hypokalaemia and thrombocytopenia are not uncommon.

Lipid formulations of amphotericin B (p. 158) are less toxic and have been tested widely for the treatment of VL. AmBisome is approved by the US Food and Drug Administration and is first-line therapy in Europe for VL. Drug doses vary according to geographical location. On the Indian subcontinent a total dose of 10–15 mg/kg is considered adequate, whereas in Africa 14–18 mg, and in South America and Europe 21–24 mg, is needed for immunocompetent patients. High daily doses (5–7.5 mg/kg) of the lipid formulations are well tolerated, thus reducing hospital stay, but the high price of lipid formulations has limited their use in endemic regions. AmBisome has been made available at a preferential low price for developing countries, and greater use of this drug for treatment of VL is expected.

Other drugs

The oral drug miltefosine, an alkyl phospholipid, has been approved in several countries for the treatment of VL. A daily dose of 50 mg (patient's body weight < 25 kg) to 100 mg (≥ 25 kg), or 2.5 mg/kg body weight for children, for 28 days cures over 90% of patients. Side-effects include mild to moderate vomiting and diarrhoea, and rarely skin allergy or renal or liver toxicity. Since it is a teratogenic drug, it cannot be used in pregnancy; female patients are advised not to become pregnant for the duration of treatment and 3 months thereafter, because of its half-life of nearly 1 week.

Paromomycin is an aminoglycoside that has undergone trials in India and Africa, and is highly effective if given intramuscularly at 11 mg/kg body weight of paromomycin base, daily for 3 weeks. No significant auditory or renal toxicity is seen. The drug has been approved in India for the treatment of VL.

Pentamidine isetionate was used to treat Sb-refractory patients with VL. However, declining efficacy and serious side-effects, such as type 1 diabetes mellitus, hypoglycaemia and hypotension, have led to it being abandoned.

Response to treatment

A good response results in abatement of fever, a feeling of well-being, gradual decrease in spleen size, weight gain and recovery of blood counts. Patients should be followed regularly for a period of 6–12 months, as a small minority may experience a relapse of the disease during this period, irrespective of the treatment regimen.

HIV-visceral leishmaniasis co-infection

HIV-induced immunosuppression (Ch. 14) increases the risk of contracting VL 100–1000 times. Most cases of HIV-VL co-infection have been reported from Spain, France, Italy and Portugal. Highly active antiretroviral therapy (HAART) has led to a remarkable decline in the incidence of VL co-infection in Europe. However, numbers are increasing in Africa (mainly Ethiopia) and Brazil and on the Indian subcontinent.

The clinical triad of fever, splenomegaly and hepatomegaly is found in fewer than half of patients with a CD4 count < 50 cells/mm³. Atypical clinical presentations of VL pose a diagnostic challenge. VL may present with gastrointestinal involvement (stomach, duodenum or colon), ascites, pleural or pericardial effusion, or involvement of lungs, tonsil, oral mucosa or skin. Diagnostic principles remain the same as those in non-HIV patients. Parasites are numerous and easily demonstrable, even in buffy coat preparations. Sometimes amastigotes are found in unusual sites, such as bronchoalveolar lavage fluid, pleural fluid or biopsies of the gastrointestinal tract. Immunofluorescence, Western blot, ELISA and other serological tests used singly have low sensitivity. DNA detection by PCR of the blood or its buffy coat are ≥ 95% sensitive, and accurately track recovery and relapse.

Treatment of VL with HIV co-infection is essentially the same as in immunocompetent patients but there are some differences in outcome. Conventional amphotericin B (0.7 mg/kg/day for 28 days) may be more effective in achieving initial cure than Sb (20 mg/kg/day for 28 days). Using high-dose AmBisome (4 mg/kg on days 1–5, 10, 17, 24, 31 and 38), a high cure rate is possible. However, these co-infected patients have a tendency to relapse within 1 year. For prevention of relapse, maintenance chemotherapy with monthly liposomal amphotericin B is useful.

Post-kala-azar dermal leishmaniasis (PKDL)

After treatment and apparent recovery from the visceral disease in India and Sudan, some patients develop dermatological manifestations due to local parasitic infection.

Clinical features

In India dermatological changes occur in a small minority of patients 6 months to ≥ 3 years after the initial infection. They are seen as macules, papules, nodules (most frequently) and plaques which have a predilection for the face, especially the area around the chin. The face often appears erythematous (Fig. 13.40A). Hypopigmented macules can occur over all parts of the body and are highly variable in extent and location. There are no systemic symptoms and no spontaneous healing.

In Sudan approximately 50% of patients with VL develop PKDL, experiencing skin manifestations concurrently with VL or within 6 months afterwards. In addition to the dermatological features described above, a measles-like micropapular rash (Fig. 13.40B) may be seen all over the body. In Sudan, children are more frequently affected than in India. Spontaneous healing occurs in about three-quarters of cases within 1 year.

Investigations and management

The diagnosis is clinical, supported by demonstration of scanty parasites in lesions by slit-skin smear and culture.

Fig. 13.40 Post-kala-azar dermal leishmaniasis. **A** In India, with macules, papules, nodules and plaques. **B** In Sudan, with micronodular rash.

Immunofluorescence and immunohistochemistry may demonstrate the parasite in skin tissues. In the majority of patients serological tests (direct agglutination test or k39 strip tests) are positive.

Treatment of PKDL is difficult. In India, Sb for 120 days or several courses of amphotericin B infusions are required. In Sudan, Sb for 2 months is considered adequate. In the absence of a physical handicap, most patients are reluctant to complete the treatment. PKDL patients are a human reservoir, and focal outbreaks have been linked to patients with PKDL in areas previously free of VL.

Prevention and control

Sandflies are extremely sensitive to insecticides, and vector control through insecticide spray is very important. Mosquito nets or curtains treated with insecticides will keep out the tiny sandflies. In endemic areas with zoonotic transmission, infected or stray dogs should be destroyed.

In areas with anthroponotic transmission, early diagnosis and treatment of human infections, to reduce the reservoir and control epidemics of VL, is extremely important. Serology is useful in diagnosis of suspected cases in the field. No vaccine is currently available.

Cutaneous and mucosal leishmaniasis

Cutaneous leishmaniasis (CL)

CL (oriental sore) occurs in both the Old World and the New World (the Americas). Transmission is described on page 357.

In the Old World, CL is mild. It is found around the Mediterranean basin, throughout the Middle East and Central Asia as far as Pakistan, and in sub-Saharan West Africa and Sudan (Fig. 13.41). The causative organisms for Old World zoonotic CL are *L. major*, *L. tropica* and *L. aethiopica* (Box 13.61). Anthroponotic CL is caused by *L. tropica*, and is confined to urban or suburban areas of the Old World. Afghanistan is currently the biggest focus, but infection is endemic in Pakistan, the western deserts of India, Iran, Iraq, Syria and other areas of the Middle East. In recent years there has been an increase in the incidence of zoonotic CL in both the Old and the New World due to urbanisation and deforestation which led to peridomestic transmission (in and around human dwellings).

New World CL is a more significant disease, which may disfigure the nose, ears and mouth, and is caused

Fig. 13.41 World distribution of cutaneous leishmaniasis.

13.61 Types of Old World <i>Leishmania</i>		
<i>Leishmania</i> spp.	Host	Clinical features
<i>L. tropica</i>	Dogs	Slow evolution, less severe
<i>L. major</i>	Gerbils, desert rodents	Rapid necrosis, wet sores
<i>L. aethiopica</i>	Hyraxes	Solitary facial lesions with satellites

by the *L. mexicana* complex (comprising *L. mexicana*, *L. amazonensis* and *L. venezuelensis*) and by the *Viannia* subgenus *L. (V.) brasiliensis* complex (comprising *L. (V.) guyanensis*, *L. (V.) panamensis*, *L. (V.) brasiliensis* and *L. (V.) peruviana*).

CL is commonly imported and should be considered in the differential diagnosis of an ulcerating skin lesion, especially in travellers who have visited endemic areas of the Old World or forests in Central and South America.

Pathogenesis

Inoculated parasites are taken up by dermal macrophages, in which they multiply and form a focus for lymphocytes, epithelioid cells and plasma cells. Self-healing may occur with necrosis of infected macrophages, or the lesion may become chronic with ulceration of the overlying epidermis, depending upon the aetiological pathogen.

Clinical features

The incubation period is typically 2–3 months (range 2 weeks to 5 years). In all types of CL, the common feature is development of a papule followed by ulceration of the skin with raised borders, usually at the site of the bite of the vector. Lesions, single or multiple, start as small red papules that increase gradually in size, reaching 2–10 cm in diameter. A crust forms, overlying an ulcer with a granular base (Fig. 13.42). These ulcers develop a few weeks or months after the bite. There can be satellite lesions, especially in *L. major* and occasionally in *L. tropica* infections. Regional lymphadenopathy, pain, pruritus and secondary bacterial infections may occur.

Clinically, lesions of *L. mexicana* and *L. peruviana* closely resemble those seen in the Old World, but lesions

on the pinna of the ear are common, and are chronic and destructive. *L. mexicana* is responsible for chiclero ulcers, the self-healing sores of Mexico.

If immunity is good, there is usually spontaneous healing in *L. tropica*, *L. major* and *L. mexicana* lesions. In some patients with anergy to *Leishmania*, the skin lesions of *L. aethiopica*, *L. mexicana* and *L. amazonensis* infections progress to the development of diffuse CL; this is characterised by spread of the infection from the initial ulcer, usually on the face, to involve the whole body in the form of non-ulcerative nodules. Occasionally, in *L. tropica* infections, sores that have apparently healed relapse persistently (recidivans or lupoid leishmaniasis).

Mucosal leishmaniasis (ML)

The *Viannia* subgenus extends widely from the Amazon basin as far as Paraguay and Costa Rica, and is responsible for deep sores and ML. In *L. (V.) brasiliensis* complex infections, cutaneous lesions may be followed by mucosal spread of the disease simultaneously or even years later. Young men with chronic lesions are particularly at risk, and between 2% and 40% of infected persons develop 'espundia', metastatic lesions in the mucosa of the nose or mouth. This is characterised by thickening and erythema of the nasal mucosa, typically starting at the junction of the nose and upper lip. Later, ulceration develops. The lips, soft palate, fauces and larynx may also be invaded and destroyed, leading to considerable suffering and deformity. There is no spontaneous healing, and death may result from severe respiratory tract infections due to massive destruction of the pharynx.

Investigations in CL and ML

CL is often diagnosed on the basis of clinical characteristics of the lesions. However, parasitological confirmation is important because clinical manifestations may be mimicked by other infections. Amastigotes can be demonstrated on a slit-skin smear with Giemsa staining; alternatively, they can be cultured from the sores early during the infection. Parasites seem to be particularly difficult to isolate from sores caused by *L. brasiliensis*, responsible for the vast majority of cases in Brazil. Touch preparations from biopsies and histopathology usually have a low sensitivity. Culture of fine needle aspiration material has been reported to be the most sensitive method.

Fig. 13.42 Cutaneous leishmaniasis. **A** Papule. **B** Ulcer.

ML is more difficult to diagnose parasitologically. The leishmanin skin test measures delayed-type hypersensitivity to killed *Leishmania* organisms. A positive test is defined as induration > 5 mm 48 hours after intradermal injection. The test is positive, except in diffuse CL and during active VL. PCR is used increasingly for diagnosis and speciation, which is useful in selecting therapy.

Management of CL and ML

Small lesions may self-heal or are treated by freezing with liquid nitrogen or curettage. There is no ideal antimicrobial therapy. Treatment should be individualised on the basis of the causative organism, severity of the lesions, availability of drugs, tolerance of the patient for toxicity, and local resistance patterns.

In CL, topical application of paromomycin 15% plus methylbenzethonium chloride 12% is beneficial. Intralesional antimony (Sb: 0.2–0.8 mL/lesion) up to 2 g seems to be rapidly effective in suitable cases, well tolerated and economic, and is safe in patients with cardiac, liver or renal diseases.

In ML, and in CL when the lesions are multiple or in a disfiguring site, it is better to treat with parenteral Sb in a dose of 20 mg/kg/day (usually given for 20 days for CL and 28 days for ML), or with conventional or liposomal amphotericin B (see treatment of VL above). Sb is also indicated to prevent the development of mucosal disease, if there is any chance that a lesion acquired in South America is due to an *L. brasiliensis* strain. Refractory CL or ML should be treated with an amphotericin B preparation.

Other regimens may be effective. Two to four doses (2–4 mg/kg) of alternate-day administration of pentamidine are effective in New World CL. In ML, 8 injections of pentamidine (4 mg/kg on alternate days) cure the majority of patients. Ketoconazole 600 mg daily for 4 weeks

has shown some potential against *L. mexicana* infection. In Saudi Arabia, fluconazole 200 mg daily for 6 weeks reduced healing times and cured 79% of patients with CL due to *L. major*. In India itraconazole 200 mg daily for 6 weeks produced good results in CL.

Prevention of CL and ML

Personal protection against sandfly bites is important. No effective vaccine is yet available.

Gastrointestinal protozoal infections

Amoebiasis

Amoebiasis is caused by *Entamoeba histolytica*, which is spread between humans by its cysts. It is one of the leading parasitic causes of morbidity and mortality in the tropics and is occasionally acquired in other countries, such as the UK. Two non-pathogenic *Entamoeba* species (*E. dispar* and *E. moshkovskii*) are morphologically identical to *E. histolytica*, and are distinguishable only by molecular techniques, isoenzyme studies or monoclonal antibody typing. However, only *E. histolytica* causes amoebic dysentery or liver abscess. The life cycle of the amoeba is shown in Figure 13.43A.

Pathology

Cysts of *E. histolytica* are ingested in water or uncooked foods contaminated by human faeces. Infection may also be acquired through anal/oral sexual practices. In the colon, vegetative trophozoite forms emerge from the cysts. The parasite may invade the mucous membrane of the large bowel, producing lesions that are maximal in the caecum but found as far down as the anal canal. These are flask-shaped ulcers, varying greatly in size and surrounded by healthy mucosa. A localised granuloma

Fig. 13.43 Amoebiasis. **A** The life cycle of *Entamoeba histolytica*. **B** The chocolate-brown appearance of aspirated material from an amoebic liver abscess.

(amoeboma), presenting as a palpable mass in the rectum or a filling defect in the colon on radiography, is a rare complication which should be differentiated from colonic carcinoma. Amoebic ulcers may cause severe haemorrhage but rarely perforate the bowel wall.

Amoebic trophozoites can emerge from the vegetative cyst from the bowel and be carried to the liver in a portal venule. They can multiply rapidly and destroy the liver parenchyma, causing an abscess (see also p. 972). The liquid contents at first have a characteristic pinkish colour which may later change to chocolate brown (like anchovy sauce).

Cutaneous amoebiasis, though rare, causes progressive genital, perianal or peri-abdominal surgical wound ulceration.

Clinical features

Intestinal amoebiasis—amoebic dysentery

Most amoebic infections are asymptomatic. The incubation period of amoebiasis ranges from 2 weeks to many years, followed by a chronic course with abdominal pains and two or more unformed stools a day. Offensive diarrhoea alternating with constipation, and blood or mucus in the stool, are common. There may be abdominal pain, especially right lower quadrant (which may simulate acute appendicitis). A dysenteric presentation with passage of blood, simulating bacillary dysentery or ulcerative colitis, occurs particularly in older people, in the puerperium and with superadded pyogenic infection of the ulcers.

Amoebic liver abscess

The abscess is usually found in the right hepatic lobe. There may not be associated diarrhoea. Early symptoms may be local discomfort only and malaise; later, a swinging temperature and sweating may develop, usually without marked systemic symptoms or associated cardiovascular signs. An enlarged, tender liver, cough and pain in the right shoulder are characteristic, but symptoms may remain vague and signs minimal. A large abscess may penetrate the diaphragm and rupture into the lung, from where its contents may be coughed up. Rupture into the pleural cavity, the peritoneal cavity or pericardial sac is less common but more serious.

Investigations

The stool and any exudate should be examined at once under the microscope for motile trophozoites containing red blood cells. Movements cease rapidly as the stool preparation cools. Several stools may need to be examined in chronic amoebiasis before cysts are found. Sigmoidoscopy may reveal typical flask-shaped ulcers, which should be scraped and examined immediately for *E. histolytica*. In endemic areas one-third of the population are symptomless passers of amoebic cysts.

An amoebic abscess of the liver is suspected on clinical grounds; there is often a neutrophil leucocytosis and a raised right hemidiaphragm on chest X-ray. Confirmation is by ultrasonic scanning. Aspirated pus from an amoebic abscess has the characteristic anchovy sauce or chocolate brown appearance but only rarely contains free amoebae (Fig. 13.43B).

Serum antibodies are detectable by immunofluorescence in over 95% of patients with hepatic amoebiasis

and intestinal amoeboma, but in only about 60% of dysenteric amoebiasis. DNA detection by PCR has been shown to be useful in diagnosis of *E. histolytica* infections but is not generally available.

Management

Intestinal and early hepatic amoebiasis responds quickly to oral metronidazole (800 mg 8-hourly for 5–10 days) or other long-acting nitroimidazoles like tinidazole or ornidazole (both in doses of 2 g daily for 3 days). Nitaxozanide (500 mg 12-hourly for 3 days) is an alternative drug. Either diloxanide furoate or paromomycin, in doses of 500 mg orally 8-hourly for 10 days after treatment, should be given to eliminate luminal cysts.

If a liver abscess is large or threatens to burst, or if the response to chemotherapy is not prompt, aspiration is required and is repeated if necessary. Rupture of an abscess into the pleural cavity, pericardial sac or peritoneal cavity necessitates immediate aspiration or surgical drainage. Small serous effusions resolve without drainage.

Prevention

Personal precautions against contracting amoebiasis consist of not eating fresh uncooked vegetables or drinking unclean water.

Giardiasis

Infection with *Giardia lamblia* is found world-wide and is common in the tropics. It particularly affects children, tourists and immunosuppressed individuals, and is the parasite most commonly imported into the UK. In cystic form it remains viable in water for up to 3 months and infection usually occurs by ingesting contaminated water. Its flagellar trophozoite form attaches to the duodenal and jejunal mucosa, causing inflammation.

Clinical features and investigations

After an incubation period of 1–3 weeks, there is diarrhoea, abdominal pain, weakness, anorexia, nausea and vomiting. On examination there may be abdominal distension and tenderness.

Stools obtained at 2–3-day intervals should be examined for cysts. Duodenal or jejunal aspiration by endoscopy gives a higher diagnostic yield. The 'string test' may be used, in which one end of a piece of string is passed into the duodenum by swallowing, retrieved after an overnight fast, and expressed fluid examined for the presence of *G. lamblia* trophozoites. A number of stool antigen detection tests are available. Jejunal biopsy specimens may show *G. lamblia* on the epithelial surface.

Management

Treatment is with a single dose of tinidazole 2 g, or metronidazole 400 mg 8-hourly for 10 days.

Cryptosporidiosis

Cryptosporidium spp. are coccidian protozoal parasites of humans and domestic animals. Infection is acquired by the faecal–oral route through contaminated water supplies. The incubation period is approximately 7–10 days, and is followed by watery diarrhoea and abdominal cramps. The illness is usually self-limiting, but in immunocompromised patients, especially those with HIV, the

illness can be devastating, with persistent severe diarrhoea and substantial weight loss (p. 393).

Cyclosporiasis

Cyclospora cayentanensis is a globally distributed coccidian protozoal parasite of humans. Infection is acquired by ingestion of contaminated water. The incubation period is approximately 2–11 days, and is followed by acute onset of diarrhoea with abdominal cramps, which may remit and relapse. Although usually self-limiting, the illness may last as long as 6 weeks with significant associated weight loss and malabsorption, and is more severe in immunocompromised individuals. Diagnosis is by detection of oöcysts on faecal microscopy. Treatment may be necessary in a few cases, and the agent of choice is co-trimoxazole 960 mg 12-hourly for 7 days.

INFECTIONS CAUSED BY HELMINTHS

Helminths (from the Greek *Helmins*, meaning worm) include three groups of parasitic worm (Box 13.62), large multicellular organisms with complex tissues and organs.

Intestinal human nematodes

Diseases are caused by adult nematodes living in the human gut. There are two types:

- the hookworms, which have a soil stage in which they develop into larvae that then penetrate the host
- a group of nematodes which survive in the soil merely as eggs that have to be ingested for their life cycle to continue.

The geographical distribution of hookworms is limited by the larval requirement for warmth and humidity. Soil-transmitted nematode infections can be prevented

by avoidance of faecal soil contamination (adequate sewerage disposal) or skin contact (wearing shoes), and by strict personal hygiene.

Ancylostomiasis (hookworm)

Ancylostomiasis is caused by parasitisation with *Ancylostoma duodenale* or *Necator americanus*. The complex life cycle is shown in Figure 13.44. The adult hookworm is 1 cm long and lives in the duodenum and upper jejunum. Eggs are passed in the faeces. In warm, moist, shady soil the larvae develop into rhabditiform and then the infective filariform stages; they then penetrate human skin and are carried to the lungs. After entering the alveoli they ascend the bronchi, are swallowed and mature in the small intestine, reaching maturity 4–7 weeks after infection. The worms attach themselves to the mucosa of the small intestine by their buccal capsule (Fig. 13.45) and withdraw blood. The mean daily

Fig. 13.44 Ancylostomiasis. Life cycle of *Ancylostoma*.

Fig. 13.45 *Ancylostoma duodenale*. Electron micrograph showing the ventral teeth.

13.62 Classes of helminth that parasitise humans

Nematodes or roundworms

- Intestinal human nematodes: *Ancylostoma duodenale*, *Necator americanus*, *Strongyloides stercoralis*, *Ascaris lumbricoides*, *Enterobius vermicularis*, *Trichuris trichiura*
- Tissue-dwelling human nematodes: *Wuchereria bancrofti*, *Brugia malayi*, *Loa loa*, *Onchocerca volvulus*, *Dracunculus medinensis*, *Mansonella perstans*, *Dirofilaria immitis*
- Zoonotic nematodes: *Trichinella spiralis*

Trematodes or flukes

- Blood flukes: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi*, *S. intercalatum*
- Lung flukes: *Paragonimus* spp.
- Hepatobiliary flukes: *Clonorchis sinensis*, *Fasciola hepatica*, *Opisthorchis felinus*
- Intestinal flukes: *Fasciolopsis buski*

Cestodes or tapeworms

- Intestinal tapeworms: *Taenia saginata*, *T. solium*, *Diphyllobothrium latum*, *Hymenolepis nana*
- Tissue-dwelling cysts or worms: *Taenia solium*, *Echinococcus granulosus*

loss of blood from one *A. duodenale* is 0.15 mL and from *N. americanus* 0.03 mL.

Hookworm infection is one of the main causes of anaemia in the tropics and subtropics. *A. duodenale* is endemic in the Far East and Mediterranean coastal regions, and is also present in Africa, while *N. americanus* is endemic in West, East and Central Africa, and Central and South America, as well as in the Far East.

Clinical features

An allergic dermatitis, usually on the feet (ground itch), may be experienced at the time of infection. The passage of the larvae through the lungs in a heavy infection causes a paroxysmal cough with blood-stained sputum, associated with patchy pulmonary consolidation and eosinophilia. When the worms have reached the small intestine, vomiting and epigastric pain resembling peptic ulcer disease may occur. Sometimes frequent loose stools are passed. The degree of iron and protein deficiency which develops depends not only on the load of worms but also on the nutrition of the patient and especially on the iron stores. Anaemia with high-output cardiac failure may result. The mental and physical development of children may be retarded in severe infection.

Investigations

There is eosinophilia. The characteristic ovum can be recognised in the stool. If hookworms are present in numbers sufficient to cause anaemia, faecal occult blood testing will be positive and many ova will be present.

Management

A single dose of albendazole (400 mg) is the treatment of choice. Alternatively, mebendazole 100 mg 12-hourly for 3 days may be used. Anaemia and heart failure associated with hookworm infection respond well to oral iron, even when severe; blood transfusion is rarely required.

Strongyloidiasis

Strongyloides stercoralis is a very small nematode (2 mm × 0.4 mm) which parasitises the mucosa of the upper part of the small intestine, often in large numbers, causing persistent eosinophilia. The eggs hatch in the bowel but only larvae are passed in the faeces. In moist soil they moult and become the infective filariform larvae. After penetrating human skin, they undergo a development cycle similar to that of hookworms, except that the female worms burrow into the intestinal mucosa and submucosa. Some larvae in the intestine may develop into filariform larvae, which may then penetrate the mucosa or the perianal skin and lead to autoinfection and persistent infection. Patients with *Strongyloides* infection persisting for more than 35 years have been described. Strongyloidiasis occurs in the tropics and subtropics, and is especially prevalent in the Far East.

Clinical features

These are shown in Box 13.63. The classic triad of symptoms consists of abdominal pain, diarrhoea and urticaria. Cutaneous manifestations, either urticaria or larva currens (a highly characteristic pruritic, elevated, erythematous lesion advancing along the course of larval migration), are characteristic and occur in 66% of patients.

13.63 Clinical features of strongyloidiasis

Penetration of skin by infective larvae

- Itchy rash

Presence of worms in gut

- Abdominal pain, diarrhoea, steatorrhoea, weight loss

Allergic phenomena

- Urticarial plaques and papules, wheezing, arthralgia

Autoinfection

- Transient itchy linear urticarial weals across abdomen and buttocks (larva currens)

Systemic (super)infection

- Diarrhoea, pneumonia, meningoencephalitis, death

Systemic strongyloidiasis (the *Strongyloides* hyperinfection syndrome), with dissemination of larvae throughout the body, occurs in association with immune suppression (intercurrent disease, HIV and HTLV-1 infection, corticosteroid treatment). Patients present with severe, generalised abdominal pain, abdominal distension and shock. Massive larval invasion of the lungs causes cough, wheeze and dyspnoea; cerebral involvement has manifestations ranging from subtle neurological signs to coma. Gram-negative sepsis frequently complicates the picture.

Investigations

There is eosinophilia. Serology (ELISA) is helpful, but definitive diagnosis depends upon finding the larvae. The faeces should be examined microscopically for motile larvae; excretion is intermittent so repeated examinations may be necessary. Larvae can also be found in jejunal aspirate or detected using the string test (p. 363). Larvae may also be cultured from faeces.

Management

Ivermectin 200 µg/kg as a single dose, or two doses of 200 µg/kg on successive days, is effective. Alternatively, albendazole is given orally in a dose of 15 mg/kg body weight 12-hourly for 3 days. A second course may be required. For the *Strongyloides* hyperinfection syndrome, ivermectin is given at 200 µg/kg on days 1, 2, 15 and 16.

Ascaris lumbricoides (roundworm)

This pale yellow nematode is 20–35 cm long. Humans are infected by eating food contaminated with mature ova. *Ascaris* larvae hatch in the duodenum, migrate through the lungs, ascend the bronchial tree, are swallowed and mature in the small intestine. This tissue migration can provoke both local and general hypersensitivity reactions, with pneumonitis, eosinophilic granulomas, bronchial asthma and urticaria.

Clinical features

Intestinal ascariasis causes symptoms ranging from occasional vague abdominal pain through to malnutrition. The large size of the adult worm and its tendency to aggregate and migrate can result in obstructive complications. Tropical and subtropical areas are endemic for ascariasis, and in these areas it causes up to 35% of all intestinal obstructions, most commonly in the terminal

ileum. Obstruction can be complicated further by intussusception, volvulus, haemorrhagic infarction and perforation. Other complications include blockage of the bile or pancreatic duct and obstruction of the appendix by adult worms.

Investigations

The diagnosis is made microscopically by finding ova in the faeces. Adult worms are frequently expelled rectally or orally. Occasionally, the worms are demonstrated radiographically by a barium examination. There is eosinophilia.

Management

A single dose of albendazole (400 mg), pyrantel pamoate (11 mg/kg; maximum 1 g), piperazine (4 g) or mebendazole (100 mg 12-hourly for 3 days) is effective for intestinal ascariasis. Patients should be warned that they might expel numerous whole, large worms. Obstruction due to ascariasis should be treated with nasogastric suction, piperazine and intravenous fluids.

Prevention

Community chemotherapy programmes have been used to reduce *Ascaris* infection. The whole community can be treated every 3 months for several years. Alternatively, schoolchildren can be targeted; treating them lowers the prevalence of ascariasis in the community.

Enterobius vermicularis (threadworm)

This helminth is common throughout the world. It affects mainly children. After the ova are swallowed, development takes place in the small intestine, but the adult worms are found chiefly in the colon.

Clinical features

The gravid female worm lays ova around the anus, causing intense itching, especially at night. The ova are often carried to the mouth on the fingers and so reinfection or human-to-human infection takes place (Fig. 13.46). In females the genitalia may be involved. The adult worms may be seen moving on the buttocks or in the stool.

Investigations

Ova are detected by applying the adhesive surface of cellophane tape to the perianal skin in the morning. This is then examined on a glass slide under the microscope. A perianal swab, moistened with saline, is an alternative sampling method.

Management

A single dose of mebendazole (100 mg), albendazole (400 mg), pyrantel pamoate (11 mg/kg) or piperazine (4 g) is given and may be repeated after 2 weeks to control auto-reinfection. If infection recurs in a family, each member should be treated as above. During this period all nightclothes and bed linen are laundered. Fingernails must be kept short and hands washed carefully before meals. Subsequent therapy is reserved for those family members who develop recurrent infection.

Trichuris trichiura (whipworm)

Infections with whipworm are common all over the world under unhygienic conditions. Infection is contracted by

Fig. 13.46 Threadworm. Life cycle of *Enterobius vermicularis*.

the ingestion of earth or food contaminated with ova which have become infective after lying for 3 weeks or more in moist soil. The adult worm is 3–5 cm long and has a coiled anterior end resembling a whip. Whipworms inhabit the caecum, lower ileum, appendix, colon and anal canal. There are usually no symptoms, but intense infections in children may cause persistent diarrhoea or rectal prolapse, and growth retardation. The diagnosis is readily made by identifying ova in faeces. Treatment is with mebendazole in doses of 100 mg 12-hourly for 3–5 days or a single dose of albendazole 400 mg.

Tissue-dwelling human nematodes

Filarial worms are tissue-dwelling nematodes. The larval stages are inoculated by biting mosquitoes or flies, each specific to a particular filarial species. The larvae develop into adult worms (2–50 cm long) which, after mating, produce millions of microfilariae (170–320 µm long) that migrate in blood or skin. The life cycle is completed when the vector takes up microfilariae while feeding on humans. In the insect, ingested microfilariae develop into infective larvae for inoculation in humans, normally the only host.

Disease is due to the host's immune response to the worms (both adult and microfilariae), particularly dying worms, and its pattern and severity vary with the site and stage of each species (Box 13.64). The worms are long-lived; microfilariae survive 2–3 years and adult worms 10–15 years. The infections are chronic and worst in individuals constantly exposed to reinfection.

Lymphatic filariasis

Infection with the filarial worms *Wuchereria bancrofti* and *Brugia malayi* is associated with clinical outcomes ranging from subclinical infection to hydrocele and elephantiasis.

W. bancrofti is transmitted by night-biting culicine or anopheline mosquitoes in most areas (Fig. 13.47). The adult worms, 4–10 cm in length, live in the lymphatics,

13.64 Pathogenicity of filarial infections depending on site and stage of worms

(+++ severe; ++ moderate; + mild; - rarely pathogenic)		

Fig. 13.47 *Wuchereria bancrofti* and *Brugia malayi*. Life cycle of organisms and pathogenesis of lymphatic filariasis.

and the females produce microfilariae which circulate in large numbers in the peripheral blood, usually at night. The infection is widespread in tropical Africa, the North African coast, coastal areas of Asia, Indonesia and northern Australia, the South Pacific islands, the West Indies and also in North and South America.

B. malayi is similar to *W. bancrofti* and is found in Indonesia, Borneo, Malaysia, Vietnam, South China, South India and Sri Lanka.

Pathology

Several factors contribute to the pathogenesis of lymphatic filariasis. Toxins released by the adult worm cause lymphangiectasia; this dilatation of the lymphatic vessels leads to lymphatic dysfunction and the chronic clinical manifestations of lymphatic filariasis, lymphoedema and hydrocele. Death of the adult worm results

in acute filarial lymphangitis. The filariae are symbiotically infected with rickettsia-like bacteria (*Wolbachia* spp.) and release of lipopolysaccharide from these bacteria contributes to inflammation. Lymphatic obstruction persists after death of the adult worm. Secondary bacterial infections cause tissue destruction. The host response to microfilariae is central to the pathogenesis of tropical pulmonary eosinophilia.

Clinical features

Acute filarial lymphangitis presents with fever, pain, tenderness and erythema along the course of inflamed lymphatic vessels. Inflammation of the spermatic cord, epididymis and testis is common. The whole episode lasts a few days but may recur several times a year. Temporary oedema becomes more persistent and regional lymph nodes enlarge. Progressive enlargement, coarsening, corrugation, fissuring and bacterial infection of the skin and subcutaneous tissue develop gradually, causing irreversible 'elephantiasis'. The scrotum may reach an enormous size. Chyluria and chylous effusions are milky and opalescent; on standing, fat globules rise to the top.

The acute lymphatic manifestations of filariasis must be differentiated from thrombophlebitis and infection. The oedema and lymphatic obstructive changes must be distinguished from congestive cardiac failure, malignancy, trauma and idiopathic abnormalities of the lymphatic system. Silicates absorbed from volcanic soil can also cause non-filarial elephantiasis.

Tropical pulmonary eosinophilia is a complication seen mainly in India and is likely to be due to microfilariae trapped in the pulmonary capillaries and destroyed by allergic inflammation. Patients present with paroxysmal cough, wheeze and fever. If untreated, this progresses to debilitating chronic interstitial lung disease.

Investigations

In the earliest stages of lymphangitis the diagnosis is made on clinical grounds, supported by eosinophilia and sometimes by positive filarial serology. Filarial infections cause the highest eosinophil counts of all helminthic infections.

Microfilariae can be found in the peripheral blood at night, and either are seen moving in a wet blood film or are detected by microfiltration of a sample of lysed blood. They are usually present in hydrocele fluid, which may occasionally yield an adult filaria. By the time elephantiasis develops, microfilariae become difficult to find. Calcified filariae may sometimes be demonstrable by radiography. Movement of adult worms can be seen on scrotal ultrasound. PCR-based tests for detection of *W. bancrofti* and *B. malayi* DNA from blood have been developed.

Indirect fluorescence and ELISA detect antibodies in over 95% of active cases and 70% of established elephantiasis. The test becomes negative 1–2 years after cure. Serological tests cannot distinguish the different filarial infections. Highly sensitive and specific immunochromatographic card tests for detection of filarial infection are now commercially available; finger prick blood taken at any time of the day can be used for these.

In tropical pulmonary eosinophilia, serology is strongly positive and IgE levels are massively elevated,

but circulating microfilariae are not found. The chest X-ray shows miliary changes or mottled opacities. Pulmonary function tests show a restrictive picture.

Management

Treatment of the individual is aimed at reversing and halting disease progression. Diethylcarbamazine (DEC) kills microfilariae and adult worms. The dose is 6mg/kg daily orally in three divided doses for 12 days. Most adverse effects seen with DEC treatment are due to the host response to dying microfilariae, and the reaction intensity is directly proportional to the microfilarial load. The main symptoms are fever, headache, nausea, vomiting, arthralgia and prostration. These usually occur within 24–36 hours of the first dose of DEC. Antihistamines or corticosteroids may be required to control these allergic phenomena. Both the 12-day course and a single dose of DEC reduce microfilaria levels by about 90% 6–12 months after treatment. No carefully controlled trials have evaluated the effects of DEC treatment alone on the chronic manifestations of lymphatic filariasis.

A single dose of either ivermectin (200 µg/kg) or albendazole (400mg) in combination with DEC (300mg) also eliminates microfilariae for 1 year. With the discovery of an endosymbiotic bacterium, *Wolbachia*, in most of the filarial worms, there is a possible role for doxycycline in eliminating the bacteria; the drug leads to interruption of embryogenesis and hence the production of microfilariae.

For tropical pulmonary eosinophilia, DEC (6mg/kg daily orally in three divided doses for 14 days) is the treatment of choice.

Chronic lymphatic pathology

Experience in India and Brazil shows that active management of chronic lymphatic pathology can alleviate symptoms. Patients should be taught meticulous skin care of their lymphoedematous limbs to prevent secondary bacterial and fungal infections. Tight bandaging, massage and bed rest with elevation of the affected limb may help to control the lymphoedema. Prompt diagnosis and antibiotic therapy of bacterial cellulitis are important in preventing further lymphatic damage and worsening of existing elephantiasis. Plastic surgery may be indicated in established elephantiasis. Great relief can be obtained by removal of excess tissue but recurrences are probable unless new lymphatic drainage is established. Hydroceles and chyluria can be repaired surgically.

Prevention

Treatment of the whole population in endemic areas with annual single-dose DEC (6mg/kg), either alone or in combination with albendazole or ivermectin, can reduce filarial transmission. This mass treatment should be combined with mosquito control programmes.

Loiasis

Loiasis is caused by infection with the filaria *Loa loa*. The adults, 3–7cm × 4mm, chiefly parasitise the subcutaneous tissue of humans, releasing larval microfilariae into the peripheral blood in the daytime. The vector is *Chrysops*, a forest-dwelling, day-biting fly.

The host response to *Loa loa* is usually absent or mild, so that the infection may be harmless. From time to

time a short-lived, inflammatory, oedematous swelling (a Calabar swelling) is produced around an adult worm. Heavy infections, especially when treated, may cause encephalitis.

Clinical features

The infection is often symptomless. The incubation period is commonly over a year but may be just 3 months. The first sign is usually a Calabar swelling, an irritating, tense, localised swelling that may be painful, especially if it is near a joint. The swelling is generally on a limb; it measures a few centimetres in diameter but sometimes is more diffuse and extensive. It usually disappears after a few days but may persist for 2 or 3 weeks. A succession of such swellings may appear at irregular intervals, often in adjacent sites. Sometimes there is urticaria and pruritus elsewhere. Occasionally, a worm may be seen wriggling under the skin, especially that of an eyelid, and may cross the eye under the conjunctiva, taking many minutes to do so.

Investigations

Diagnosis is by demonstrating microfilariae in blood taken during the day, but they may not always be found in patients with Calabar swellings. Antifilarial antibodies are positive in 95% of patients and there is massive eosinophilia. Occasionally, a calcified worm may be seen on X-ray.

Management

DEC (see above) is curative, in a dose of 9–12mg/kg daily which is continued for 21 days. Treatment may precipitate a severe reaction in patients with a heavy microfilaraemia characterised by fever, joint and muscle pain, and encephalitis; microfilaraemic patients should be given corticosteroid cover.

Prevention

Protection is afforded by building houses away from trees and by having dwellings wire-screened. Protective clothing and insect repellents are also useful. DEC in a dose of 5mg/kg daily for 3 days each month is partially protective.

Onchocerciasis (river blindness)

Onchocerciasis is the result of infection by the filarial *Onchocerca volvulus*. The infection is conveyed by flies of the genus *Simulium*, which breed in rapidly flowing, well-aerated water. Adult flies inflict painful bites during the day, both inside and outside houses. While feeding, they pick up the microfilariae, which mature into the infective larva and are transmitted to a new host in subsequent bites. Humans are the only known hosts (Fig. 13.48).

Onchocerciasis is endemic in sub-Saharan Africa, Yemen, and a few foci in Central and South America. It is estimated that 17.7 million people are infected, of whom 500 000 are visually impaired and 270 000 blind. Due to onchocerciasis huge tracts of fertile land lie virtually untitled, and individuals and communities are impoverished.

Pathology

After inoculation of larvae by a bite from an infected fly, the worms mature in 2–4 months and live for up to

Fig. 13.48 *Onchocerca volvulus*. Life cycle of organism and pathogenesis of onchocerciasis.

17 years in subcutaneous and connective tissues. At sites of trauma, over bony prominences and around joints, fibrosis may form nodules around adult worms which otherwise cause no direct damage. Innumerable microfilariae, discharged by the female *O. volvulus*, move actively in these nodules and in the adjacent tissues, are widely distributed in the skin, and may invade the eye. Live microfilariae elicit little tissue reaction, but dead ones may cause severe allergic inflammation leading to hyaline necrosis and loss of collagen and elastin. Death of microfilariae in the eye causes inflammation and may lead to blindness.

Clinical features

The infection may remain symptomless for months or years. The first symptom is usually itching, localised to one quadrant of the body and later becoming generalised and involving the eyes. Transient oedema of part or all of a limb is an early sign, followed by papular urticaria spreading gradually from the site of infection. This is difficult to see on dark skins, in which the most common signs are papules excoriated by scratching, spotty hyperpigmentation from resolving inflammation, and more chronic changes of a rough, thickened or inelastic, wrinkled skin. Both infected and uninfected superficial lymph nodes enlarge and may hang down in folds of loose skin at the groins. Hydrocele, femoral hernias and scrotal elephantiasis can occur. Firm subcutaneous nodules > 1 cm in diameter (onchocercomas) occur in chronic infection.

Eye disease is most common in highly endemic areas and is associated with chronic heavy infections and nodules on the head. Early manifestations include itching, lacrimation and conjunctival injection. These lead to conjunctivitis, sclerosing keratitis with pannus formation, uveitis which may lead to glaucoma and cataract, and, less commonly, choroiditis and optic neuritis.

Classically, 'snowflake' deposits are seen in the edges of the cornea.

Investigations

The finding of nodules or characteristic lesions of the skin or eyes in a patient from an endemic area, associated with eosinophilia, is suggestive. Skin snips or shavings, taken with a corneoscleral punch or scalpel blade from calf, buttock and shoulder, are placed in saline under a cover slip on a microscope slide and examined after 4 hours. Microfilariae are seen wriggling free in all but the lightest infections. Slit-lamp examination may reveal microfilariae moving in the anterior chamber of the eye or trapped in the cornea. A nodule may be removed and incised, showing the coiled, thread-like adult worm.

Filarial antibodies may be detected in up to 95% of patients. Several promising rapid strip tests based on antibody or antigen detection are under clinical evaluation. In patients with strong suspicion of onchocerciasis but negative tests, a provocative Mazzotti test, in which administration of 0.5–1.0 mg/kg of DEC exacerbates pruritus or dermatitis, strongly suggests onchocerciasis.

Management

Ivermectin, in a single dose of 100–200 µg/kg, repeated several times at 3-monthly intervals to prevent relapses, is recommended. It kills microfilariae, and is non-toxic and does not trigger severe reactions. In the rare event of a severe reaction causing oedema or postural hypotension, prednisolone 20–30 mg may be given daily for 2 or 3 days. Eradication of *Wolbachia* with doxycycline (100 mg daily for 6 weeks) prevents reproduction of the worm.

Prevention

Mass treatment with ivermectin is practised. It reduces morbidity in the community and prevents eye disease from getting worse. *Simulium* can be destroyed in its larval stage by the application of insecticide to streams. Long trousers, skirts and sleeves discourage the fly from biting.

Dracunculiasis (Guinea worm)

Infestation with the Guinea worm *Dracunculus medinensis* manifests itself when the female worm, over a metre long, emerges from the skin. Humans are infected by ingesting a small crustacean, *Cyclops*, which inhabits wells and ponds, and contains the infective larval stage of the worm. The worm was widely distributed across Africa and the Middle East but after a successful eradication programme is now seen only in sub-Saharan Africa.

Management and prevention

Traditionally, the protruding worm is extracted by winding it out gently over several days on a matchstick. The worm must never be broken. Antibiotics for secondary infection and prophylaxis of tetanus are also required.

A global elimination campaign is based on the provision of clean drinking water and eradication of water fleas from drinking water. The latter is being achieved by simple filtration of water through a plastic mesh filter and chemical treatment of water supplies.

Other filariases

Mansonella perstans

This filarial worm is transmitted by the midges *Culicoides austeni* and *C. grahami*. It is common throughout equatorial Africa as far south as Zambia, and also in Trinidad and parts of northern and eastern South America.

M. perstans has never been proven to cause disease but it may be responsible for a persistent eosinophilia and occasional allergic manifestations. *M. perstans* is resistant to ivermectin and DEC, and the infection may persist for many years.

Dirofilaria immitis

This dog heart worm infects humans, causing skin and lung lesions. It is not uncommon in the USA, Japan and Australia.

Zoonotic nematodes

Trichinosis (trichinellosis)

Trichinella spiralis is a nematode that parasitises rats and pigs, and is only transmitted to humans if they eat partially cooked infected pork, usually as sausage or ham. Bear meat is another source. Symptoms result from invasion of intestinal submucosa by ingested larvae, which develop into adult worms, and the secondary invasion of striated muscle by fresh larvae produced by these adult worms. Outbreaks have occurred in the UK, as well as in other countries where pork is eaten.

Clinical features

The clinical features of trichinosis are determined by the larval numbers. A light infection with a few worms may be asymptomatic; a heavy infection causes nausea and diarrhoea 24–48 hours after the infected meal. A few days later, the symptoms associated with larval invasion predominate: there is fever and oedema of the face, eyelids and conjunctivae; invasion of the diaphragm may cause pain, cough and dyspnoea; and involvement of the muscles of the limbs, chest and mouth causes stiffness, pain and tenderness in affected muscles. Larval migration may cause acute myocarditis and encephalitis. An eosinophilia is usually found after the 2nd week. An intense infection may prove fatal but those who survive recover completely.

Investigations

Commonly, a group of people who have eaten infected pork from a common source develop symptoms at about the same time. Biopsy from the deltoid or gastrocnemius after the 3rd week of symptoms in suspected cases may reveal encysted larvae. Serological tests are also helpful.

Management

Treatment is with albendazole 20mg/kg daily for 7 days. Given early in the infection, this may kill newly formed adult worms in the submucosa and thus reduce the number of larvae reaching the muscles. Corticosteroids are necessary to control the serious effects of acute inflammation.

Cutaneous larva migrans (CLM)

CLM is the most common linear lesion seen in travellers (Fig. 13.49). Intensely pruritic, linear, serpiginous lesions

Fig. 13.49 Cutaneous larva migrans.

result from the larval migration of the dog hookworm (*Ancylostoma caninum*). The track moves across the skin at a rate of 2–3cm/day. This contrasts with the rash of *Strongyloides* (p. 365), which is fast-moving and transient. Although the larvae of dog hookworms frequently infect humans, they do not usually develop into the adult form. The most common site for CLM is the foot but elbows, breasts and buttocks may be affected. Most patients with CLM have recently visited a beach where the affected part was exposed. The diagnosis is clinical. Treatment may be local with 12-hourly application of 15% thiabendazole cream, or systemic with a single dose of albendazole (400mg) or ivermectin (150–200 µg/kg).

Trematodes (flukes)

These leaf-shaped worms are parasitic to humans and animals. Their complex life cycles may involve one or more intermediate hosts, often freshwater molluscs.

Schistosomiasis

Schistosomiasis is one of the most important causes of morbidity in the tropics. There are five species of the genus *Schistosoma* which commonly cause disease in humans: *S. haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi* and *S. intercalatum*. *S. haematobium* was discovered by Theodor Bilharz in Cairo in 1861 and the disease is sometimes called bilharzia or bilharziasis. Schistosome eggs have been found in Egyptian mummies dated 1250 BC.

The life cycle is shown in Figure 13.50A. The ovum is passed in the urine or faeces of infected individuals and gains access to fresh water, where the ciliated miracidium inside it is liberated; it enters its intermediate host, a species of freshwater snail, in which it multiplies. Large numbers of fork-tailed cercariae are then liberated into the water, where they may survive for 2–3 days. Cercariae can penetrate the skin or the mucous membrane of the mouth of humans. They transform into schistosomulae and moult as they pass through the lungs; thence they are carried by the blood stream to the liver, and so to the portal vein, where they mature. The

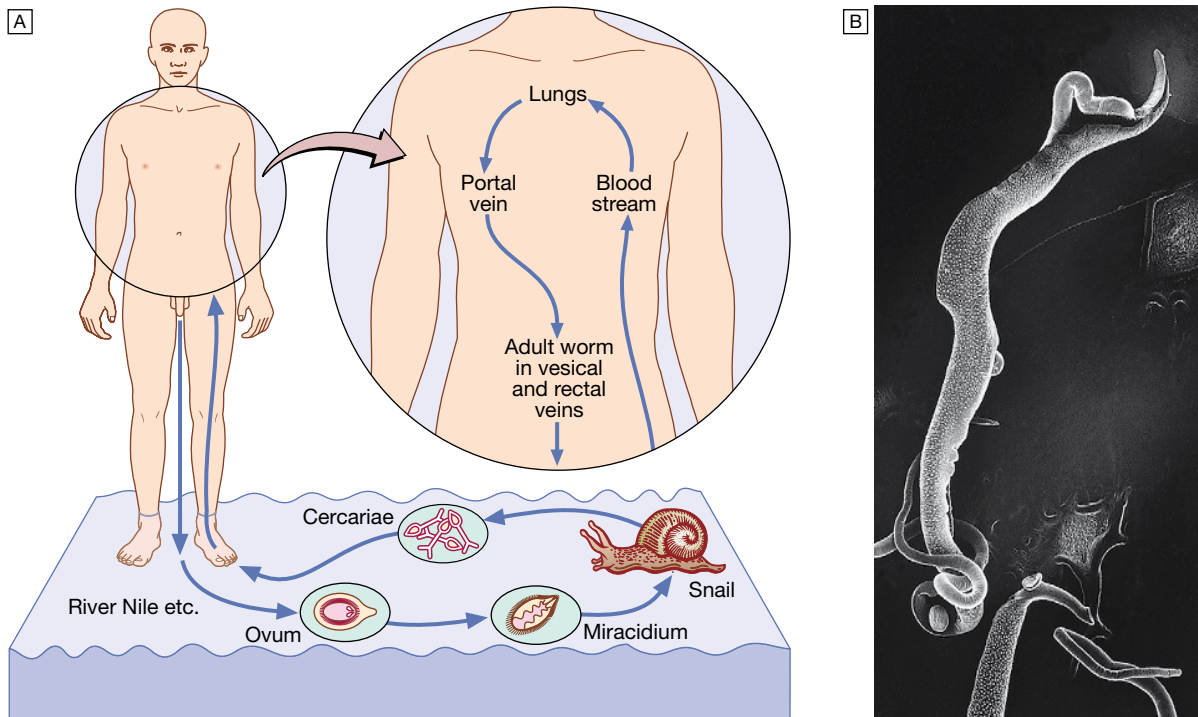

Fig. 13.50 *Schistosoma*. **A** Life cycle. **B** Scanning electron micrograph of adult schistosome worms showing the larger male worm embracing the thinner female.

male worm is up to 20 mm in length and the more slender cylindrical female, usually enfolded longitudinally by the male, is rather longer (Fig. 13.50B). Within 4–6 weeks of infection they migrate to the venules draining the pelvic viscera, where the females deposit ova.

Pathology

This depends on the species and the stage of infection (Box 13.65). Most disease is due to the passage of eggs through mucosa and to the granulomatous reaction to eggs deposited in tissues. The eggs of *S. haematobium* pass mainly through the wall of the bladder, but may also involve rectum, seminal vesicles, vagina, cervix and uterine tubes. *S. mansoni* and *S. japonicum* eggs pass mainly through the wall of the lower bowel or are carried to the liver. The most serious, although rare, site of ectopic deposition of eggs is in the CNS. Granulomas are composed of macrophages, eosinophils, and epithelioid and giant cells around an ovum. Later there is fibrosis and eggs calcify, often in sufficient numbers to become radiologically visible. Eggs of *S. haematobium* may leave the vesical plexus and be carried directly to the lung. Those of *S. mansoni* and *S. japonicum* may also reach the lungs after the development of portal hypertension and consequent portasystemic collateral circulation. In both circumstances egg deposition in the pulmonary vasculature, and the resultant host response, can lead to the development of pulmonary hypertension.

Clinical features

Recent travellers, especially those overlanding through Africa, may present with allergic manifestations and eosinophilia; residents of schistosomiasis-endemic areas

13.65 Pathogenesis of schistosomiasis

Time	<i>S. haematobium</i>	<i>S. mansoni</i> and <i>S. japonicum</i>
Cercarial penetration		
Days	Papular dermatitis at site of penetration	As for <i>S. haematobium</i>
Larval migration and maturation		
Weeks	Pneumonitis, myositis, hepatitis, fever, 'serum sickness', eosinophilia, seroconversion	As for <i>S. haematobium</i>
Early egg deposition		
Months	Cystitis, haematuria	Colitis, granulomatous hepatitis, acute portal hypertension
	Ectopic granulomatous lesions: skin, CNS etc. Immune complex glomerulonephritis	As for <i>S. haematobium</i>
Late egg deposition		
Years	Fibrosis and calcification of ureters, bladder: bacterial infection, calculi, hydronephrosis, carcinoma	Colonic polyposis and strictures, periportal fibrosis, portal hypertension
	Pulmonary granulomas and pulmonary hypertension	As for <i>S. haematobium</i>

are more likely to present with chronic urinary tract pathology or portal hypertension.

During the early stages of infection there may be itching lasting 1–2 days at the site of cercarial penetration. After a symptom-free period of 3–5 weeks, acute schistosomiasis (Katayama syndrome) may present with allergic manifestations such as urticaria, fever, muscle aches, abdominal pain, headaches, cough and sweating. On examination hepatomegaly, splenomegaly, lymphadenopathy and pneumonia may be present. These allergic phenomena may be severe in infections with *S. mansoni* and *S. japonicum*, but are rare with *S. haematobium*. The features subside after 1–2 weeks.

Chronic schistosomiasis is due to egg deposition and occurs months to years after infection. The symptoms and signs depend upon the intensity of infection and the species of infecting schistosome (see Box 13.65).

Schistosoma haematobium

Humans are the only natural hosts of *S. haematobium*, which is highly endemic in Egypt and East Africa, and occurs throughout Africa and the Middle East (Fig. 13.51). Infection can be acquired after a brief exposure, such as swimming in freshwater lakes in Africa.

Painless terminal haematuria is usually the first and most common symptom. Frequency of micturition follows, due to bladder neck obstruction. Later the disease may be complicated by frequent urinary tract infections, bladder or ureteric stone formation, hydronephrosis, and

ultimately renal failure with a contracted calcified bladder. Pain is often felt in the iliac fossa or in the loin, and radiates to the groin. In several endemic areas there is a strong epidemiological association of *S. haematobium* infection with squamous cell carcinoma of the bladder. Disease of the seminal vesicles may lead to haemospermia. Females may develop schistosomal papillomas of the vulva, and schistosomal lesions of the cervix may be mistaken for cancer. Intestinal symptoms may follow involvement of the bowel wall. Ectopic worms cause skin or spinal cord lesions.

The severity of *S. haematobium* infection varies greatly, and many with a light infection are asymptomatic. However, as adult worms can live for 20 years or more and lesions may progress, these patients should always be treated.

Schistosoma mansoni

S. mansoni is endemic throughout Africa, the Middle East, Venezuela, Brazil and the Caribbean (see Fig. 13.51).

Characteristic symptoms begin 2 months or more after infection. They may be slight, no more than malaise, or consist of abdominal pain and frequent stools which contain blood-stained mucus. With severe advanced disease, increased discomfort from rectal polyps may be experienced. The early hepatomegaly is reversible, but portal hypertension may cause massive splenomegaly, fatal haematemesis from oesophageal varices, or progressive ascites (p. 945). Liver function is initially preserved because the pathology is fibrotic rather than cirrhotic.

Fig. 13.51 Geographical distribution of schistosomiasis.

S. mansoni and other schistosoma infections predispose to the carriage of *Salmonella*, in part because *Salmonella* may attach to the schistosomes and in part because shared antigens on schistosomes may induce immunological tolerance to *Salmonella*.

Schistosoma japonicum, *S. mekongi* and *S. intercalatum*

In addition to humans, the adult worm of *S. japonicum* infects the dog, rat, field mouse, water buffalo, ox, cat, pig, horse and sheep. Although other *Schistosoma* spp. can infect species other than humans, the non-human reservoir seems to be particularly important in transmission for *S. japonicum* but not for *S. haematobium* or *S. mansoni*. *S. japonicum* is prevalent in the Yellow River and Yangtze-Jiang basins in China, where the infection is a major public health problem. It also has a focal distribution in the Philippines, Indonesia and Thailand (see Fig. 13.51). The related *S. mekongi* occurs in Laos, Thailand and Myanmar, and *S. intercalatum* in West and Central Africa.

The pathology of *S. japonicum* is similar to that of *S. mansoni*, but as this worm produces more eggs, the lesions tend to be more extensive and widespread. The clinical features resemble those of severe infection with *S. mansoni*, with added neurological features. The small and large bowel may be affected, and hepatic fibrosis with splenic enlargement is usual. Deposition of eggs or worms in the CNS, especially in the brain or spinal cord, causes symptoms in about 5% of infections, notably epilepsy, blindness, hemiplegia or paraplegia.

Investigations

There is marked eosinophilia. Serological tests (ELISA) are useful as screening tests but remain positive after chemotherapeutic cure.

In *S. haematobium* infection, dipstick urine testing shows blood and albumin. The eggs can be found by microscopic examination of the centrifuged deposit of terminal stream urine (Fig. 13.52). Ultrasound is useful for assessing the urinary tract; bladder wall thickening, hydronephrosis and bladder calcification can be detected. Cystoscopy reveals 'sandy' patches, bleeding mucosa and later distortion.

In a heavy infection with *S. mansoni* or *S. japonicum* the characteristic egg with its lateral spine can usu-

ally be found in the stool. When the infection is light or of long duration, a rectal biopsy can be examined. Sigmoidoscopy may show inflammation or bleeding. Biopsies should be examined for ova.

Management

The object of specific treatment is to kill the adult schistosomes and so stop egg-laying. Praziquantel is the drug of choice for all forms of schistosomiasis. The drug produces parasitological cure in 80% of treated individuals and over 90% reduction in egg counts in the remainder. Side-effects are uncommon but include nausea and abdominal pain. Praziquantel therapy in early infection reverses pathologies such as hepatomegaly and bladder wall thickening and granulomas.

Surgery may be required to deal with residual lesions such as ureteric stricture, small fibrotic urinary bladders, or granulomatous masses in the brain or spinal cord. Removal of rectal papillomas by diathermy or by other means may provide symptomatic relief.

Prevention

So far no satisfactory single means of controlling schistosomiasis has been established. The life cycle is terminated if the ova in urine or faeces are not allowed to contaminate fresh water containing the snail host. The provision of latrines and of a safe water supply, however, remains a major problem in rural areas throughout the tropics. Furthermore, *S. japonicum* has so many hosts besides humans that latrines would be of little avail. Annual mass treatment of the population helps against *S. haematobium* and *S. mansoni*, but this method has so far had little success with *S. japonicum*. Attack on the intermediate host, the snail, presents many difficulties and has not on its own proved successful on any scale. For personal protection, contact with infected water must be avoided.

Liver flukes

Liver flukes infect at least 20 million people and remain an important public health problem in many endemic areas. They are associated with abdominal pain, hepatomegaly and relapsing cholangitis. *Clonorchis sinensis* is a major aetiological agent of bile duct cancer. The three major liver flukes have similar life cycles and pathologies, as outlined in Box 13.66.

Other flukes of medical importance include lung and intestinal flukes (see Box 13.62, p. 364).

Cestodes (tapeworms)

Cestodes are ribbon-shaped worms which inhabit the intestinal tract. They have no alimentary system and absorb nutrients through the tegumental surface. The anterior end, or scolex, has suckers for attaching to the host. From the scolex arises a series of progressively developing segments, the proglottides, which, when shed, may continue to show active movements. Cross-fertilisation takes place between segments. Ova, present in large numbers in mature proglottides, remain viable for weeks and during this period they may be consumed by the intermediate host. Larvae liberated from the ingested ova pass into the tissues, forming larval cysticerci.

Tapeworms cause two distinct patterns of disease, either intestinal infection or systemic cysticercosis (Fig. 13.53).

Fig. 13.52 Ova of *Schistosoma haematobium* in urine. Note the terminal spine.

13.66 Diseases caused by flukes in the bile duct

	Clonorchiasis	Opisthorchiasis	Fascioliasis
Parasite	<i>Clonorchis sinensis</i>	<i>Opisthorchis felineus</i>	<i>Fasciola hepatica</i>
Other mammalian hosts	Dogs, cats, pigs	Dogs, cats, foxes, pigs	Sheep, cattle
Mode of spread	Ova in faeces, water	As for <i>C. sinensis</i>	Ova in faeces on to wet pasture
1st intermediate host	Snails	Snails	Snails
2nd intermediate host	Freshwater fish	Freshwater fish	Encysts on vegetation
Geographical distribution	Far East, especially S. China	Far East, especially NE Thailand	Cosmopolitan, including UK
Pathology	<i>E. coli</i> cholangitis, abscesses, biliary carcinoma	As for <i>C. sinensis</i>	Toxaemia, cholangitis, eosinophilia
Symptoms	Often symptom-free, recurrent jaundice	As for <i>C. sinensis</i>	Unexplained fever, tender liver, may be ectopic, e.g. subcutaneous fluke
Diagnosis	Ova in stool or duodenal aspirate	As for <i>C. sinensis</i>	As for <i>C. sinensis</i> , also serology
Prevention	Cook fish	Cook fish	Avoid contaminated watercress
Treatment	Praziquantel 25 mg/kg 8-hourly for 2 days	As for <i>C. sinensis</i> but for 1 day only	Triclabendazole 10 mg/kg single dose; repeat treatment may be required*

*In the UK, available from the Hospital for Tropical Diseases, London.

Taenia saginata (beef tapeworm) and *Diphyllobothrium latum* (fish tapeworm) cause only intestinal infection, following human ingestion of intermediate hosts that contain cysticerci (the larval stage of the tapeworm). *Taenia solium* causes intestinal infection if a cysticerci-containing intermediate host is ingested, and cysticercosis (systemic infection from larval migration) if ova are ingested. *Echinococcus granulosus* (dog tapeworm) does not cause human intestinal infection, but causes hydatid disease (which is analogous to cysticercosis) following ingestion of ova and subsequent larval migration.

Intestinal tapeworm

Humans acquire tapeworm by eating undercooked beef infected with the larval stage of *T. saginata*, undercooked pork containing the larval stage of *T. solium*, or undercooked freshwater fish containing larvae of *D. latum*. Usually only one adult tapeworm is present in the gut but up to ten have been reported. The ova of *T. saginata* and *T. solium* are indistinguishable microscopically. However, examination of scolex and proglottids can differentiate between them. *T. solium* has a rostellum and two rows of hooklets on the scolex, and discharges multiple proglottids (3–5) attached together with lower degrees of uterine branching (approximately 10); *T. saginata* has only four suckers in its scolex, and discharges single proglottids with greater uterine branching (up to 30).

Taenia saginata

Infection with *T. saginata* occurs in all parts of the world. The adult worm may be several metres long and produces little or no intestinal upset in human beings, but knowledge of its presence, by noting segments in the faeces or on underclothing, may distress the patient. Ova may be found in the stool. Praziquantel is the drug of choice; niclosamide or nitazoxanide are alternatives. Prevention depends on efficient meat inspection and the thorough cooking of beef.

Taenia solium

T. solium, the pork tapeworm, is common in central Europe, South Africa, South America and parts of Asia. It is not as large as *T. saginata*. The adult worm is found

Fig. 13.53 Cysticercosis. Life cycle of *Taenia solium*.

only in humans following the eating of undercooked pork containing cysticerci. Niclosamide, followed by a mild laxative (after 1–2 hours) to prevent retrograde intestinal autoinfection, is effective for intestinal infection. Cooking pork well prevents intestinal infection. Great care must be taken by nurses and other adults while attending a patient harbouring an adult worm to avoid ingestion of ova or segments.

Cysticercosis

Human cysticercosis is acquired by ingesting *T. solium* tapeworm ova, from either contaminated fingers or food (see Fig. 13.53). The larvae are liberated from eggs in the stomach, penetrate the intestinal mucosa and are carried to many parts of the body where they develop and form cysticerci, 0.5–1 cm cysts that contain the head of a young worm. They do not grow further or migrate. Common locations are the subcutaneous tissue, skeletal muscles and brain.

Clinical features

When superficially placed, cysts can be palpated under the skin or mucosa as pea-like ovoid bodies. Here they cause few or no symptoms, and will eventually die and become calcified.

Heavy brain infections, especially in children, may cause features of encephalitis. More commonly, however, cerebral signs do not occur until the larvae die, 5–20 years later. Epilepsy, personality changes, staggering gait or signs of internal hydrocephalus are the most common features.

Investigations

Calcified cysts in muscles can be recognised radiologically. In the brain, however, less calcification takes place

and larvae are only occasionally visible by plain X-ray; usually CT or MRI will show them. Epileptic fits starting in adult life suggest the possibility of cysticercosis if the patient has lived in or travelled to an endemic area. The subcutaneous tissue should be palpated and any nodule excised for histology. Radiological examination of the skeletal muscles may be helpful. Antibody detection is available for serodiagnosis.

Management and prevention

Albendazole, 15 mg/kg daily for a minimum of 8 days, has now become the drug of choice for parenchymal neurocysticercosis. Praziquantel is another option, 50 mg/kg in three divided doses daily for 10 days. Prednisolone, 10 mg 8-hourly, is also given for 14 days, starting 1 day before the albendazole or praziquantel. In addition, anti-epileptic drugs should be given until the reaction in the brain has subsided. Operative intervention is indicated for hydrocephalus. Studies from India and Peru suggest that most small solitary cerebral cysts will resolve without treatment.

Echinococcus granulosus (*Taenia echinococcus*) and hydatid disease

Dogs are the definitive hosts of the tiny tapeworm *E. granulosus*. The larval stage, a hydatid cyst, normally occurs in sheep, cattle, camels and other animals that are infected from contaminated pastures or water. By handling a dog or drinking contaminated water, humans may ingest eggs (Fig. 13.54). The embryo is liberated from the ovum in the small intestine and gains access to the blood stream and thus to the liver. The resultant cyst grows very slowly, sometimes intermittently. It is composed of an enveloping fibrous

Fig. 13.54 Hydatid disease. **A** Life cycle of *Echinococcus granulosus*. **B** Daughter cysts removed at surgery. **C** Within the daughter cysts are the protoscolices.

pericyst, laminated hyaline membrane (ectocyst) and inner germinal layers (endocyst) which gives rise to daughter cysts, or germinating cystic brood capsule in which larvae (protoscolices) develop. Over time some cysts may calcify and become non-viable. The disease is common in the Middle East, North and East Africa, Australia and Argentina. Foci of infection persist in rural Wales and Scotland. *E. multilocularis*, which has a cycle between foxes and voles, causes a similar but more severe infection, 'alveolar hydatid disease', which invades the liver like cancer.

Clinical features

A hydatid cyst is typically acquired in childhood and may, after growing for some years, cause pressure symptoms. These vary, depending on the organ or tissue involved. In nearly 75% of patients with hydatid disease the right lobe of the liver is invaded and contains a single cyst (p. 972). In others a cyst may be found in lung, bone, brain or elsewhere.

Investigations

The diagnosis depends on the clinical, radiological and ultrasound findings in a patient who has lived in close contact with dogs in an endemic area. Complement fixation and ELISA are positive in 70–90% of patients.

Management and prevention

Hydatid cysts should be excised wherever possible. Great care is taken to avoid spillage and cavities are sterilised with 0.5% silver nitrate or 2.7% sodium chloride. Albendazole (400mg 12-hourly for 3 months) should also be used. The drug is now often combined with PAIR (percutaneous puncture, aspiration, injection of scolicidal agent and re-aspiration) to good effect. Praziquantel 20mg/kg 12-hourly for 14 days also kills protoscolices perioperatively.

Prevention is difficult in situations where there is a close association with dogs and sheep. Personal hygiene, satisfactory disposal of carcasses, meat inspection and deworming of dogs can greatly reduce the prevalence of disease.

Other tapeworms

There are many other cestodes whose adult or larval stages may infect humans. Sparganosis is a condition in which an immature worm develops in humans, usually subcutaneously, as a result of eating or applying to the skin the secondary or tertiary intermediate host.

ECTOPARASITES

Ectoparasites only interact with the outermost surfaces of the host; see also pages 1273–1274

Jiggers (tungiasis)

This is widespread in tropical America and Africa, and is caused by the sand flea *Tunga penetrans*. The pregnant flea burrows into the skin around toes and produces large numbers of eggs. The burrows are intensely irritating and the whole inflammatory nodule should be removed with a sterile needle. Secondary infection of tunga lesions is common.

Myiasis

Myiasis is due to skin infestation with larvae of the South American botfly, *Dermatobia hominis*, or the African Tumbu fly, *Cordylobia anthropophaga*. The larvae develop in a subcutaneous space with a central sinus. This orifice is the air source for the larvae, and periodically the larval respiratory spiracles protrude through the sinus. Patients with myiasis feel movement within the larval burrow and can experience intermittent sharp, lancinating pains. Myiasis is diagnosed clinically and should be suspected with any furuncular lesion accompanied by pain and a crawling sensation in the skin. The larva may be suffocated by blocking the respiratory orifice with petroleum jelly and gently removing it with tweezers. Secondary infection of myiasis is remarkably infrequent and rapid healing follows removal of intact larvae.

FUNGAL INFECTIONS

Fungal infections, or mycoses, are classified as superficial, subcutaneous or systemic (deep), depending on the degree of invasion of the host. They are also classified by the kind of fungus which causes the infection, which may be a filamentous fungus (mould) or a yeast, or may vary between these two forms depending on the environmental conditions (dimorphic fungi; Fig. 13.55).

Superficial mycoses

Superficial cutaneous fungal infections caused by dermatophyte fungi are described in Chapter 27.

Candidiasis (thrush)

Superficial candidiasis is caused by *Candida* spp. yeasts (mainly *C. albicans*). Common disease manifestations include oropharyngeal (pp. 863 and 392) and vaginal candidiasis ('thrush'), intertrigo and chronic paronychia. Oral and vaginal thrush often follow treatment with broad-spectrum antibiotics. Intertrigo is characterised by inflammation in skin folds with surrounding 'satellite lesions'. Chronic paronychia is associated with occupations involving frequent wetting of the hands. Treatment of superficial candidiasis is mainly with topical antifungal azoles (pp. 157–158), with oral azoles reserved for refractory or recurrent disease (mainly thrush). Severe oropharyngeal and oesophageal candidiasis is a consequence of CD4+ T lymphocyte depletion/dysfunction, as in HIV infection (p. 392), and recurrent vaginal or penile candidiasis may be an early manifestation of diabetes mellitus.

Subcutaneous mycoses

Chromoblastomycosis

Chromoblastomycosis is a predominantly tropical or subtropical fungal disease caused by environmental dematiaceous (dark-pigmented) fungi, most commonly *Fonsecaea pedrosoi*. Other causes include *F. compacta*, *Cladophiala carrionii* and *Phialophora verrucosa*. The disease is a cutaneous/subcutaneous mycosis acquired by traumatic inoculation. Consequently, the most

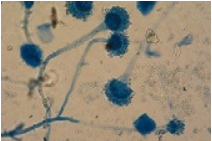

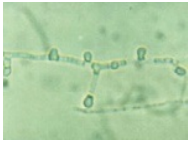

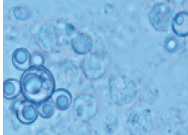

Filamentous fungi (moulds)	Dimorphic fungi	Yeasts

Fig. 13.55 Classification of medically important fungi. Fungal classification is based on simple morphological characteristics. *Pneumocystis jirovecii* (*carinii*) is morphologically distinct from other fungi and does not fit into this classification. *Candida albicans* is capable of hypha production and therefore is technically 'dimorphic'. However, in this classification scheme, 'dimorphic' is reserved for fungi for which transformation from hypha to yeast is associated with infection.

commonly affected areas are the foot, ankle and lower leg. Lesions may start several months after the initial injury, and medical attention is often sought several years later. The initial lesion is a papule. Further papules develop, and coalesce to form irregular plaques. Nodular lesions may produce a characteristic 'cauliflower' appearance.

Diagnosis is by histopathological examination of infected material, which shows dematiaceous, rounded, thick-walled 'sclerotic bodies' with septa at right angles to each other. The aetiological agent is confirmed by culture. Many therapeutic approaches have been explored, including antifungal agents, cryosurgery and surgical excision, alone or in combination, but the optimal therapy is unknown. Of the antifungal agents, itraconazole and terbinafine are considered to be the most effective. However, posaconazole has also been used with a good outcome.

Mycetoma

Mycetoma is a chronic suppurative infection of the deep soft tissues and bones, most commonly of the limbs but also of the abdominal or chest wall or head. It is caused by either aerobic or anaerobic branching Gram-positive bacilli, *Actinomycetales* (actinomycetoma—60%), or by true fungi, Eumycetes (eumycetoma—40%). Many fungi cause eumycetomas, the most common being *Madurella mycetomatis*, *M. grisea*, *Leptosphaera senegalensis* and *Scedosporium apiospermum*. Actinomycetomas are caused by *Actinomadura*, *Nocardia* and *Streptomyces* spp. Both groups produce characteristically coloured grains, the colour depending on the organism (black grains—eumycetoma, red and yellow grains—actinomycetoma,

white grains—either). The disease occurs mostly in the tropics and subtropics.

Clinical features

The disease is acquired by inoculation (e.g. from a thorn) and most commonly affects the foot (Madura foot). The mycetoma begins as a painless swelling at the site of implantation, which grows and spreads steadily within the soft tissues, causing further swelling and eventually penetrating bones. Nodules develop under the epidermis and these rupture, revealing sinuses through which grains (*Actinomycete*/fungal colonies) may be discharged. Some sinuses may heal with scarring while fresh sinuses appear elsewhere. Deeper tissue invasion and involvement of bone are rapid and greater in actinomycetoma than eumycetoma. There is little pain and usually no fever or lymphadenopathy, but there is progressive disability.

Investigations

Diagnosis is confirmed by demonstration of fungal grains in pus, and/or histopathological examination of tissue. Culture is necessary for species identification and (for actinomycetoma) susceptibility testing. Serological tests are not available.

Management

Eumycetoma is generally treated with surgery plus antifungal therapy, and actinomycetoma with antibacterial therapy alone. Antifungal therapy for eumycetoma depends on the specific fungus isolated. Itraconazole and ketoconazole (both 200–400 mg/day) are used commonly, and success has also been reported with

voriconazole and posaconazole. Therapy is continued for 6–12 months. In extreme cases amputation may be required.

In general actinomycetoma is treated with cotrimoxazole for several months. Disease caused by *Nocardia* spp. is treated with dapsone plus co-trimoxazole. In extensive disease amikacin or netilmicin may be added. Other agents, including minocycline, co-amoxiclav, streptomycin, imipenem and rifampicin, have been used successfully.

Phaeohyphomycosis

Phaeohyphomycosis is a heterogeneous group of fungal diseases caused by a large number (> 70) of dematiaceous fungi. In phaeohyphomycosis the tissue form of the fungus is predominantly mycelial (filamentous), as opposed to eumycetoma (grain) or chromoblastomycosis (sclerotic body). Disease may be superficial, subcutaneous or deep. The most serious manifestation is cerebral phaeohyphomycosis, which presents with a ring-enhancing, space-occupying cerebral lesion. Optimal therapy for this condition has not been established, but treatment usually consists of neurosurgical intervention and antifungal (usually triazole) therapy. Causative agents are *Cladophialophora bantiana*, *Fonsecaea* spp. and *Rhinocladiella* (formerly *Ramichloridium*) *mackenziei*, which occurs in the Middle East and is usually fatal.

Sporotrichosis

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungal saprophyte of plants in tropical and sub-tropical regions. Disease is caused by accidental dermal inoculation of the fungus, usually from a thorn (occasionally from a cat scratch). In fixed cutaneous sporotrichosis a subcutaneous nodule develops at the site of infection and subsequently ulcerates, with a purulent discharge. The disease may then spread along the cutaneous lymphatic channels, resulting in multiple cutaneous nodules along their route, which ulcerate and discharge (lymphocutaneous sporotrichosis). Rarer forms of disease are seen, for example, in patients with cutaneous disease presenting with arthritis. Later, draining sinuses may form. Pulmonary sporotrichosis occurs as a result of inhalation of the conidia and manifests itself as chronic cavitary fibronodular disease with haemoptysis and constitutional symptoms. Disseminated disease may occur, especially in patients with HIV.

Investigations

Typical yeast forms detected on histology of the biopsy confirm the diagnosis but are rarely seen; the fungus can be grown from the specimen in culture. A latex agglutination test is available to detect *S. schenckii* antibodies in serum.

Management

Cutaneous and lymphocutaneous disease is treated with oral itraconazole (200–400 mg daily, best absorbed as the oral solution formulation) for 3–6 months. Alternative agents include a saturated solution of potassium iodide (SSKI, given orally), initiated with 5 drops and increased to 40–50 drops 8-hourly, or terbinafine (500 mg 12-hourly). Localised hyperthermia may be used in pregnancy (to avoid azole use). Osteoarticular disease requires a longer course of therapy (≥ 12 months). Severe

or life-threatening disease is treated with amphotericin B (lipid formulation preferred).

Systemic mycoses

Aspergillosis

Aspergillosis is an opportunistic systemic mycosis, which affects predominantly the respiratory tract. It is described on page 696.

Candidiasis

Systemic candidiasis is an opportunistic mycosis caused by *Candida* spp. The most common cause is *C. albicans*. Other agents include *C. dubliniensis*, *C. glabrata*, *C. krusei*, *C. parapsilosis* and *C. tropicalis*. Species distribution varies geographically. *Candida* species identification often enables prediction of susceptibility to fluconazole; *C. krusei* is universally resistant, many *C. glabrata* isolates are either 'susceptible-dose dependent' (S-DD) or resistant, and other species are mostly susceptible. Candidiasis is usually an endogenous disease that originates from oropharyngeal, genitourinary or skin colonisation, although nosocomial spread has been reported.

Syndromes of systemic candidiasis

Acute disseminated candidiasis

This usually presents as candidaemia (isolation of *Candida* spp. from the blood). The main predisposing factor is the presence of a central venous catheter. Other major factors include recent abdominal surgery, total parenteral nutrition (TPN), recent antibiotic therapy and localised *Candida* colonisation. Up to 40% of cases will have ophthalmic involvement, with characteristic retinal 'cotton wool' exudates. As this is a sight-threatening condition, candidaemic patients should be assessed by detailed ophthalmoscopy. Skin lesions (non-tender pink/red nodules) may be seen. Although predominantly a disease of intensive care and surgical patients, acute disseminated candidiasis and/or *Candida* endophthalmitis is seen occasionally in injection drug-users, thought to be due to candidal contamination of citric acid or lemon juice used to dissolve heroin.

Chronic disseminated candidiasis (CDC, hepatosplenic candidiasis)

In this condition a neutropenic patient has a persistent fever despite antibacterial therapy. The fever persists despite neutrophil recovery, and is associated with the development of abdominal pain, raised alkaline phosphatase and multiple lesions in abdominal organs (e.g. liver, spleen and/or kidneys) on radiological imaging. CDC may represent an immune reconstitution inflammatory syndrome (IRIS, p. 136), and usually lasts for several months despite appropriate therapy.

Other manifestations

Renal tract candidiasis, osteomyelitis, septic arthritis, peritonitis, meningitis and endocarditis are all well recognised, and are usually sequelae of acute disseminated disease. Diagnosis and treatment of these conditions require specialist mycological advice.

Management

Blood cultures positive for *Candida* spp. must never be ignored. Acute disseminated candidiasis is treated with

antifungal therapy, removal of any in-dwelling central venous catheter (whether known to be the source of infection or not) and removal of any known source. Initial therapy is usually with fluconazole, unless the patient has recently received this agent, is known to be colonised with a resistant *Candida* strain, or is considered to be unstable (i.e. exhibiting signs of sepsis); in this case, an echinocandin (p. 158) is preferred. Therapy is adjusted according to clinical response, species involved and susceptibility testing, and continues for at least 14 days. Other appropriate therapies include voriconazole and amphotericin B formulations.

CDC is treated with fluconazole or other agents, depending on species and clinical response, and is prolonged (several months). There is some evidence that duration may be reduced by adjuvant therapy with systemic corticosteroids.

Cryptococcosis

Cryptococcosis is an opportunistic systemic mycosis caused by two environmental yeast species, *Cr. neoformans* and *Cr. gattii*. *Cr. neoformans* is distributed worldwide and causes opportunistic disease associated with many immunosuppressed states, predominantly HIV infection (p. 400). *Cr. gattii* is a primary pathogen, mainly of the tropics and subtropics.

Although the disease is acquired by inhalation of yeasts, isolated pulmonary disease is rare. The fungus may disseminate to any organ, most commonly the CNS (cryptococcal meningitis/cryptococcoma; Fig. 13.56) and skin. Cryptococcal meningitis is characterised by an indolent presentation with headache and visual loss. CSF is predominantly lymphocytic, although there may be few or no white blood cells, and frequently an elevated

opening pressure. Diagnosis is by direct detection or culture. Microscopy of infected specimens shows encapsulated yeasts (India ink test); cryptococcal antigen (capsular polysaccharide) may be detected in blood and/or CSF; or the organism may be cultured from blood, CSF or lesions (e.g. skin nodules, bone). Serological testing (i.e. antibody detection) is not appropriate.

Antifungal treatment of cryptococcal meningitis consists of induction therapy with intravenous amphotericin B (lipid formulation if available) and oral 5-flucytosine (5-FC), followed by consolidation therapy with an azole (usually fluconazole). Therapy with fluconazole is continued for as long as the patient has significant immunosuppression. If CSF pressure is elevated, regular lumbar drainage may be used to prevent features of raised intracranial pressure. Monitoring of recovery by changes in antigen titre is unreliable, and is not recommended.

Fusariosis

Fusarium spp. cause disseminated disease in patients with profound or prolonged neutropenia. The disease presents with antibiotic-resistant fever and evidence of dissemination (e.g. skin nodules, endophthalmitis, septic arthritis, pulmonary disease; Fig. 13.57). In contrast to *Aspergillus* spp., *Fusarium* spp. is often recovered from blood cultures. Treatment is challenging, because of resistance to several antifungal agents. Voriconazole, posaconazole and lipid-formulated amphotericin B are the most commonly used antifungal agents.

Mucormycosis

Mucormycosis is a severe but uncommon opportunistic systemic mycosis caused by any of the Mucorales, mainly *Myocladus* (formerly *Absidia*) spp., *Rhizomucor* spp., *Mucor* spp. and *Rhizopus* spp. Disease patterns include rhinocerebral/craniofacial, pulmonary, cutaneous and systemic disease. All are characterised by the rapid development of severe tissue necrosis, which is almost always fatal if left untreated. The major predisposing factors are uncontrolled diabetes mellitus, iron chelation therapy with desferrioxamine, severe burns and, most commonly, profound immunosuppression from neutropenia or bone marrow transplant in association with the use of broad-spectrum azole prophylaxis with agents like voriconazole.

Diagnosis is by culture, but histopathological confirmation is required as the fungi may be environmental contaminants. Treatment requires a combination of antifungal therapy and surgical débridement, with correction of predisposing factor(s) if possible. High-dose lipid-formulated amphotericin B is used most commonly, although posaconazole is active in vitro and has been used successfully.

Penicillium marneffei infection

P. marneffei is a thermally dimorphic pathogen (filamentous in environmental conditions and yeast at body temperature), which causes disease in South-east Asia, mainly in association with HIV infection (although immunocompetent patients may also be infected). Acquisition is most likely to be by inhalation of environmental spores, with primary lung infection followed by haematogenous dissemination. A generalised papular rash, which progresses to widespread necrosis and

Fig. 13.56 Cryptococcal disease. A 23-year-old HIV-positive male developed headache and left-sided weakness. **[A]** MRI scan of the brain showed a space-occupying lesion (arrow) with surrounding oedema. **[B]** Histopathological examination of the lesion stained with Grocott's silver stain showed encapsulated yeasts. *Cryptococcus neoformans* was cultured from the lesion.

Fig. 13.57 *Fusarium* infection. A patient presented with fever and skin nodules after a prolonged severe neutropenia secondary to acute myeloid leukaemia. **A** Skin nodule on her hand. **B** *Fusarium* sp. was cultured from skin scrapings and blood cultures (Gram's stain of blood culture medium).

ulceration, is a characteristic feature. Skin lesions may resemble those of molluscum contagiosum. Diagnosis is by histopathology and/or culture of respiratory secretions, blood or any infected clinical material (e.g. skin lesions, bone marrow, biopsies). Recommended treatment is with an amphotericin B formulation (in severe infection), followed by itraconazole.

Histoplasmosis

Histoplasmosis is a primary systemic mycosis caused by *Histoplasma capsulatum*, a dimorphic fungus. *H. capsulatum* is considered to consist of two variants, var. *capsulatum* and var. *duboisii*. *H. capsulatum* var. *capsulatum* is endemic to the Mississippi and Ohio river valleys and found throughout east-central USA. Less commonly, it is found in Latin America from Mexico to Argentina, Europe, Africa, India, Malaysia, Indonesia and Australia. *H. capsulatum* var. *duboisii* is found mainly in tropical parts of West Africa and Madagascar. The taxonomic status of *H. capsulatum* is subject to ongoing re-evaluation.

Habitat

The primary reservoir of *H. capsulatum* is soil enriched by bird and bat droppings, in which the fungus remains viable for many years. Infection is by inhalation of dust from such soil. Natural infections are found in bats, which represent a secondary reservoir of infection (via bat faeces). Histoplasmosis is a specific hazard for explorers of caves and people who clear out bird (including chicken) roosts.

Pathology

The organism is inhaled in the form of conidia (spores) or hyphal fragments and transforms to the yeast phase during infection. Conidia or yeasts are phagocytosed by alveolar macrophages and neutrophils, and this may be followed by haematogenous dissemination to any organ. Subsequent development of a T-lymphocyte response brings the infection under control, resulting in a latent state in most exposed individuals.

Clinical features

Disease severity depends on the quantity of spores inhaled and the immune status of the host. In most cases infection is asymptomatic. Pulmonary symptoms are the most common disease presentation, with fever, non-productive cough and an influenza-like illness. Erythema nodosum, myalgia and joint pain are common, and chest radiography may reveal a pneumonitis with hilar or mediastinal lymphadenopathy.

Patients with pre-existing lung disease, such as chronic obstructive pulmonary disease (COPD) or emphysema, may develop chronic pulmonary histoplasmosis. The predominant features of this condition, which may easily be mistaken for tuberculosis, are fever, cough, dyspnoea, weight loss and night sweats. Radiological findings include fibrosis, nodules, cavitation and hilar/mediastinal lymphadenopathy.

Disease caused by *H. capsulatum* var. *duboisii* presents more commonly with papulonodular and ulcerating lesions of the skin and underlying subcutaneous tissue and bone (sometimes referred to as 'African histoplasmosis'). Multiple lesions of the ribs are common and the bones of the limbs may be involved. Lung involvement is relatively rare. Radiological examination may show rounded foci of bone destruction, sometimes associated with abscess formation. Other disease patterns include a visceral form with liver and splenic invasion, and disseminated disease.

Acute disseminated histoplasmosis is seen in association with immunocompromise, including HIV infection. Features include fever, pancytopenia, hepatosplenomegaly, lymphadenopathy and often a papular skin eruption. Chronic disseminated disease presents with fever, anorexia and weight loss. Cutaneous and mucosal lesions, lymphadenopathy, hepatosplenomegaly and meningitis may also develop.

Investigations

In areas where the disease occurs, histoplasmosis should be suspected in every undiagnosed infection in which

there are pulmonary signs, enlarged lymph nodes, hepatosplenomegaly or characteristic cutaneous/bony lesions. Radiological examination in long-standing cases may show calcified lesions in the lungs, spleen or other organs. In the more acute phases of the disease, single or multiple soft pulmonary shadows with enlarged tracheobronchial nodes are seen on chest X-ray.

Laboratory diagnosis is by direct detection (histopathology or antigen detection), culture and serology, with antigen and antibody detection being most effective (antigen detection, however, is not widely available). Antibody is detected by complement fixation testing or immunodiffusion; the pattern of antibody production is complex, and the results require specialist interpretation. *Histoplasma* antigen may be detectable in blood or urine. Culture is definitive but slow (up to 12 weeks). Histopathology may show characteristic intracellular yeasts. Diagnosis of subcutaneous or bony infection is mainly by histopathological examination and/or culture.

Management

Mild pulmonary disease does not require treatment. However, if prolonged, it may be treated with itraconazole. More severe pulmonary disease is treated with an amphotericin B formulation for 2 weeks, followed by itraconazole for 12 weeks, with methylprednisolone added for the first 2 weeks of therapy if there is hypoxia or ARDS. Chronic pulmonary histoplasmosis is treated with itraconazole (ideally the oral solution, which has better bio-availability than the capsule formulation) for 12–24 months, and disseminated histoplasmosis with an amphotericin B formulation followed by itraconazole. Lipid formulations of amphotericin B are preferred, but their use is subject to availability. Treatment should be guided by current evidence-based guidelines (e.g. Infectious Diseases Society of America practice guidelines; www.idsociety.org). In subcutaneous and bone infection patterns of remission and relapse are more common than cure. A solitary bony lesion may require only local surgical treatment.

Coccidioidomycosis

This is a primary systemic mycosis caused by the dimorphic fungi *Coccidioides immitis* and *C. posadasii*, found in the south-western USA, and Central and South America. The disease is acquired by inhalation of conidia (arthrospores). In 60% of cases it is asymptomatic, but in the remainder it affects the lungs, lymph nodes and skin. Rarely (approx. 0.5%), it may spread haematogenously to bones, adrenals, meninges and other organs.

Pulmonary coccidioidomycosis has two forms: primary and progressive. If symptomatic, primary coccidioidomycosis presents with cough, fever, chest pain, dyspnoea and (commonly) arthritis and a rash (erythema multiforme). Progressive disease presents with systemic upset (e.g. fever, weight loss, anorexia) and features of lobar pneumonia, and may resemble tuberculosis.

Coccidioides meningitis (which may be associated with CSF eosinophils) is the most severe disease manifestation, which is fatal if untreated, and requires life-long suppressive therapy with antifungal azoles.

Investigations and management

Diagnosis is by direct detection (histopathological examination of infected tissue), culture of infected tissue or fluids, or antibody detection. IgM may be detected after 1–3 weeks of disease by precipitin tests. IgG appears later and is detected with the complement fixation test. Change in IgG titre may be used to monitor clinical progress.

Treatment depends on specific disease manifestations, and ranges from regular clinical re-assessment without antifungal therapy (in mild pulmonary, asymptomatic cavitory or single nodular disease) to high-dose treatment with an antifungal azole, which may be continued indefinitely (e.g. in meningitis). Amphotericin B is used in diffuse pneumonia, disseminated disease and, intrathecally, in meningitis. Posaconazole has been used successfully in refractory disease.

Paracoccidioidomycosis

This is a primary systemic mycosis caused by inhalation of the dimorphic fungus *Paracoccidioides brasiliensis* which is restricted to South America. The disease affects the lungs, mucous membranes (painful destructive ulceration in 50% of cases), skin, lymph nodes and adrenal glands (hypoadrenalism). Diagnosis is by microscopy and culture of lesions, and antibody detection. Oral itraconazole solution 200mg/day has demonstrated 98% efficacy, and is currently the treatment of choice (mean duration 6 months). Ketoconazole, fluconazole and voriconazole have also been used, as have long (2–3-year) courses of sulphonamides. Amphotericin B may be used in severe or refractory disease, followed by an azole or sulphonamide.

Blastomycosis

Blastomyces dermatitidis is a dimorphic fungus endemic to restricted parts of North America, mainly around the Mississippi and Ohio rivers. Very occasionally, it is reported from Africa. The disease usually presents as a chronic pneumonia similar to pulmonary tuberculosis. Bones, skin and the genitourinary tract may also be affected. Diagnosis is by culture of the organism or identification of the characteristic yeast form in a clinical specimen. Antibody detection is rarely helpful. Treatment is with amphotericin B (severe disease) or itraconazole.

Respiratory disease 395
Nervous system and eye disease 397
Miscellaneous conditions 401
HIV-related cancers 402

Management of HIV 403

Drugs 404
Treatment 405
Special situations 406
Prevention of HIV 407

1 HIV indicator presentations

- Herpes zoster, severe seborrhoeic dermatitis or psoriasis
- Tuberculosis, recurrent bacterial pneumonia (especially pneumococcal)
- Hepatitis B or hepatitis C
- Recurrent oral or vaginal candidiasis
- Anal cancer, lymphoma (Hodgkin or non-Hodgkin), Castleman's disease
- Aseptic meningitis, dementia
- Other HIV symptomatic disease (see Box 14.4, p. 390)
- Other AIDS-defining disease (see Box 14.5, p. 390)

Unexplained presentation

- Lymphadenopathy
- Pyrexia of unknown origin (PUO)
- Weight loss

Abnormal investigations

- Thrombocytopenia, lymphopenia or neutropenia

2 Pre-test counselling

- Discuss purpose of test
- Carry out risk assessment
- Explore knowledge and explain natural history of HIV
- Discuss transmission and risk reduction
- Assess likely coping strategy
- Explain test procedure
- Obtain informed consent

3 Laboratory confirmation

Serology using commercial ELISA screening test¹

- Test result negative:
Second test 3 months after last exposure
- Test result positive:
Result confirmed using two different immunoassays and/or Western blot
Second sample checked

Nucleic acid amplification test² if:

- Seroconversion suspected
- Confirming vertical transmission

¹ Commonly for HIV-1 antibody, HIV-2 antibody and p24 antigen.
² E.g. PCR or branched-chain DNA assay.
(ELISA = enzyme-linked immunosorbent assay; PCR = polymerase chain reaction)

6 Clinical examination

- See opposite.

5 Key history points

HIV (assessing time of HIV acquisition/likelihood of resistance)

- Previous negative HIV test
- History consistent with seroconversion
- Known HIV-infected ex-/current partner
- Episodes of 'unsafe' sex in high-risk situations (e.g. saunas)
- Previous antenatal screening
- Presence of 'HIV indicator disease'

General

- Birthplace, residence, occupation
- Tuberculosis: past history or contact
- Travel history/animal contacts
- Immunisation history (BCG, hepatitis A and B)
- Recreational drug use
- Past STIs
- Partner and children
- Others' knowledge of status (to contact if needed)
- GP awareness and permission to inform

4 Post-test counselling

Test result negative

- Discuss transmission and need for behaviour modification
e.g. Safer sex
Needle exchange
- Advise second test 3 months after last exposure
- Support if uninfected partner

Test result positive

- Explain significance and implications of result
- Organise urgent medical follow-up
- Assess coping strategy
e.g. Fear of disclosure
Discrimination/social rejection
- Provide verbal and written information
- Discuss confidentiality issues
- Organise emotional and practical support (provide names/phone numbers)

7 Baseline investigations

All

- CD4 count
- Viral load
- Hepatitis B (HBV) status
- Hepatitis C (HCV) antibody
- HIV resistance test
- Hepatitis A (HAV) IgG antibody
- *Toxoplasma* and cytomegalovirus (CMV) IgG antibody
- *Treponema* serology
- HLA-B*5701 screen for hypersensitivity to abacavir (p. 406)
- Lipid profile and urinalysis
- Cervical smear in women
- STI screen

Consider depending on ethnicity, exposure risk, CD4 count and baseline laboratory results

- Chest X-ray
- HCV-RNA
- Cryptococcal antigen
- CMV-PCR
- Dilated fundoscopy

8 Other issues

Immunisations

- Hepatitis A and hepatitis B if non-immune
- Pneumovax (at initial diagnosis and then 3–5-yearly)
- Influenza (yearly)
- Consider tetanus booster (if injection drug-user)

Counselling

- Safe sex/behaviour modification
- Cryptosporidial risk: need to boil water
- *Toxoplasma* risk: safe handling of cats/litter, avoidance of undercooked meat
- Live vaccines and travel
- Avoiding over-the-counter medicines if on highly active antiretroviral therapy (HAART)
- Planning pregnancy

Repeat tests

- *Treponemal* antibody 3–4 times/yr
- HBV markers every 1–2 yrs
- HCV antibody every 1–2 yrs
- HBV surface antibody in those immunised, to assess need for booster
- Cervical smear yearly
- *Toxoplasma* and CMV serology: if negative initially, check annually

EPIDEMIOLOGY AND BIOLOGY OF HIV

The acquired immunodeficiency syndrome (AIDS) was first recognised in 1981, although the earliest documented case has been traced to a blood sample from 1959. It is caused by the human immunodeficiency virus (HIV-1), which has evolved a number of mechanisms to elude immune control and has thereby prevented effective control of the epidemic. HIV-2 causes a similar illness to HIV-1 but is less aggressive and restricted mainly to western Africa. The origin of HIV is a non-human primate simian virus which probably passed from chimpanzees to humans via bush hunters. AIDS remains the second leading cause of disease burden world-wide and the leading cause of death in Africa, although downward trends in prevalence are occurring in several countries, partly as a result of effective prevention measures and partly due to scaling up of antiretroviral access. Highly active retroviral therapy (HAART) with three or more drugs has improved life expectancy to near normal in the majority of patients receiving it, with an 80% reduction of mortality since its introduction.

Global epidemic and regional patterns

In 2007, the World Health Organization (WHO) estimated that there were 33.2 million people living with HIV/AIDS, 2.5 million new infections and 2.1 million deaths (Fig. 14.1). The cumulative death toll since the epidemic began is over 20 million, the vast majority of cases occurring in sub-Saharan Africa where over 11.4 million children are now orphaned. In eight Southern African countries (Botswana, South Africa, Swaziland, Mozambique, Lesotho, Namibia, Zaire and Zimbabwe) the prevalence exceeds 15%, and for many others, such as Cameroon, Central African Republic and Cote d'Ivoire, it is over 5%. Between 2001 and 2007, the steepest increases have been seen in Asia (>90%) and Eastern Europe/Central Asia (150%), predominantly India, China, Russia and Ukraine. In South-east Asia, the epidemic is well developed but prevalence is falling in Thailand, Cambodia and Myanmar, although still increasing in Vietnam and Indonesia. In India, the national prevalence is 0.36% (varying from 0.07% in Uttar Pradesh to 1.13% in Manipur) and

it is estimated that 2.5 million persons were infected in 2006. Given that Asia is home to 60% of the world's population, these changes have huge implications.

Many different cultural, social and behavioural aspects determine the regional characteristics of HIV disease. Historically, the epidemic in North America and northern Europe has been in men who have sex with men (MSM), whereas in southern and Eastern Europe, Vietnam, Malaysia, Indonesia, North-east India and China the incidence has been greatest in injection drug-users. In Africa, the Caribbean and much of South-east Asia the dominant route of transmission remains heterosexual and from mother to child. However, the epidemic in many nations is changing. Heterosexual transmission has become a significant and often dominant route with racial and ethnic minorities representing an increasing fraction, largely as a consequence of the influx of migrants from high-prevalence countries. In the European Union (EU) in 2006, more than half of patients were infected heterosexually, with a doubling of new cases in the UK over the last 5 years. Additionally, there has been a 50% increase in reported new diagnoses in MSM, although some of this may be accounted for by an increased uptake in testing. It is of concern that around 30% of patients are unaware of their diagnosis and one-quarter of these present with late disease. This underlies the importance of having a low threshold to test individuals, especially when they present with any condition that has been associated with HIV.

The economic and demographic impact of HIV infection in developing countries is profound, as it affects those at their most economically productive and fertile age, and is also eroding the health and economic advances made in the last few decades. Although roll-out of drugs and access to care has improved dramatically recently, less than one-quarter of patients in many resource-poor countries are able to access antiretrovirals.

Modes of transmission

HIV is present in blood, semen and other body fluids such as breast milk and saliva. Exposure to infected fluid leads to a risk of contracting infection, which is dependent on

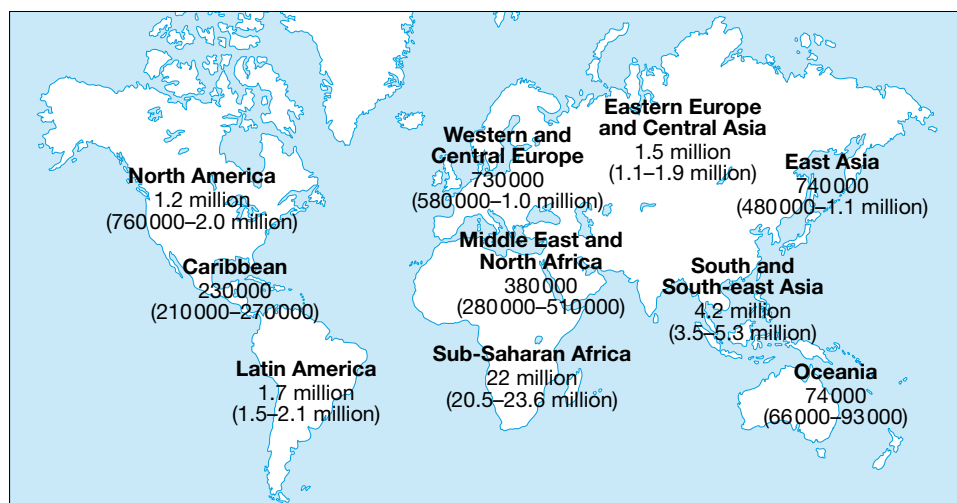

Fig. 14.1 World-wide distribution of HIV infection.

the integrity of the exposed site, the type and volume of body fluid, and the viral load. HIV can enter either as free virus or within cells. The modes of spread are sexual (man to man, heterosexual and oral), parenteral (blood or blood product recipients, injection drug-users and those experiencing occupational injury) and vertical. The transmission risk after exposure is over 90% for blood or blood products, 15–40% for the vertical route, 0.5–1.0% for injection drug use, 0.2–0.5% for genital mucous membrane spread and under 0.1% for non-genital mucous membrane spread. Box 14.1 outlines the important factors increasing the risk of acquisition and Box 14.2 how this information is used to target HIV testing.

World-wide, the major route of transmission (> 75%) is heterosexual. About 5–10% of new HIV infections are in children and more than 90% of these are infected during pregnancy, birth or breastfeeding. The rate of mother-to-child transmission is higher in developing countries (25–44%) than in industrialised nations (13–25%). Postnatal transmission via breast milk accounts for some of this increased risk. Of those infected vertically, 80% are infected close to the time of delivery and 20% in utero. Around 70% of patients with haemophilia A and 30% of those with haemophilia B had been infected through contaminated blood products by the time HIV antibody screening was adopted in the USA and Europe in 1985. In developed nations, because of routine antibody screening, the likelihood of acquiring HIV from blood products is now less than 1:500 000 and arises from donors in the seroconverting phase of infection. However, the WHO estimates that because of the lack of adequate screening

14.1 Factors increasing the risk of acquisition of HIV

Common to all transmission categories

- High viral load
- Lower CD4 cell count
- AIDS
- Seroconversion

Vertical transmission

- Older gestational age
- Prolonged rupture of membranes
- Chorioamnionitis
- Fetal trauma (e.g. scalp electrodes)
- Lower birth weight
- Vaginal vs. elective caesarean delivery
- No peripartum prophylaxis
- First-born twin

Breastfeeding

- Longer-duration feeding
- Lower parity
- Younger age
- Mastitis

Sexual transmission

- STIs, especially genital ulcers
- Cervical ectopy
- Receptive vs. insertive anal sex
- Rectal or vaginal trauma
- Menstruation
- Male–male vs. heterosexual sex
- Non-circumcised
- Increased number of partners

Injection drug use transmission

- Sharing equipment
- Frequency of use
- Linked commercial sex
- Lower income
- Intravenous use
- Cocaine use
- Incarceration

Occupational transmission

- Deep injury
- Visible blood on device
- Previous arterial or venous device siting

14.2 HIV testing

Services where testing is recommended to all

- Genitourinary medicine or sexual health
- Antenatal
- Termination of pregnancy
- Drug dependency
- Hepatitis B, hepatitis C, tuberculosis and lymphoma

Individuals to whom testing is routinely offered and recommended

- People known to be from a country of high HIV prevalence (> 1%), or their sexual partners
- Men who have sex with men (MSM)
- Commercial sex workers
- Patients with a sexually transmitted infection (STI)
- Sexual partners of HIV-positive individuals
- Health-care workers or transfusion recipients from a country of high HIV prevalence (> 1%)
- Those with possible primary HIV infection (e.g. mononucleosis-like syndrome)
- Those with history of injection drug use

Settings where testing should be considered

- Areas where diagnosed HIV prevalence exceeds 2 in 1000 population

facilities in resource-poor countries, 5–10% of blood transfusions globally are with HIV-infected blood. There have been approximately 100 definite and 200 possible cases of HIV acquired occupationally in health-care workers. Such infections are substantially more frequent in developing nations, where it is estimated that 40% of syringes/needles used in injections are reused without sterilisation.

Virology and immunology

HIV is a single-stranded RNA retrovirus from the Lenti-virus family. After mucosal exposure, HIV is transported to the lymph nodes via dendritic, CD4 T lymphocytes or Langerhans cells, where infection becomes established. Dendritic cells express various receptors (e.g. DC-SIGN) that facilitate capture and transport of HIV-1. Free or cell-associated virus is then disseminated widely through the blood with seeding of 'sanctuary' sites (e.g. central nervous system (CNS)) and latent CD4 cell reservoirs.

Each mature virion is spherical and has a lipid membrane lined by a matrix protein that is studded with glycoprotein (gp) 120 and gp41 spikes surrounding a cone-shaped protein core. This core houses two copies of the single-stranded RNA genome and viral enzymes. The virus infects the CD4 cell in a complicated sequence of events beginning with engagement of the viral gp120 and the CD4 cell receptor (stage 1, Fig. 14.2), which results in a conformational change in gp120. This permits interaction with one of two chemokine co-receptors (CXCR4 or CCR5: stage 2), which is followed by membrane fusion and cellular entry involving gp41 (stage 3). Monocyte-macrophages, follicular dendritic cells and microglial cells in the central nervous system also express the CD4 cell receptor and are permissive to infection.

After penetrating the cell and uncoating, a DNA copy is transcribed from the RNA genome by the reverse transcriptase (RT) enzyme (stage 4) that is carried by the

Stage	Steps in replication	Drug targets
1	Attachment to CD4 receptor

Fig. 14.2 Life cycle of HIV.

infecting virion. Reverse transcription is an error-prone process and multiple mutations arise with ongoing replication (hence the rapid generation of viral resistance to drugs). This DNA is transported into the nucleus and integrated randomly within the host cell genome via integrase enzyme (stage 5). Integrated virus is known as proviral DNA. On host-cell activation, this DNA copy is used as a template to transcribe new RNA copies (stage 6), which are processed and exported from the nucleus, viral mRNA then being translated into viral peptide chains (stage 7). The precursor polypeptides are then cleaved by the viral protease enzyme to form new viral structural proteins and viral enzymes such as the reverse transcriptase and protease. These then migrate to the cell surface and are assembled using the host cellular apparatus to produce infectious viral particles. These bud from the cell surface, incorporating the host cell membrane as their own lipid bilayer coat, and cell lysis occurs (stage 9). Once maturation is complete, the new infectious virus (virion) is then available to infect uninfected cells and repeat the process. All of these processes are enabled by three viral genes (*Gag*, *Pol* and *Env*), as well as the products of six regulatory genes (*Vif*, *Vpr*, *Vpu*, *Nef*, *Tat* and *Rev*). It has been calculated that each day more than 10^{10} virions are produced and 10^9 CD4 cells destroyed. This represents a daily turnover of 30% of the total viral burden and 6–7% of the total body CD4 cells.

A small percentage of T cells ($<0.01\%$) either produce small quantities of virus or enter a post-integration latent phase and represent the main reservoir of HIV. Together

with virion-associated immune complexes bound to follicular dendritic cells, they can refuel infection if host defences fail or HAART is discontinued. There is ongoing low-level replication within these cells, even when plasma levels of HIV are below the level of detection as a result of antiretroviral treatment. They are important as sanctuary sites from antiviral therapy, as continuing sources of virus (including the generation of drug-resistant strains) and as eventual targets for eradication strategies. The half-life of the virus is 1–2 hours in plasma, 1.5 days in productively infected CD4 cells and over 12 months in latently infected CD4 cells.

With time, there is gradual attrition of the CD4 cell population and, as CD4 cells are pivotal in orchestrating the immune response, any depletion renders the body susceptible to opportunistic infections and oncogenic virus-related tumours. The predominant opportunistic infections seen in HIV disease are intracellular parasites (e.g. *Mycobacterium tuberculosis*) or pathogens susceptible to cell-mediated rather than antibody-mediated immune responses. The exact mechanism underlying the CD4 decline is not fully understood, but it is not restricted to virus-infected cells and is linked to the height of plasma viral load. Both are monitored closely in patients and used as measures of disease progression. Virus-specific CD8 cytotoxic T lymphocytes develop rapidly after infection and are crucial in recognising, binding and lysing infected CD4 cells, thus controlling HIV replication after infection and the subsequent rate of disease progression.

On the basis of DNA sequencing, HIV-1 can be subdivided into group M ('major', world-wide distribution), group O ('outlier', divergent from group M) and group N ('non-major and non-outlier', highly divergent) types. Groups O and N are restricted to West Africa and may screen weakly positive or negative on routine antibody testing. Group M can be subdivided further into subtypes; 9 are currently recognised (A–K), with numerous subsubtypes (e.g. A1–A4) and circulating recombinant forms (e.g. CRF01_AE). Globally, subtype C (Africa and India) accounts for half of strains. Subtype A (Africa, Asia and Eastern Europe) and subtype B (Western Europe, the Americas and Australia) are responsible for approximately 10% each, and in many countries, more than one subtype or recombinant exists, or is emerging in restricted groups (e.g. West Africa, South-east Asia, southern Europe, and Russia). Increased HIV diversity has implications for diagnostic tests, treatments and vaccine development. It may also influence transmission (more frequent with subtype C), disease progression (faster with subtypes A and D), co-receptor usage (CXCR4 used early with subtype D) and emergent resistance patterns (subtype C). In Europe, the prevalence of non-B subtypes is increasing because of migrants (predominantly from Africa) and now accounts for a significant proportion of newly diagnosed infection. HIV-2 is an important but separate retrovirus which has at least five subtypes. The virus differs from HIV-1 in that patients have lower viral loads, slower CD4 decline, lower rates of vertical transmission and 12-fold lower progression to AIDS.

NATURAL HISTORY AND CLASSIFICATION OF HIV

Primary infection

Primary infection is symptomatic in 70–80% of cases and usually occurs 2–6 weeks after exposure. The major clinical manifestations are listed in Box 14.3. Rarely, presentation may be with neurological features (pp. 397–401). This coincides with high plasma HIV-RNA levels and a fall in the CD4 count to 300–400 cells/mm³, but occasionally to below 200 (Fig. 14.3) when opportunistic infections

14.3 Clinical features of primary infection

- Fever with rash
- Pharyngitis with cervical lymphadenopathy
- Myalgia/arthralgia
- Headache
- Mucosal ulceration

(e.g. oropharyngeal candidiasis, *Pneumocystis jirovecii* pneumonia (PCP)) may rarely occur. Symptomatic recovery parallels the return of the CD4 count (although this rarely recovers to its previous value) and fall in the viral load. In many patients, the illness is mild and only identified on retrospective enquiry at later presentation.

Diagnosis is made by detecting HIV-RNA in the serum or by immunoblot assay (which shows antibodies developing to early proteins). The appearance of specific anti-HIV antibodies in serum (seroconversion) takes place later at 3–12 weeks (median 8 weeks). Factors likely to indicate faster disease progression are the presence and duration of symptoms, evidence of candidiasis, and neurological involvement. The level of the viral load post-seroconversion correlates with subsequent progression of disease. The differential diagnosis of primary HIV includes acute Epstein-Barr virus (EBV), cytomegalovirus (CMV), streptococcal pharyngitis, toxoplasmosis and secondary syphilis.

Asymptomatic infection

Asymptomatic infection (category A disease in the Centers for Disease Control (CDC) classification) follows and lasts for a variable period, during which the infected individual remains well with no evidence of disease except for the possible presence of persistent generalised lymphadenopathy (PGL, defined as enlarged glands at ≥2 extra-inguinal sites). At this stage the bulk of virus replication takes place within lymphoid tissue (e.g. follicular dendritic cells). There is sustained viraemia with a decline in CD4 count dependent on the height of the viral load but usually between 50 and 150 cells/year (see Fig. 14.3).

Mildly symptomatic disease

Mildly symptomatic disease (CDC classification category B disease) then develops in the majority, indicating

Fig. 14.3 Virological and immunological progression of HIV infection. (ARC = AIDS-related complex)

14.4 HIV symptomatic/indicator diseases

- Oral hairy leucoplakia
- Recurrent oropharyngeal candidiasis
- Recurrent vaginal candidiasis
- Severe pelvic inflammatory disease
- Bacillary angiomatosis
- Cervical dysplasia
- Idiopathic thrombocytopenic purpura
- Weight loss
- Chronic diarrhoea
- Herpes zoster
- Peripheral neuropathy
- Low-grade fever/night sweats

14.5 AIDS-defining diseases

- Oesophageal candidiasis
- Cryptococcal meningitis
- Chronic cryptosporidial diarrhoea
- Cerebral toxoplasmosis
- CMV retinitis or colitis
- Chronic mucocutaneous herpes simplex
- Disseminated *Mycobacterium avium intracellulare* (MAI)
- Pulmonary or extrapulmonary tuberculosis
- *Pneumocystis jirovecii* (carinii) pneumonia
- Progressive multifocal leucoencephalopathy
- Recurrent non-typhi *Salmonella* septicaemia
- Extrapulmonary coccidioidomycosis
- Invasive cervical cancer
- Extrapulmonary histoplasmosis
- Kaposi's sarcoma
- Non-Hodgkin lymphoma
- Primary cerebral lymphoma
- HIV-associated wasting
- HIV-associated dementia

some impairment of cellular immunity but which is not AIDS-defining (Box 14.4). The median interval from infection to the development of symptoms is around 7–10 years, although subgroups of patients exhibit 'fast' or 'slow' rates of progression.

Acquired immunodeficiency syndrome (AIDS)

AIDS (CDC classification category C disease) is defined by the development of specified opportunistic infections, tumours and presentations (Box 14.5). Box 14.6 outlines the correlation between CD4 count and HIV-related diseases.

PRESENTING PROBLEMS IN HIV INFECTION

Before discussion of these, it is important to understand the principles of HAART, described in detail on pages 404–407. Initial HAART is introduced when the CD4 count falls below 350 cells/mm³ or an AIDS-defining illness develops. Over 85% of cases achieve complete virological suppression by 3 months, a steady increase in CD4 count and a return to good health. Occasionally, patients with low CD4 counts can experience immune reconstitution disease (IRD). This indicates either sub-clinical infection which has become manifest with HAART, or an enhanced reaction to dying or dead microorganisms which results in clinical illness.

14.6 Correlations between CD4 count and HIV-associated diseases

- Lymphoma
- CMV

with other pathologies and be harder to manage than in an HIV-negative patient. Type and severity of rash are often dependent upon the level of CD4 count. The presence of either oropharyngeal candidiasis or oral hairy leucoplakia in a young person is suggestive of HIV infection. Anyone with an unusual rash, especially one persistent and unresponsive to topical antifungal/corticosteroid combinations, or in the presence of severe immune compromise ($CD4 < 50$ cells/mm³), merits a skin biopsy for histology and culture.

Specific skin conditions

Fungal infections

Early HIV-associated skin diseases include xerosis with pruritus, seborrhoeic dermatitis, and an itchy folliculitic rash which may be fungal (*Malassezia furfur*), staphylococcal or eosinophilic in aetiology. Dermatophyte infection affecting skin (feet, body and face) and nails is also common, and may be extensive and difficult to treat. Seborrhoeic dermatitis is very common in HIV and is present in up to 80% of patients with AIDS; severity increases as the CD4 count falls. It presents as dry scaly red patches on the face (typically on the cheeks, in the nasolabial folds, around the eyebrows, behind the ears and on the scalp). The cause is multifactorial but *M. furfur* is important. It responds well to a combined topical antifungal/steroid.

Viral infections

The major viral infections affecting the skin are herpes simplex, varicella zoster (VZV), human papillomavirus (HPV) and molluscum contagiosum.

Herpes simplex (type 1 or 2). This may affect the lips, mouth and skin or anogenital area and is seen in 20% of cases. In later-stage HIV, the lesions are usually chronic, extensive, harder to treat and recurrent. Persistent and severe anogenital ulceration is usually herpetic and a marker for underlying HIV (Fig. 14.4).

VZV. This usually presents with a dermatomal vesicular rash on an erythematous base, and may be the first clue to a diagnosis of HIV infection. It can occur at any stage but is more frequent with failing immunity. In patients with a CD4 count < 100 cells/mm³, the rash may be more severe, multidermatomal, persistent or recurrent, or may become disseminated. Involvement of the trigeminal nerve, scarring on recovery and associated motor defects are probably also more common. Diagnosis of herpetic infection can be confirmed by culture, smear preparations showing characteristic inclusion bodies, electron microscopy or biopsy. Treatment should be given for all cases of active disease, irrespective of the time since onset of rash. In patients with severe mucocutaneous herpes simplex or herpes zoster which is disseminated, multiderma-

Fig. 14.4 Severe mucocutaneous herpes simplex. Perianal or perioral infection is not uncommon in later-stage HIV infection.

tomal, ophthalmic or very dense, or when the CD4 count is < 200 cells/mm³, parenteral aciclovir must be used.

HPV infection. This is frequent amongst HIV patients and is usually anogenital; disease may be extensive and very difficult to manage. Warts on the hands and feet (especially periungual) are also common and may attain considerable size, requiring surgery. Occasionally, myriads of flat-topped papules occur over the body and face. Both oncogenic (16, 18, 31, 33) and non-oncogenic (6, 11) genotypes are found. There is often improvement on HAART.

Molluscum contagiosum. This is an epidermal poxvirus infection. It is found in approximately 10% of AIDS patients. The lesions are usually 2–5 mm diameter papules with a central umbilicus and most frequently affect the face, neck, scalp and genital region (p. 384). Lesions may become widespread and attain a large size (giant mollusca). Treatment is with curettage or cryotherapy, and with improvement in CD4 counts, lesions usually disappear.

Bacterial and parasitic infections

Bacterial infections include *Staphylococcus aureus* (folliculitis, cellulitis and abscesses), bacillary angiomatosis and syphilis (primary and secondary, p. 417). Bacillary angiomatosis is a bacterial infection due to the cat-scratch bacillus, *Bartonella henselae*. Skin lesions range from solitary superficial reddish-purple lesions resembling Kaposi's sarcoma or pyogenic granuloma, to multiple subcutaneous nodules or even hyperpigmented plaques. Lesions are painful and may bleed or ulcerate. The infection may become disseminated with fevers, lymphadenopathy and hepatosplenomegaly. Diagnosis is made by biopsy of a lesion and Warthin–Starry silver staining which reveals aggregates of bacilli. Treatment with doxycycline or azithromycin is effective.

In HIV, scabies (due to the mite *Sarcoptes scabiei*, p. 1273) may cause intensely pruritic, encrusted papules affecting most areas. Classically, the interdigital web spaces, wrists, periumbilical area, buttock and sides of the feet are involved. Commonly in HIV the infestation may be heavy, the rash hyperkeratotic (Norwegian scabies) and the patient highly infectious. Uniquely, the face and neck are often affected.

Rarely, cutaneous disease may be a manifestation of mycobacterial infection (tuberculosis or an atypical mycobacterium) or disseminated fungal infection.

Papular pruritic eruption is an itchy symmetrical rash affecting the extremities and resulting in

hyper-/hypopigmentation. It is seen mainly in those from sub-Saharan Africa where it is the most common skin manifestation of HIV, and is highly indicative of HIV when present. Topical steroids, emollients and antihistamines are useful but response is variable.

Specific oral conditions

Candidiasis

Candida infection in HIV is almost exclusively mucosal, affecting nearly all patients with CD4 counts < 200 cells/mm³. In early disease, it is nearly always caused by *C. albicans* (p. 376). Pseudomembranous candidiasis describes white patches on the buccal mucosa that can be scraped off to reveal a red raw surface (p. 384). The tongue, palate and pharynx may also be involved. Less common is erythematous candidiasis; patients present with a sore mouth, reddened mucosa and a smooth shiny tongue. Hypertrophic candidiasis (leucoplakia-like lesions which do not scrape off but respond to antifungal treatment) and angular cheilitis may also be present.

Diagnosis is clinical but it is important to perform a mouth swill for culture, speciation and sensitivities in patients unresponsive to fluconazole or other azole drugs. The cause is usually *C. albicans*. Prophylaxis is not recommended and therapeutic courses of azoles should be given with each attack.

Oesophageal infection may coexist, although no oropharyngeal candidiasis is visible in up to 30%. Up to 80% of patients with pain on swallowing have *Candida* oesophagitis (see Fig. 14.6 below for differential diagnosis), with pseudomembranous plaques visible on barium swallow and endoscopy (Fig. 14.5). The pain is usually associated with dysphagia and, when untreated, leads to weight loss. Treatment is with an oral azole drug,

Fig. 14.5 Oesophageal candidiasis. Endoscopy may show pseudomembranous plaques or extensive confluent infection.

usually fluconazole. Where azole-resistant *Candida* is present, caspofungin or amphotericin can be used.

Oral hairy leucoplakia

Oral hairy leucoplakia appears as corrugated white plaques running vertically on the side of the tongue, and is virtually pathognomonic of HIV disease in the context of HIV risk factors (p. 385). It is usually asymptomatic and does not require treatment. The aetiology is closely associated with EBV. High-dose aciclovir or valaciclovir is sometimes effective in eradicating the infection but relapse often follows cessation of treatment.

Kaposi's sarcoma

This is discussed on page 402.

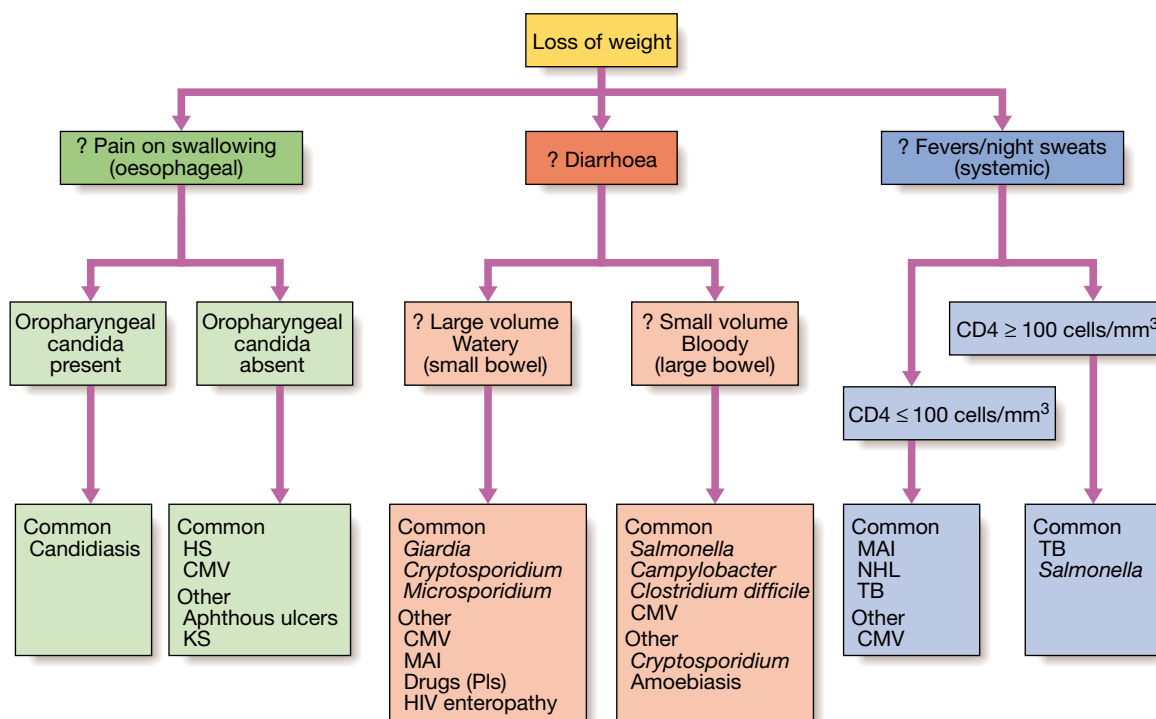

Fig. 14.6 Presentation and differential diagnosis of HIV-related gastrointestinal disorders. (CMV = cytomegalovirus; HS = herpes simplex; KS = Kaposi's sarcoma; MAI = *Mycobacterium avium intracellulare*; NHL = non-Hodgkin lymphoma; PI = protease inhibitor; TB = tuberculosis)

Gastrointestinal disease

Pain on swallowing, weight loss and chronic diarrhoea are common presenting features of later-stage HIV. A range of opportunistic organisms and HIV-related tumours may be responsible (Fig. 14.6).

Specific conditions

Cytomegalovirus (CMV) (Box 14.9)

Gastrointestinal CMV is now infrequent and is only seen if the CD4 count is < 100 cells/mm³ (usually < 50). It may cause disease throughout the entire gastrointestinal tract,

including the liver and biliary tree, but most commonly affects the oesophagus, where it accounts for 10–20% of disease, and the colon.

Cryptosporidium and Microsporidium

Cryptosporidium (Box 14.10 and Fig. 14.6) is a highly contagious zoonotic protozoal enteric pathogen that infects a wide range of animals.

Microsporidia are water-borne zoonoses, of which four main species infect humans: *Encephalitozoon bienersi*, *E. hellem*, *E. cuniculi* and *E. intestinalis*. They are intracellular spore-forming protozoa which cause a mild inflammatory infiltrate and are carried by a wide range of animals, birds and fish.

Both *Cryptosporidium* and *Microsporidium* complete their life cycle in a single host. Together they account for 10–20% of cases of diarrhoea in HIV patients. This may vary from a mild illness to severe diarrhoea, and may be complicated by malabsorption and biliary disease. Encephalitis, sinusitis, and ocular and disseminated infection may rarely occur with *E. intestinalis*.

i

14.9 CMV oesophagitis and colitis

Epidemiology	Reactivation of latent herpes virus infection Develops in $< 5\%$ of patients
At-risk CD4 count	< 100 cells/mm ³
Pathology	Intracellular and intracytoplasmic 'owl's-eye' inclusion bodies pathognomonic
Clinical features	
Presentation	2–4-wk history <i>Oesophageal</i> : gradual onset of localised pain on swallowing, retrosternal pain, dysphagia, fever and weight loss <i>Colitis</i> : watery diarrhoea often accompanied by blood, colicky abdominal pain, weight loss and fever
Suspect if	<i>Oesophageal</i> : empirical fluconazole fails <i>Colitis</i> : pathogen-negative bloody diarrhoea or thickened dilated bowel on X-ray
Differential diagnosis	<i>Oesophageal</i> : <i>Candida</i> , herpes simplex, aphthous ulcers, lymphoma, KS <i>Colitis</i> : standard enteric pathogens
Complications	<i>Oesophageal</i> : strictures <i>Colitis</i> : toxic megacolon, haemorrhage and perforation
Key investigations and diagnosis	
Endoscopy	<i>Oesophageal</i> : large shallow erosions/ulcers distally with inflammation at ulcer edge <i>Colitis</i> : generalised hyperaemia to segmental or confluent shallow or deep ulcers. 20% have disease proximal to splenic flexure so colonoscopy preferable
Blood	CMV viraemia in high titre
Tissue biopsy	Evidence of inclusion bodies and CMV on immunofluorescence/PCR. May be seen in the absence of clinical disease
Management	
Treatment	<i>Induction</i> : First-line: i.v. ganciclovir or oral valganciclovir for 3 wks <i>Maintenance</i> : valganciclovir Commence/optimize HAART (p. 404) Consider stopping CMV therapy when CD4 > 100 cells/mm ³ , CMV and HIV viral loads undetectable, and on HAART
Prophylaxis	Not recommended; consider if recurrent relapses with persistently low CD4 count
Prognosis	Good if uncomplicated and immune restoration

i

14.10 Cryptosporidiosis

Epidemiology	Most common species are <i>C. hominis</i> , <i>C. parvum</i> and <i>C. meleagridis</i> . Transmitted through ingestion of <i>Cryptosporidium</i> oöcysts from animals or contaminated water. Resistant to standard chlorination
At-risk CD4 count	< 100 cells/mm ³
Pathology	Intracellular extracytoplasmic protozoan on brush border
Clinical features	
Presentation	History is acute or subacute Large-volume watery stools, vomiting, abdominal pain and weight loss
Suspect if	Watery stools negative for standard pathogens
Differential diagnosis	Giardiasis, microsporidiosis
Complications	Cholera-like illness and malabsorption. Rarely, acalculous cholecystitis, sclerosing cholangitis, pancreatitis and pneumonitis
Key investigations and diagnosis	
Faeces	Oöcysts by acid-fast stain or antigen testing on microscopy in 90%. Electron microscopy increases yield
Other	Duodenal biopsy if stools negative (see Fig. 14.7) ERCP or MRCP if sclerosing cholangitis possible
Management	
Treatment	Commence/optimize HAART Some effect with nitazoxanide or azithromycin and paromomycin Anti-motility agents Stop therapy on completion of treatment course and CD4 restoration > 200 cells/mm ³
Prevention/prophylaxis	Boil water if CD4 < 200 cells/mm ³
Prognosis	Good with immune restoration

Fig. 14.7 Cryptosporidial infection. Duodenal biopsy may be necessary to confirm cryptosporidiosis or microsporidiosis.

Diagnosis is usually made by stool microscopy, although duodenal biopsy (Fig. 14.7) is occasionally necessary. Electron microscopy is essential for speciation of microsporidia. Although treatment for cryptosporidiosis (see Box 14.10) and microsporidiosis (albendazole \pm itraconazole for *E. intestinalis* and nitazoxanide or fumagillin for *E. bienersi*) may be effective, reconstitution of the immune system with HAART is the most important component of treatment and offers the best chance of cure.

Other infections

Isospora (Africa and Latin America) and *Cyclospora* (Asia) cause watery diarrhoea, weight loss and malabsorption akin to *Cryptosporidium*, accounting overall for 2–4% of cases in the UK. Diagnosis is by stool microscopy and treatment for both is co-trimoxazole. *Giardia*, *Entamoeba histolytica*, adenovirus and bacterial overgrowth also occur more frequently in HIV patients. Of the standard enteric pathogens, *Salmonella* is important because of the increased probability of bacteraemia and recurrent disease.

Mycobacterium avium intracellulare (MAI)

Until the introduction of HAART and primary prophylaxis, disseminated MAI (Box 14.11) occurred in up to 35% of all patients. Like other opportunistic infections, the incidence has now fallen but it remains a problem in late-stage AIDS, especially those cases that are newly diagnosed. Patients present with fever and weight loss. Combination antibacterial therapy is essential to prevent resistance, but reconstitution of the immune system with HAART is necessary for cure.

Liver disease

Hepatitis B and hepatitis C

The importance of hepatitis B and C co-infection is increasingly recognised. For both HBV and HCV, co-infection is associated with higher HBV or HCV viral loads, accelerated natural progression to cirrhosis (5–8 years after infection), an increased rate of hepatoma and higher mortality. Hepatitis B and C are further described on pages 948–954.

Hepatitis B

The majority of those with HIV have evidence of HBV exposure. HBV carriage rate depends on the mode of

i

14.11 *Mycobacterium avium intracellulare*

Epidemiology	Due to environmental <i>M. avium</i> complex via GI and respiratory routes
At-risk CD4 count	< 50 cells/mm ³
Pathology	Heavy mycobacterial load with little inflammatory response on microscopy. Reticuloendothelial system bears the major burden of infection
Clinical features	
Presentation	History over weeks to months Fever, sweats, weight loss, anorexia, chronic diarrhoea and abdominal pain. Hepatosplenomegaly and lymphadenopathy
Suspect if	PUO and weight loss with low CD4 count
Differential diagnosis	TB, lymphoma, cryptococcosis, histoplasmosis, CMV
Complications	Focal disease: oral ulceration, arthritis/osteomyelitis, endophthalmitis, pericarditis or pulmonary disease
Key investigations and diagnosis	
Culture of sterile specimens	Mycobacterial stain and liquid culture of blood (> 95% positive) or bone marrow, liver or duodenal biopsy Speciation using DNA probes or conventional tests confirms mycobacterium as MAI
Culture of non-sterile specimens	Sputum and faeces: not diagnostic
CT	Abdominal lymphadenopathy
Other	Anaemia, leucopenia, \uparrow alkaline phosphatase, hypoalbuminaemia
Management	
Treatment	<i>First-line:</i> clarithromycin or azithromycin, ethambutol, rifabutin Ciprofloxacin or moxifloxacin, and amikacin if treatment failure or resistance Commence/optimize HAART Stop therapy after 12 mths, CD4 restoration to > 100 cells/mm ³ and on suppressive HAART
Immune restoration syndrome	Common on starting HAART. Usually focal disease, particularly lymphadenitis
Prophylaxis	<i>Primary:</i> CD4 < 50 cells/mm ³ <i>First-line:</i> azithromycin weekly
Prognosis	5% mortality

acquisition, place of birth and ethnic group (reflecting vertical transmission), immunisation history (although response rates are lower in HIV patients) and likelihood of immune clearance after infection. Although HBV co-infected patients have more aggressive disease, the immunosuppression seen in more advanced HIV affords some protection because hepatic damage is immune-mediated. Treatment with antivirals should be considered for all patients who have active viral replication (HBVAg-positive or HBV-DNA > 2000 U/mL) and/or evidence of inflammation, fibrosis or scarring on

liver biopsy. When the CD4 is ≥ 500 cells/mm³ and in the absence of cirrhosis, pegylated interferon or adefovir can be considered. Otherwise, antivirals should ordinarily be used. A combination of either lamivudine (3TC) or emtricitabine (FTC) with tenofovir and an additional anti-HIV drug provides effective anti-HIV and anti-HBV treatment. A flare of hepatitis may be associated with improved immune function consequent to HAART or interruption of therapy and rebound HIV viraemia. All patients should be immunised against HAV.

Hepatitis C

Most patients with HCV have acquired their infection from injection drug use but increasingly acute infection is being seen in MSM. The major determinant of co-infection rate is the mode of acquisition: > 80% for haemophiliacs, 70–80% for injection drug-users, 10–15% for MSM and 3–5% for heterosexuals. Only 15–20% of patients ever clear their initial infection, but this rate is higher in females, those with higher CD4 counts, and those with raised transaminases. Response to 12 months' combination therapy with pegylated α -interferon and weight-based ribavirin is dependent on the HCV genotype (approximately 65% with genotypes 2 or 3 as opposed to approximately 27% with other genotypes), HCV viral load, CD4 count and the presence of cirrhosis; those acutely infected also have an improved response rate. HIV treatment is usually initiated first to optimise the CD4 count to ≥ 350 cells/mm³. Because of interactions with ribavirin, some nucleotide reverse transcriptase inhibitors (ZDV, didanosine (ddI) and possibly abacavir, p. 404) should be avoided if HAART is being co-administered. Therapy may be associated with a flare of hepatitis because of improved immune responsiveness. All patients should be screened for HBV and HAV, and immunised if not protected.

Respiratory disease

Many patients with HIV will develop pulmonary disease at some time. Several factors influence the likely cause, including CD4 count, ethnicity, age, risk group, prophylactic history and geographical location. The history is vital in discriminating acute bacterial pneumonia (rapid onset, pleuritic chest pain, rigors) from *Pneumocystis jirovecii* pneumonia (subacute onset, breathlessness, dry cough), a common differential in later-stage disease. The chest X-ray is also important in distinguishing presenting syndromes (Box 14.12).

14.12 Differential diagnosis of HIV-related pulmonary disease: chest X-ray findings

Appearance	Major causes
Diffuse infiltrate	PCP pneumonia, tuberculosis, Kaposi's sarcoma, non-Hodgkin lymphoma, atypical bacterial pneumonia, lymphoid interstitial pneumonitis
Nodules/focal consolidation	Tuberculosis, Kaposi's sarcoma, non-Hodgkin lymphoma, <i>Cryptococcus</i> , <i>Histoplasma</i>
Hilar lymphadenopathy	Tuberculosis, Kaposi's sarcoma, non-Hodgkin lymphoma; <i>Cryptococcus</i> , <i>Histoplasma</i>
Pleural effusion	Kaposi's sarcoma, tuberculosis, pyogenic bacterial pneumonia, primary effusion lymphoma

Specific conditions

Pneumocystis jirovecii

Pneumocystis jirovecii (previously *carinii*) pneumonia (PCP, Box 14.13) was the first major indicator disease for HIV at the beginning of the epidemic, and still

14.13 *Pneumocystis* pneumonia

Epidemiology	Caused by <i>P. jirovecii</i> . Likely to represent reinfection from other humans by respiratory transmission
At-risk CD4 count	< 200 cells/mm ³ , with risk increasing as count falls
Pathology	Extracellular fungus with cyst, merozoite and trophozoite morphology. Cannot be cultured but cyst and trophozoite can be visualised by (e.g.) Giemsa, silver or immunofluorescence stains Causes interstitial plasma cell pneumonia with 'foamy' exudates in the alveoli
Clinical features	
Presentation	History over days to weeks Progressive and disproportionate exertional dyspnoea, fever, dry cough and difficulty in taking deep breath Few signs on auscultation
Suspect if	Subacute history of fever, cough and breathlessness, or failure to respond to antibiotics
Differential diagnosis	TB, Kaposi's sarcoma, unusual fungi (<i>Histoplasma</i> , <i>Penicillium</i> , <i>Cryptococcus</i> , <i>Coccidioides</i>), atypical pneumonia, <i>Nocardia</i> and lymphoma
Complications	Respiratory failure, pneumothorax, bacterial superinfection, extrapulmonary disease (rare)
Key investigations and diagnosis	
Chest X-ray	Normal early <i>Moderate disease</i> : perihilar interstitial haze <i>Severe disease</i> : white-out with relative sparing of apices and costophrenic angles
Sputum	Positive cytology or PCR on induced sputum (50–90%), or bronchoalveolar lavage (90–95%)
Other	Raised lactate dehydrogenase (LDH); O ₂ saturations < 90% on exercise PaO ₂ reduced (mild > 11 kPa; moderate 8.1–11 kPa; severe < 8 kPa)
Management	
Treatment	<i>First-line</i> : co-trimoxazole for 3 wks <i>Second-line</i> : clindamycin and primaquine Steroids for moderate to severe disease. CPAP and ventilation/ICU may be necessary Commence/optimize HAART Stop therapy when CD4 > 200 cells/mm ³ for 3 mths on HAART
Immune restoration syndrome	Rare but described
Prophylaxis	Primary prophylaxis when CD4 < 200/mm ³ <i>First-line</i> : co-trimoxazole <i>Second-line</i> : dapsone or atovaquone
Prognosis	10% mortality, 5% morbidity

Fig. 14.8 *Pneumocystis pneumonia*: typical chest X-ray appearance. Note the sparing at the apex and base of both lungs.

accounts for 25% of AIDS-defining illness. The incidence of PCP has fallen dramatically with HAART and primary prophylaxis. Presentation is with fever, breathlessness, and dry cough, and other markers of

HIV (e.g. oropharyngeal candidiasis or mucocutaneous herpes simplex) may be present. The chest X-ray is usually typical (Fig. 14.8), but 20% are atypical with unilateral infiltration, upper lobe disease (often when on inhaled pentamidine prophylaxis), focal consolidation, cavitation or nodular shadows. Clinical and radiological deterioration within the first 48 hours of treatment is not uncommon.

Mycobacterium tuberculosis

Tuberculosis (TB) is the most common global infection (p. 688), affecting up to one-third of the estimated 40 million HIV patients (Boxes 14.14 and 14.15). Estimated annual new case and death rates (8 million and 2 million respectively) are expected to continue

14.14 Tuberculosis in HIV

Patients with HIV are at greater risk of:

- Infection after exposure
- Progressive primary disease after infection
- Reactivation of latent infection
- Reinfection with new strain
- Disseminated and extrapulmonary (e.g. meningeal and pericardial) disease
- Adverse drug reactions

14.15 Pulmonary tuberculosis

Epidemiology	Due to <i>M. tuberculosis</i> , <i>M. bovis</i> or <i>M. africanum</i> <i>Mycobacterium</i> enhances HIV replication and acceleration of the disease; HIV causes immunosuppression and increases risk of reactivation and susceptibility to infection	Sputum	Organisms seen on Ziehl–Neelsen and auramine stains, and grown by radiometric culture Nucleic acid amplification allows rapid speciation and identification of rifampicin resistance; also used in smear-negative samples to increase diagnostic yield
At-risk CD4 count	Any, with risk increasing as count falls	Other	Positive mycobacterial cultures from blood identified in 50% of those with CD4 < 200 cells/mm ³
Pathology	Granulomas and caseating necrosis	Management	
Clinical features		Treatment	<i>First-line:</i> rifampicin, isoniazid, ethambutol and pyrazinamide for 2 mths, then rifampicin and isoniazid for 4 mths. Drug reactions more common Consider steroids for moderate to severe disease Commence/optimize HAART. Efavirenz (with two NRTIs) first line because metabolism of protease inhibitors (PIs) is induced by rifampicin (p. 404) Stop therapy when complete
Presentation	History over weeks to months Fever, night sweats and weight loss <i>CD4 count > 200 cells/mm³:</i> reactivated upper-lobe cavitary disease is more likely with cough and haemoptysis <i>CD4 count ≤ 200 cells/mm³:</i> miliary, atypical pulmonary and extrapulmonary TB become more common	Immune restoration syndrome	Occurs in 10–15%. Most common in those with a nadir CD4 < 50 cells/mm ³ and a brisk CD4 response to HAART. Commonly presents as focal disease Treatment: NSAIDs or steroids
Suspect if	PUO, pneumonia failing to respond to antibiotics, exudative pleural effusion, unexplained weight loss, or TB is endemic in patient's country of origin	Prophylaxis	Isoniazid (with or without rifampicin) reduces the risk of TB by 60% in patients with positive tuberculin skin tests (less in those with negative tests) Protection limited to 2–4 yrs probably because of reinfection
Differential diagnosis	PCP, Kaposi's sarcoma, unusual fungi (<i>Histoplasma</i> , <i>Penicillium</i> , <i>Cryptococcus</i> , <i>Coccidioides</i>), atypical pneumonia, <i>Nocardia</i> and lymphoma	Prognosis	Mortality 5%
Complications	Massive haemoptysis, empyema, acute respiratory distress syndrome (ARDS), cor pulmonale, aspergilloma		
Key investigations and diagnosis			
Chest X-ray	Cavities, miliary shadowing, pleural effusion, mediastinal lymphadenopathy, collapse and consolidation (see Fig. 14.8) 5% with smear-positive disease have a normal chest X-ray		

Fig. 14.9 Chest X-ray of pulmonary tuberculosis in HIV infection. Appearances are often atypical but in this case there are multiple cavities and focal consolidation.

to rise inexorably. In some countries up to 30% of patients presenting with TB are co-infected with HIV. Presentation is invariably with fever, weight loss and site-specific symptoms (pulmonary, meningeal, pericardial, etc.). Diagnosis may be difficult, as smear-positive rates are reduced in pulmonary TB, and chest X-ray appearances may be atypical with less cavitation (Fig. 14.9). Standard quadruple therapy (see Box 14.15) is curative in the majority, with mortality often being attributable to other disseminated bacterial infections (e.g. *Salmonella* and pneumococcus). If compliance is likely to be a problem, daily or thrice-weekly directly observed therapy (DOT) should be considered. Multidrug-resistant TB (MDRTB) presents a seri-

ous clinical and public health problem in many areas of the world (e.g. Eastern Europe, South Africa). In addition, extensively drug-resistant TB (XDRTB) has now been reported from South Africa, where it has become a significant problem, and also in small numbers from over 100 countries. MDRTB and XDRTB are described in detail on pages 693–694. Treatment often entails hospital admission and 6–7 drug combinations.

Bacterial infections

Bacterial pneumonia is a common cause of morbidity and mortality in HIV. The incidence, severity, likelihood of bacteraemia and recurrent pneumonia, and mortality rate are all increased compared to non-HIV-infected patients. Susceptibility to particular respiratory pathogens is influenced by risk group, level of immune depletion, age and presence of neutropenia. There is a 150-fold greater risk of pneumococcal pneumonia in advanced HIV, when it is the cause of 40% of all pneumonias in which a pathogen is identified, and 70% of those with bacteraemia. *Pseudomonas* (5%) and *Nocardia* infections are more likely in later-stage disease. *Legionella* is also found more frequently. Chest X-ray appearances may be atypical. Infection usually responds to standard antibiotic therapy.

Nervous system and eye disease

Disease of the central and peripheral nervous system is common in HIV. It may be a direct consequence of HIV infection or an indirect result of CD4 cell depletion. Presentations are outlined in Box 14.16 and Figure 14.10.

Toxoplasma gondii

Toxoplasma infection results in a mild or subclinical illness in immunocompetent individuals, with the formation of latent tissue cysts that persist for life (Box 14.17).

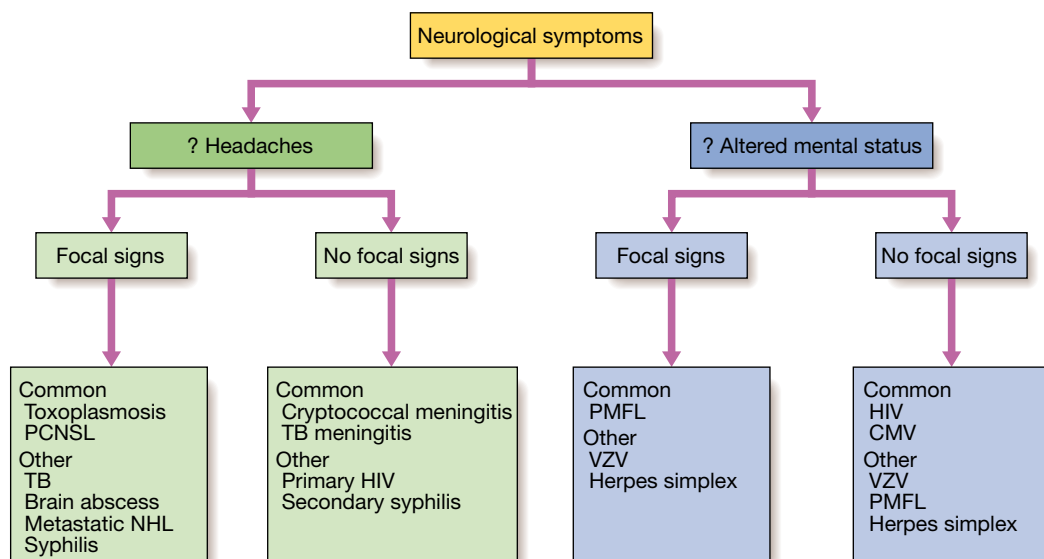

Fig. 14.10 Presentation and differential diagnosis of HIV-related neurological disorders. (CMV = cytomegalovirus; NHL = non-Hodgkin lymphoma; PCNSL = primary CNS lymphoma; PMFL = progressive multifocal leucoencephalopathy; TB = tuberculosis; VZV = varicella zoster virus)

14.16 Differential diagnosis of HIV-related disorders of the nervous system

Presentation	Main causes
Space-occupying lesion(s)	Toxoplasmosis, primary CNS lymphoma, progressive multifocal leucoencephalopathy (PML), TB
Cognitive impairment	AIDS dementia, PML, CMV, syphilis
Encephalitis	HIV, varicella zoster virus, herpes simplex, syphilis
Meningitis	HIV seroconversion, <i>Cryptococcus</i> , TB, syphilis
Spastic paraparesis	HIV-vacuolar myelopathy, transverse myelitis from varicella zoster, herpes simplex, human T-cell lymphotropic virus 1, syphilis
Polyradiculitis	CMV, non-Hodgkin lymphoma
Peripheral neuropathy	HIV, drugs (e.g. d4T, ddI, p. 404)
Retinitis	CMV, toxoplasmosis, retinal necrosis, HIV, syphilis

Fig. 14.11 Cerebral toxoplasmosis. Multiple cortical ring-enhancing lesions with surrounding oedema are characteristic.

The infection rate, as judged by seroconversion, is 0.5–1% per year. In advanced HIV, reactivation of these cysts may occur with the development of cerebral toxoplasmosis. Despite the characteristic findings on imaging (Fig. 14.11), it is often impossible to distinguish *Toxoplasma* encephalitis from primary CNS lymphoma (Fig. 14.12). However, the response to a trial of anti-*Toxoplasma* therapy is usually diagnostic, with clinical improvement within 1 week in 50% and 2 weeks in 90%; shrinkage of lesions on MRI is usual by 2–4 weeks.

i

14.17 Cerebral toxoplasmosis

Epidemiology	Reactivation of latent primary CNS infection. Acquired from ingestion of food contaminated by cat's faeces or undercooked meat Prevalence age- and region-dependent
At-risk CD4 count	< 100 cells/mm ³
Pathology	Spherical tachyzoites within inflammatory granulomas and surrounding oedema
Clinical features	
Presentation	History < 2 wks Headache, fever, drowsiness, fits (33%) and focal neurological signs. Retinitis may coexist
Suspect if	Short history of headache, fever, fits and focal signs
Differential diagnosis	Primary CNS lymphoma, PML, TB, <i>Cryptococcus</i>
Complications	Raised intracranial pressure (ICP)
Key investigations and diagnosis	
MRI	Multiple ring-enhancing lesions in cortical grey–white matter interface, basal ganglia or brain stem. Associated oedema and mass effect
Other	85% are <i>Toxoplasma</i> IgG antibody-positive Brain biopsy PCR positive on CSF (but lumbar puncture often contraindicated) Response to empirical anti- <i>Toxoplasma</i> therapy
Management	
Treatment	<i>First-line:</i> sulphadiazine or clindamycin with pyrimethamine and folinic acid for 6 wks, with dexamethasone if mass effect Commence/optimize HAART <i>Maintenance:</i> same drugs at lower dose Stop therapy when CD4 > 200 cells/mm ³ for 3 mths on suppressive HAART
Immune restoration syndrome	Well recognised but uncommon
Prophylaxis	<i>Primary:</i> co-trimoxazole <i>Secondary:</i> sulphadiazine or clindamycin with pyrimethamine and folinic acid
Prognosis	5% acute mortality, 15% neurological morbidity

Progressive multifocal leucoencephalopathy (PML)

PML (Box 14.18) is a demyelinating disease caused by the JC papovavirus; it occurs at very low CD4 counts. Seroprevalence studies demonstrate that up to 90% of young adults have been exposed to JC virus, most infections occurring in childhood. A combination of characteristic appearances on MRI (Fig. 14.13) and positive JC virus in CSF is diagnostic. No specific treatment exists and prognosis remains poor despite HAART.

Primary CNS lymphoma (PCNSL)

PCNSLs are high-grade, diffuse, B-cell lymphomas which usually complicate late-stage HIV (CD4 < 50 cells/mm³).

Fig. 14.12 Primary CNS lymphoma. A single enhancing periventricular lesion with moderate oedema is typical.

Fig. 14.13 Progressive multifocal leucoencephalopathy. Non-enhancing white matter lesions without surrounding oedema are seen.

14.18 Progressive multifocal leucoencephalopathy (PML)

Epidemiology	Reactivation of latent virus with transport to brain, where it infects oligodendrocytes via serotonin receptor
At-risk CD4 count	< 50 cells/mm ³
Pathology	Multifocal demyelination and enlarged oligodendrocytes with nuclear inclusions at edges
Clinical features	
Presentation	History over weeks to months Hemiparesis, visual/speech defects (25%), altered mental/mood status, ataxia. Seizures rare and fever absent
Suspect if	Gradual-onset focal neurology without fever
Differential diagnosis	HIV encephalopathy, CMV, herpes simplex, VZV, toxoplasmosis, primary CNS lymphoma
Key investigations and diagnosis	
MRI	Bilateral, asymmetric, well-demarcated, non-enhancing lesions, predominantly affecting the white matter. No oedema or shift
CSF	JC papovavirus PCR-positive
Management	
Treatment	Commence/optimize HAART
Immune restoration syndrome	Well characterised and may be presenting diagnosis
Prophylaxis	Nil
Prognosis	50% mortality at 3–12 mths. 35% neurological disability

They occur in approximately 5% of AIDS patients and account for 20% of all focal CNS lesions. The history is 2–8 weeks of headache, focal features and sometimes confusion; seizures occur in 15% but fever is absent. Characteristically, imaging demonstrates a large, single, homogeneously enhancing periventricular lesion with mild to moderate surrounding oedema and mass effect. Multiple lesions may occur on MRI (see Fig. 14.12) but a solitary lesion is four times more likely to be PCNSL than *Toxoplasma*. The presence of EBV-DNA in the CSF has a high sensitivity and specificity for PCNSL. Biopsy is definitive, but carries a small risk of morbidity and may be non-diagnostic in up to one-third. Failure to improve clinically or on scanning with a trial of anti-*Toxoplasma* therapy after 2–4 weeks is consistent with PCNSL and is an indication for brain biopsy. Treatment can be tried with HAART and high-dose methotrexate, but the prognosis is poor.

Other focal brain disease

M. tuberculosis, *Cryptococcus neoformans* and *Treponema pallidum* predominantly affect the meninges but can produce mass lesions with focal neurology. A less frequent cause of focal disease is CMV, which presents with a subacute history of progressive disorientation, withdrawal, apathy, cranial nerve palsies and nystagmus. Bilateral enhancing periventricular changes on MRI are characteristic and retinitis is present in over half. Diagnosis is made by identifying CMV-DNA in the CSF.

HIV-associated encephalopathy

HIV is a neurotropic virus and infects the CNS early during infection. Aseptic meningitis or encephalitis may occur at seroconversion, and minor cognitive defects such as mental slowness and poor memory may develop as the disease progresses. The incidence has fallen dramatically as a result of HAART. Dementia occurs in late disease and

is characterised by global deterioration of cognitive function, severe psychomotor retardation, paraparesis, ataxia, and urinary and faecal incontinence. Changes in affect are common, and depression or psychosis may be the predominant feature. Higher plasma and CSF HIV viral load, lower CD4 count and age are predictors. Investigations show diffuse cerebral atrophy with widened sulci and enlarged ventricles on imaging, and a raised protein in the CSF. Combination therapy using agents providing optimal CNS penetration may slow or even reverse the progression of HIV-associated dementia. Appropriate psychotropic medication may also be necessary.

Cryptococcosis

Cryptococcus neoformans (Box 14.19) is the most important cause of meningitis associated with late-stage HIV and occurs in up to 5% of patients, who usually present with a 2–3-week history of headache, fever, vomiting and mild confusion. Neck stiffness is present in less than 25% of patients, and around 10% are asymptomatic. Diagnosis is made by CSF antigen detection and culture. Between 10% and 20% of patients require treatment for raised intracranial pressure with repeated lumbar punctures, a lumbar drain or shunting.

Spinal cord, nerve root and peripheral nerve disease

A variety of neuropathies occur in HIV infection. At seroconversion, Guillain-Barré syndrome, transverse myelitis, facial palsy, brachial neuritis, polyradiculitis and peripheral neuropathy have all rarely been described.

Vacuolar myelopathy is a slowly progressive myelitis resulting in paraparesis with no sensory level. Ataxia and incontinence occur in advanced cases. The CSF may show a raised protein but is frequently normal; MRI of the spine is normal, and the diagnosis is by exclusion of other causes.

A predominantly distal HIV-related sensory neuropathy of the lower limbs affects up to 30% of patients. It is associated with a lower CD4 (usually < 200 cells/mm³), higher viral load, older age and wasting, and results from axonal degeneration. Hyperaesthesia, pain in the soles of the feet and paraesthesia, with diminished pin-prick, light touch and vibration sensation, and loss of ankle reflexes (75%) are typical. The nucleoside reverse transcriptase inhibitor (NRTI) drugs, especially d4T and didanosine (ddI), can produce an identical picture but this remits if the offending agent is withdrawn early. Treatment is often difficult, although amitriptyline, lamotrigine and topical capsaicin cream may help symptoms. HAART has minimal effect on halting or reversing the process.

Polyradiculitis occurs in late-stage HIV (CD4 count < 50 cells/mm³) and is nearly always a result of CMV. It causes rapidly progressive flaccid paraparesis, saddle anaesthesia, absent reflexes and sphincter dysfunction. Pain in the legs and back is an early symptom. Nerve root involvement on nerve conduction studies, a neutrophil CSF pleocytosis and the presence of CMV-DNA demonstrated by PCR confirm the diagnosis. Despite treatment, functional recovery may not occur. CMV is discussed in more detail on page 317.

Lastly, proximal myopathy can result from HIV, when it may occur at any stage, or rarely from zidovudine (ZDV) ($< 1\%$ of patients).

14.19 Cryptococcal meningitis

Epidemiology	Caused by <i>C. neoformans</i> var. <i>grubii</i> (serotype A) and <i>C. neoformans</i> var. <i>neoformans</i> (serotype D). Found in soil and spread by birds. Infection through inhalation with rapid spread to meninges
At-risk CD4 count	< 200 cells/mm ³
Pathology	Budding encapsulated yeasts in clusters with limited inflammatory response
Clinical features	
Presentation	History < 4 wks Headache, fever, drowsiness, confusion, photophobia and blurred vision, and seizures. Meningism may be absent and papilloedema uncommon. 10% are asymptomatic Non-meningeal (lung or skin) and disseminated disease are rare
Consider if Differential diagnosis	Recent-onset headache with fever TB meningitis
Complications	Blindness and deafness due to raised ICP, arachnoiditis and direct cryptococcal nerve infiltration
Key investigations and diagnosis	
MRI	Meningeal enhancement and evidence of raised ICP, with occasional masses in the basal ganglia
CSF	Lymphocytic, raised protein, low glucose typical but may be normal High pressure on manometry India ink stain positive for organisms (60%), cryptococcal antigen ($> 95\%$) and fungal culture ($> 95\%$)
Blood	Cryptococcal antigen positive $> 99\%$, culture $> 95\%$
Other	Urine/sputum/skin fungal culture may rarely be positive Chest X-ray may be abnormal
Management	
Treatment	<i>Induction: First-line:</i> liposomal amphotericin B and 5-flucytosine for 2 wks <i>Maintenance: First-line:</i> fluconazole for 8 wks Commence/optimize HAART Raised ICP must be managed actively to maintain CSF pressure < 20 cm H ₂ O Stop therapy when CD4 > 200 cells/mm ³ , for 3 mths on suppressive HAART and negative cultures
Immune restoration syndrome	Well described
Prophylaxis	<i>Primary:</i> not recommended <i>Secondary:</i> fluconazole
Prognosis	5–10% acute mortality. 10% morbidity

Psychiatric disease

Significant psychiatric morbidity is not uncommon. Anxiety and mood disturbance may be caused by pre-test issues such as worries about being infected and disclosure, receiving a positive result (e.g. confidentiality, discrimination and stigmatisation), concerns about life expectancy, or facing up to death. Mild cognitive dysfunction is a common occurrence in later-stage disease and usually improves with HAART (see above). Disorders of mental state may also result from drugs directly (e.g. depression with efavirenz, p. 405) or indirectly (e.g. those affecting sexual dysfunction). Psychiatric morbidity is a major risk factor for poor compliance with drug treatment, which is a critical component of HAART management.

Retinitis

Since the advent of HAART, there has been a 90% fall in the incidence of CMV infections. Patients usually present with field defects and well-demarcated areas of retinal disease (Box 14.20 and p. 384). Macular dis-

ease is rare but constitutes the most sight-threatening feature. Diagnosis is usually clinical. Treatment needs to be prompt, as the leading edge will progressively advance; no recovery of vision occurs in affected areas. Some patients may develop immune recovery uveitis in response to HAART, with intra-ocular inflammation, macular oedema and cataract formation that requires prompt treatment with oral and intra-ocular corticosteroids to prevent visual loss.

Miscellaneous conditions

Haematological conditions

Disorders of all three major cell lines may occur in HIV and are most frequent in later-stage disease (anaemia 70%, leucopenia 50% and thrombocytopenia 40%), when pancytopenia may also be seen. Numerous causes for anaemia exist, including marrow infiltration with opportunistic infections (MAI or TB) or neoplasms (non-Hodgkin lymphoma); bone marrow suppression from drugs (ZDV) or as a direct effect of HIV; and chronic blood loss (Kaposi's sarcoma) or malabsorption (chronic protozoal infections) in gastrointestinal tract disease. Haemolytic anaemia is uncommon but is seen with lymphoma. Leucopenia is usually seen in the context of marrow infiltration, as above, or drug toxicity (e.g. ZDV, co-trimoxazole, ganciclovir). Lymphopenia ($< 1.0 \times 10^9/L$) is a good marker of HIV. Thrombocytopenia may appear early (5–10%) and be the first indicator of HIV, or in later-stage disease. Its behaviour is very similar to idiopathic thrombocytopenic purpura, with detectable platelet antibodies and short-lived response to intravenous immunoglobulin. However, the treatment of choice is HAART.

Renal, cardiac and endocrine conditions

With the advent of HAART, opportunistic infections have declined substantially, and non-HIV-related illnesses of the cardiovascular, liver and renal systems have emerged as more important causes of morbidity and mortality.

Acute renal failure may be associated with acute infection or medication-related nephrotoxicity; this usually resolves with appropriate management. HIV-associated nephropathy (HIVAN) is the most important cause of chronic renal failure and is seen most frequently in patients of African descent and those with low CD4 counts. Other important HIV-associated renal diseases include HIV immune complex kidney diseases and thrombotic microangiopathy. Several drugs used in HIV management are also associated with renal disease, including indinavir (causes renal stones), tenofovir, pentamidine, cidofovir and co-trimoxazole. HIVAN usually presents with nephrotic syndrome, chronic renal failure or a combination of both. With the overall improvement in life expectancy, conditions such as diabetes mellitus, hypertension and vascular disease add to the burden of chronic kidney disease. HAART has some effect in slowing progression of renal disease. Doses of NRTIs must be adjusted according to creatinine clearance. Those who progress to end-stage renal disease while receiving HAART may be eligible for renal transplant.

14.20 CMV retinitis	
Epidemiology	Reactivation of primary herpes virus infection < 1% end-organ CMV disease
At-risk CD4 count	< 50 cells/mm ³
Pathology	Necrosis and haemorrhage
Clinical features	
Presentation	Subacute history with flashing lights, floaters, field defects and reduced visual acuity Occasionally asymptomatic and picked up on screening Well-demarcated haemorrhagic exudates usually peripheral and along vessels. 10% bilateral
Consider if	Field defect with peripheral retinitis
Differential diagnosis	Retinal necrosis (acute and progressive outer, PORN), toxoplasmosis, syphilis
Complications	Macular involvement and detached retina. CNS involvement rare
Key investigations and diagnosis	
Other	Clinical diagnosis. CMV PCR vitreous (rarely done)
Blood	Quantitative CMV PCR
Management	
Treatment	<i>First-line:</i> valganciclovir (oral) or ganciclovir (i.v.) for 3 wks If central disease, consider additional ganciclovir implant or intravitreal injections Ganciclovir resistance may rarely occur <i>Maintenance:</i> valganciclovir Commence/optimize HAART Stop therapy when on suppressive HAART, CD4 > 100 cells/mm ³ and CMV viral load undetectable
Immune restoration syndrome	Immune recovery uveitis well recognised More common when > 25% retina affected
Prophylaxis	Not recommended
Prognosis	Blindness 5%, permanent deficit in affected areas

With increasing life expectancy, cardiac disease has become important. Although HIV-related dilated cardiomyopathy can be detected in 25–40% of AIDS patients, symptomatic heart disease is rare (3–6%) and zidovudine-induced cardiomyopathy rarely seen. Nevertheless, patients on certain antiretrovirals (e.g. protease inhibitors, abacavir and ddI) and those with CD4 counts < 350 cells/mm³ not taking HAART have increased rates of coronary artery disease. Moreover, there is a small but additional effect of drug-induced hyperlipidaemia with protease inhibitors and stavudine.

Patients with fatigue and low CD4 counts should be screened for hypoadrenalism, which is seen in up to one-quarter of patients, and hypogonadism (p. 757). Hypopituitarism has also been described (p. 785).

HIV-related cancers

Malignancies in HIV can be divided into AIDS-defining and non-AIDS-defining cancers. AIDS-defining cancers are characterised by a strong inverse association with CD4 count, which is also seen but to a lesser extent in many of the non-AIDS malignancies. Kaposi's sarcoma and non-Hodgkin lymphoma are the most important AIDS-defining malignancies, with anal cancer and Hodgkin disease becoming increasingly important non-AIDS-defining malignancies.

Specific conditions

Kaposi's sarcoma (KS)

Together with PCP, KS has become a hallmark of AIDS (Box 14.21 and Fig. 14.14); it is due to the herpes virus HHV-8. Prior to HIV, KS was a rare tumour restricted to elderly Mediterranean or Jewish males, immunosuppressed transplant recipients, and children and young adults in sub-Saharan Africa. Typical presentation is with raised non-pruritic papules, often found incidentally on examination in a newly diagnosed patient. As the disease progresses, the skin lesions become more numerous and larger. Visceral disease occurs in only 10% at presentation. With the widespread use of HAART, which is also the mainstay of treatment, there has been a 70% fall in incidence.

Primary-effusion lymphoma (< 2% of cases of non-Hodgkin lymphoma) and multicentric Castleman's disease, which is a rare lymphoproliferative disorder affecting mainly HIV patients who present with anaemia, fevers and multifocal lymphadenopathy, are other HHV-8-associated conditions seen rarely with HIV.

HIV-associated lymphoma

In the majority of patients, non-Hodgkin lymphoma (NHL, Box 14.22) represents a late manifestation of HIV, with risk increasing as CD4 count falls. The risk is > 50-fold greater than in HIV-negative individuals, with a lifetime risk of developing NHL of 5–10%. Over the last 10 years, the incidence of NHL has fallen by > 40% but has increased as a proportion of AIDS-defining illnesses. By comparison, the incidence of Hodgkin disease (HD) has a definite but less marked association with HIV (10–20-fold greater than in HIV-negative individuals) and CD4 count fall. For both, extranodal and advanced presentation is more likely, with the majority having B symptoms (p. 1038). Histologically, HD is more likely

14.21 Kaposi's sarcoma (KS)

Epidemiology	Due to HHV-8 and predominantly sexually transmitted (MSM) Non-sexual and non-parenteral horizontal routes of transmission (possibly salivary) more important in sub-Saharan Africa In HHV-8 co-infected, 10-yr cumulative risk for KS is 30–50% with 3–5 yrs median time to development
At-risk CD4 count	Any, but visceral and more aggressive disease more likely at lower CD4 counts
Pathology	Characteristic spindle cells
Clinical features	
Presentation	History: months to years <i>Cutaneous</i> : purple non-pruritic papules anywhere on skin but especially nose, legs and genitals; crease-line distribution over trunk. Satellite lesions, bruising, local lymphadenopathy and oedema typical <i>Oral and GI tract</i> : purple raised lesions; favoured sites palate, gums and fauces; oesophagus, stomach and large bowel. Hepatosplenomegaly <i>Pulmonary</i> : (15%) breathlessness, cough, haemoptysis, chest pain and fever
Suspect if	Raised purple spots on skin, in mouth or on endoscopy/bronchoscopy
Differential diagnosis	Bacillary angiomatosis, pyogenic granuloma for cutaneous lesions
Complications	Ulceration and chronic lymphoedema from skin lesions Anaemia and bleeding from GI tract
Key investigations and diagnosis	
Skin	Biopsy for single or atypical lesions
Chest X-ray	Typically, disease affects middle and lower zones with patchy coarse reticulonodular shadowing and mediastinal lymphadenopathy Pleural effusion in ~25%
Other	CT, bronchoscopy and endoscopy if indicated by symptoms
Management	
Treatment	<i>Cutaneous/oral</i> : First-line: commence/optimize HAART (75% response). Radiotherapy valuable for localised disease, where lymphoedema is prominent or there is mass effect <i>Visceral, widespread or HAART-unresponsive mucocutaneous</i> : First-line: cyclical liposomal doxorubicin (response rate 60%). Paclitaxel for refractory or relapsed disease Stop therapy after completion of treatment course Uncommon but described
Immune restoration syndrome	
Prognosis	Poor if low CD4, age >50 yrs, and visceral disease Majority with skin disease only enter prolonged remission

Fig. 14.14 Oral Kaposi's sarcoma. A full examination is important to detect disease that may affect the palate, gums, fauces or tongue.

i

14.22 Non-Hodgkin lymphoma

Epidemiology	Increased risk if not on HAART, increasing age and low CD4 count. Most are EBV-related Initial AIDS-defining illness in 2–3% of patients
At-risk CD4 count	< 50 cells/mm ³
Pathology	> 95% are of B-cell lineage with several histological types: diffuse large B-cell, Burkitt's, primary CNS and primary effusion (HHV-8)
Clinical features	
Presentation	Typically with fevers, sweats and weight loss over several months; extranodal disease (GI tract, liver, oral cavity, skin, lungs) and bone marrow involvement 20% with leptomeningeal CNS NHL are asymptomatic
Suspect if	Primary effusion lymphoma accounts for < 1% Persistent lymphadenopathy, PUO, weight loss with low CD4
Differential diagnosis	Mycobacterial infection (tuberculosis or MAI), cryptococcaemia
Complications	Progression of lymphoma, drug-induced neutropenia
Key investigations and diagnosis	
Biopsy	Tissue diagnosis essential
Staging	Ann Arbor/Cotswold modification (p. 1038) Patients are usually stage B4 at presentation (p. 1038)
Management	
Treatment	Cycles of multi-agent chemotherapy, e.g. CHOP ± rituximab HAART initiation/optimisation and prophylaxis for opportunist infections Stop therapy on completion of treatment course
Prognosis	Median survival 50% Poor prognostic factors: CD4 < 100 cells/mm ³ , more advanced stage, high LDH, age > 35 yrs, number of extranodal sites, injection drug-user and cell type

to show mixed cellularity or lymphocyte-depleted subtypes, as opposed to nodular sclerosis; a high percentage stain EBV-positive.

After diagnosis of NHL or Hodgkin lymphoma, a staging evaluation is required (p. 1038). For both, HAART therapy is associated with improved overall response, disease-free survival and complete remission rates, so its introduction should not be delayed. Multi-agent chemotherapy is the mainstay of treatment but intrathecal chemoprophylaxis, support of bone marrow reserves and prevention of infection are also key elements. Additional rituximab may improve response, depending on tumour cell markers. More intensive regimens are required for Burkitt's lymphoma. For HD, first-line treatment is as standard. Use of HAART with chemotherapy is safe, although drugs that have overlapping side-effects with cytotoxics should be avoided (e.g. ZDV and marrow suppression). Following chemotherapy, it may take up to 1 year for the CD4 count to return to pre-treatment levels.

Other non-AIDS-defining cancers

HIV-infected patients have a greater risk of developing anogenital (vulval/vaginal, anal, penile) and in situ cervical cancer (cervical intra-epithelial neoplasia (CIN) III), all of which are closely associated with HPV co-infection. This is more frequently observed in HIV (60% of females; 90% of males), including the most oncogenic genotypes (HPV-16, 18, 31, 33, 35). Patients are more likely to have multiple genotypes which persist with time, and to progress more rapidly from dysplasia to in situ cancer. Both a higher viral load and a lower CD4 count are associated with higher co-infection rates. Invasive cervical cancer is an AIDS-defining diagnosis, although it is unrelated to CD4 count and the risk is much lower than that for KS and NHL; by contrast, CIN is more common and more likely to recur. Disease tends to present late and is more aggressive. Annual cervical smears should be taken from all HIV-infected women.

The incidence of anal cancer is increasing (37-fold for men and 6.8-fold for women), particularly for MSM. Most are squamous cell carcinomas and tend to be advanced at presentation; treatment is with chemo- and radiotherapy. Survival rate is around 50% at 2 years.

MANAGEMENT OF HIV

Management of HIV involves both treatment of the virus and prevention of opportunistic infections. The aims of HIV treatment are to:

- reduce the viral load to an undetectable level for as long as possible
- improve the CD4 count to > 200 cells/mL so that severe HIV-related disease is unlikely
- improve the quantity and quality of life without unacceptable drug-related side-effects or lifestyle alteration
- reduce transmission.

The drugs that are most commonly used are shown in Box 14.23. The principle of combining drugs serves to provide additive antiviral activity with a reduction in the emergence of viral resistance. This is known as highly active antiretroviral therapy (HAART) and is the cornerstone of management.

14.23 Antiretroviral drugs and recommended combinations for therapy in treatment-naïve and experienced patients

NAÏVE			EXPERIENCED		
(Regimen should consist of one drug from each column)			(Regimen should include two fully active new agents from different classes)		
PIs and <i>NNRTIs</i>	NRTI-1	NRTI-2	PIs and <i>NNRTIs</i>	Entry inhibitors	Integrase inhibitors
Preferred <i>Efavirenz</i> ¹	Tenofovir ¹ Abacavir ¹	Lamivudine(3TC) ¹ Emtricitabine (FTC) ¹	Darunavir/r Tipranavir/r ² <i>Etravirine</i>	Maraviroc Enfuvirtide (T-20)	Raltegravir
Alternative Lopinavir/r ¹ Fosamprenavir/r ¹ Darunavir/r Atazanavir/r Saquinavir/r <i>Nevirapine</i>	Didanosine (ddI) Zidovudine (ZDV) ¹				

Notes With the exception of zidovudine, all drugs listed for naïve patients can be given once daily although lopinavir, fosamprenavir, saquinavir and nevirapine are usually given twice daily.
¹Fixed-dose combinations available: efavirenz/tenofovir/emtricitabine; tenofovir/emtricitabine; abacavir/lamivudine; zidovudine/lamivudine; zidovudine/lamivudine/abacavir; lopinavir/ritonavir.
²Tipranavir cannot be given with etravirine or darunavir.
 (NRTI = nucleoside reverse transcriptase inhibitor; NNRTI = non-nucleoside reverse transcriptase inhibitor (shown in italics); PI = protease inhibitor; r = ritonavir in low dose)

Drugs

Nucleoside reverse transcriptase inhibitors (NRTIs)

The drugs in this class are zidovudine (ZDV), didanosine (ddI), lamivudine (3TC), stavudine (d4T), abacavir and emtricitabine (FTC), which have been developed sequentially. The NRTIs act through intracellular phosphorylation to the triphosphate form and incorporation into the DNA, where they inhibit further lengthening of the complementary strand to the viral RNA template (see step 4, Fig. 14.2, p. 388). Each drug specifically competes with a natural nucleoside (e.g. ZDV with thymidine). CNS penetration is good with all NRTIs, and ZDV has been demonstrated to be of benefit in AIDS dementia. Tenofovir is a nucleotide drug which only requires two phosphorylation steps to the triphosphate form. Its activity and characteristics are similar to the NRTIs. The inclusion of two NRTIs, or one NRTI and tenofovir, remains the cornerstone of HAART.

Resistance occurs to all NRTIs unless they are part of a maximally suppressive HAART regimen; resistance to 3TC and FTC is rapid and high-level. Occasionally, certain single mutations in the viral reverse transcriptase may result in broad resistance to several or all of the NRTIs and tenofovir. These can be selected out by combining drugs that have overlapping resistance profiles and a low genetic barrier to resistance.

Early side-effects are uncommon with current recommended NRTIs. Abacavir can result in a hypersensitivity reaction in 3% of patients with rash, fever and an influenza-like illness, but this only occurs in those with the genetic allele HLAB57*01; this can be screened for prior to use of abacavir and the drug avoided if it is present. Abacavir also appears to be associated with

a small risk of coronary heart disease, and tenofovir with bone demineralisation and rarely renal tubular toxicity. They should be avoided if possible in those with existing cardiovascular risk factors or renal impairment respectively.

ZDV is occasionally used (mainly during pregnancy), which can result in nausea and macrocytic anaemia. In resource-poor countries, ZDV and d4T are important first-line drugs. However, lipoatrophy (fat loss from the face, limbs and buttocks, Fig. 14.15) is a frequent long-term complication, and peripheral neuropathy and lactic acidosis (ddI and d4T) may occur due to inhibition of mitochondrial DNA synthesis.

Fig. 14.15 Fat loss seen with certain NRTIs.

Fig. 14.16 Fat gain seen with PI-based HAART.

Protease inhibitors (PIs)

The first PI developed was saquinavir followed by indinavir, ritonavir, lopinavir and tipranavir; more recently, atazanavir, fosamprenavir and darunavir have become available. Currently used PIs should always be boosted by low-dose ritonavir, which is a potent inhibitor of liver metabolism. This increases drug exposure, thereby prolonging the PI's half-life, allowing reduction in pill burden and dosing frequency and so optimising adherence. It also limits the development of resistance. PIs prevent post-translational cleavage of polypeptides into functional virus proteins (see step 8, Fig. 14.2, p. 388). When they are given with two NRTIs, the combination controls viral replication in plasma and tissues, and allows reconstitution of the immune system.

Early and late side-effects are common. PI use has been linked with fat accumulation which is characterised by central adiposity and localised collections (buffalo hump, peripheral lipomatosis, and breast enlargement in women, Fig. 14.16). In addition, their use may be associated with hyperlipidaemia (mainly total cholesterol and triglyceride), and abnormal glucose tolerance; this is less marked for atazanavir and darunavir. An increased risk of myocardial infarction has been linked to certain PIs that is not explained by dyslipidaemia. Individual PI side-effects include diarrhoea (lopinavir), renal stones (indinavir), hyperbilirubinaemia (atazanavir) and rash (fosamprenavir and darunavir).

PIs are metabolised by the P450 cytochrome system (mainly the CYP3A4 isoenzyme), giving rise to the potential for multiple drug interactions. Commonly used drugs that interact with PIs (in particular ritonavir) are rifampicin, midazolam and simvastatin. Monitoring plasma levels and dose adjustments may be necessary to optimise the antiviral effect and reduce toxicity.

Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

There are two main NNRTIs used in drug-naïve patients (nevirapine and efavirenz) and one in drug-experienced (etravirine). Activity is through inhibiting reverse transcriptase by binding near to the active enzyme site (see stage 4, Fig. 14.2, p. 388). NNRTIs do not require

intracellular activation and are not active against HIV-1 subtype O or HIV-2. All have good bioavailability and, for efavirenz and nevirapine, low daily tablet number and apparent freedom from long-term side-effects.

Hypersensitivity rash and hepatitis are the major class-specific side-effects. The rash is usually mild and self-limiting but Stevens-Johnson syndrome may occur (0.3% with nevirapine, 0.1% with efavirenz). Similarly, hepatitis occurs more frequently with nevirapine, when it is gender- and CD4 count-dependent (11% in women with CD4 counts of > 250 cells/mm³), and may be fulminant. Hence its use is restricted to CD4 count thresholds of 250 cells/mm³ for women and 400 cells/mm³ for men. CNS side-effects, including dizziness, vivid dreams, insomnia, somnolence and poor concentration, are described in half the patients treated with efavirenz. These usually resolve by 2–4 weeks and are only sufficiently severe to require discontinuation in 2–5%.

The major disadvantage of efavirenz and nevirapine is the rapid development of resistance in patients with virological failure, although they usually remain susceptible to etravirine. This is commonly used in combination with boosted darunavir and/or an integrase or entry inhibitor in patients with triple-class treatment failure. Nevirapine and efavirenz reduce methadone levels by approximately 50% and may precipitate opiate withdrawal.

Entry inhibitors

Currently, two classes of entry inhibitor exist: those that interfere with fusion by binding to gp41 (see stage 3, Fig. 14.2, p. 388: e.g. enfuvirtide) and those that bind to the CCR5 co-receptor blocking attachment of the virus (see stage 2, Fig. 14.2: e.g. maraviroc). Both are given twice daily and used in patients with advanced disease and few other options. However, enfuvirtide has to be injected subcutaneously, and maraviroc can only be used in patients whose virus is CCR5-tropic (only 50% of patients with advanced disease). Together with boosted darunavir, etravirine and raltegravir (see below), these drugs have transformed the management of patients with triple-class failure or resistant virus. In these highly treatment-experienced patients, it is imperative to use two and preferably three active agents in the new regimen. Because 95% of patients with early disease harbour CCR5-tropic virus, maraviroc has also been evaluated as a drug option for treatment-naïve patients.

Integrase inhibitors

This class of drug inhibits the third and final step of proviral DNA integration: that of strand transfer (see step 5, Fig. 14.2, p. 388). Raltegravir is the first in this class and has shown high potency in heavily experienced patients irrespective of existing resistance, subtype and tropism. It is primarily metabolised by glucuronidation and therefore is not affected by co-administration with other antiviral drugs and has no major side-effects.

Treatment

The naïve patient

The decision to start therapy is a major one; it is influenced by several factors but predominantly by the CD4 count. The risk of HIV-related disease with

14.24 Indications to start HAART

CD4 count (cells/mm ³)	Decision
Seroconversion	Consider treatment ¹
≥ 350	Monitor 3–6-monthly ²
201–350	Treat as soon as patient ready
< 200	Treat as soon as possible
AIDS-defining diagnosis	Treat as soon as possible ³

¹ If neurological presentation, CD4 count < 200 cells/mm³ for > 3 mths or AIDS diagnosis.
² Consider treatment if hepatitis B or C co-infected or > 55 yrs of age.
³ Except for TB, if CD4 > 350 cells/mm³.

opportunistic infection and malignancy increases, treatment is less effective and side-effects are more common when the CD4 count is < 200 cells/mm³. When to start therapy and what to start with are outlined in Boxes 14.23, 14.24 and 14.25. Prior to commencing treatment, all patients should have hepatitis B and C status checked, along with HIV viral resistance (5–10% incidence of primary resistance in the UK and Europe) and *HLA-B*5701* tests (if abacavir is being considered an option). With careful and appropriate choice of HAART, over 80% of patients have an undetectable viral load (VL) (i.e. < 50 copies/mL) at 4–6 months (Box 14.26). The factors that reduce the probability of achieving prolonged viral suppression include low CD4 count (< 50 cells/mm³) and high VL (> 100 000 copies/mL), poor adherence, pre-existing or emergent resistance, and drug interaction or toxicity. The presence of active opportunistic infection or other HIV-related disease should not delay the introduction of HAART, which usually should be commenced as soon as the patient's condition has stabilised.

14.25 Factors to consider when choosing HAART

- Fit of the drug regimen around the patient's lifestyle
- Wishes of the patient
- Comorbidities and drug toxicity
- Potential for drug interactions with HIV and non-HIV medications
- CNS penetration
- Possibility of acquisition of resistant virus

EBM 14.26 Combination therapy for patients naïve to drugs

'Combination antiretroviral therapy (ART) containing either efavirenz or boosted lopinavir together with two NRTIs results in effective and durable virological suppression with limited side-effects. Efavirenz provides improved virological control but failure is more likely to be associated with resistance. Equivalent results are demonstrated with several first-line PIs; all protect against the development of resistance.'

- Riddler SA, et al. *N Engl J Med* 2008; 358:2095.
- Ortiz R, et al. *AIDS* 2008; 22:1389.

The drug-experienced patient

A change in antiretroviral therapy may be necessary because of drug side-effects (early or late), difficulties in adherence or virological failure (defined as detectable VL despite treatment). In a patient with a previously undetectable VL, treatment failure is indicated by viral rebound. With increasing time on a failing regimen, the VL rises towards baseline levels, resistance mounts, the CD4 count falls and clinical progression occurs. In essence, most early failures are related to adherence difficulties (sometimes resulting from toxicity) and most late failures are a result of virological resistance. A resistance test should always be obtained before switching drugs, with a new active regimen being introduced as soon as possible and guided by this result. Account should also be taken of prior drug exposure. In certain situations, therapeutic drug monitoring may be helpful in confirming that virological failure is not related to inadequate PI or NNRTI levels. The new combination should include a minimum of two fully active new agents (see Box 14.23). Occasionally, HAART must be stopped because of life-threatening drug toxicity or overriding medical problems where predicted drug interactions will occur. In this situation, the prolonged half-life of the NNRTIs should be covered by substitution of a PI or continuation of the other components of HAART for 2 weeks. Treatment interruption is associated with an increased risk of progression and non-HIV-related complications (Box 14.27).

EBM 14.27 Continuous vs. intermittent treatment strategies for managing HIV

'CD4 count-guided interruption of HAART is inferior to continuous HAART. It demonstrates significantly higher rates of death, opportunistic disease, and renal, hepatic and cardiovascular events when compared to those maintained on continuous treatment.'

- El-Sadr W, et al. *N Engl J Med* 2006; 355:2283.

Special situations

Children

The general principles of management are the same as those for adults, although the CD4 percentage is a more accurate marker of immunological health until 5 years of age. All infants should receive PCP prophylaxis and commence HAART, irrespective of CD4 count or VL. CD4 counts (cells/mm³) and CD4 percentage thresholds to initiate HAART are:

- < 1000 cells and/or < 25% at 1–2 years
- < 500 cells and/or < 20% at 3–4 years
- < 350 cells and/or < 15% if above 5 years and in any child with advanced clinical disease.

It should also be considered in those with a VL > 100 000 copies/mL. After 1 year of age, PCP prophylaxis should be given to children until they are 5 with a CD4 percentage of < 15%, and then at the same CD4 levels as for adults.

Not all antiretroviral drugs are available in a suitable formulation for children, e.g. suspension, powder, crushable tablet or a capsule that can be

opened. First-line preferred choices include boosted lopinavir, nevirapine (< 3 years) and efavirenz (> 3 years) with two NRTIs. Coordinated, comprehensive, family-centred systems of care are necessary to support the child and parents and to optimise compliance with medications.

Maternal HIV

All pregnant women should routinely be recommended for HIV testing at an early stage in pregnancy, with rapid tests considered for those presenting in or just after labour. Pre-HAART, the rate of mother-to-child transmission was 26% with rates being influenced by several factors (see Box 14.1, p. 387). The likelihood of transmission at delivery is decreased to the order of 8% with single-dose nevirapine to mother and child, 6–8% for ZDV alone, <1% for ZDV and caesarean section, and <1% for HAART and planned vaginal delivery when the viral load is < 50 copies/mL.

Treatment in pregnancy is outlined in Box 14.28. Single-dose nevirapine is used in resource-poor nations, but in the absence of other drugs is associated with a 30–50% chance of NNRTI resistance in mother and infected child.

Mothers should formula-feed their babies exclusively. Screening for HIV in the baby by proviral DNA should be performed at birth (not on cord blood), 6 weeks and 3 months. If negative, vertical transmission has not occurred. In discordant couples (i.e. only one partner is HIV-positive) who desire a family, self-insemination of the partner's semen is recommended to protect the uninfected male and sperm-washing is recommended to protect the uninfected female partner.

Post-exposure prophylaxis

Post-exposure prophylaxis with combination therapy (boosted lopinavir, tenofovir and FTC) is recommended when the risk is deemed to be significant after a careful risk assessment, in both occupational and non-occupational settings. The first dose should be given as soon as possible, preferably within 6–8 hours. However, protection is not absolute and seroconversion may occur. Non-occupational settings include condom breakage in HIV-serodiscordant partners, victims of rape, and sharps-related home exposures in families of injection drug-users or HIV patients. Many individuals experience side-effects and only half complete the recommended 4 weeks of therapy.

14.28 Treatment of HIV in pregnancy

- **Ritonavir-boosted PI (e.g. lopinavir) with zidovudine and lamivudine from 20 weeks:** all mothers, with PI plasma level monitoring. Nevirapine can be used cautiously (risk of hypersensitivity hepatitis) but only when CD4 counts < 250 cells/mm³.
- **Zidovudine monotherapy:** those with viral loads < 10 000 copies/mL and wild-type virus who are willing to have Caesarean section.
- **ZDV i.v. infusion at onset of labour:** those on ZDV alone or those on HAART but with detectable virus, undergoing normal vaginal delivery.

Prevention of opportunistic infection

Patients should be immunised with hepatitis A and hepatitis B vaccines if there is no evidence of naturally acquired infection. HBV surface antibody levels need to be monitored and boosters given when < 100 U/mL. Pneumococcal vaccine (every 3–5 years) and influenza vaccine (annually) should be given to all patients. Response to all immunisations is lower when the CD4 count is < 200 cells/mm³, although some protection is afforded. Live attenuated vaccines (BCG, oral polio) should be avoided or restricted to those with high CD4 counts (yellow fever). Nevertheless, MMR (measles/mumps/rubella) vaccine is safe and can be given.

Prophylaxis against infection is another vital aspect of management. Primary prophylaxis is to prevent the initial disease occurring, and secondary to prevent recurrence of infection. Primary prophylaxis is introduced at specified CD4 counts at which there is a risk of infection. Secondary prophylaxis is started after successful treatment of the opportunistic infection, usually with the same drug(s) that was used to treat it, but at lower doses. Drugs can usually be stopped when the CD4 threshold at which primary prophylaxis is introduced is reached. Specific details of these thresholds for each infection is given in the relevant section above.

Prevention of HIV

HIV vaccine development is slow. An effective, safe and cheap vaccine would radically alter the future global epidemic of HIV. Despite advances in the understanding of HIV pathogenesis and immunology, prototype HIV-1 vaccine candidates aimed at eliciting humoral and cellular immune responses have so far failed. Challenges include the extensive subtype and sequence diversity of HIV, the early establishment of reservoirs, the lack of a safe attenuated virus, the lack of a small animal model, and the inability of vaccines to generate protection across different viral strains. Alternative measures for the prevention of HIV transmission are shown in Boxes 14.29 and 14.30. The United Nations' aim is universal access to comprehensive prevention programmes, treatment, care and support by 2010. To achieve this, access to HIV testing needs to be widened, and strategies are required to protect the HIV non-infected person (e.g. promoting consistent condom use, improved STI management, male circumcision), for effective mother-to-child prevention programmes, and for scaling up of antiretroviral drug access.

EBM 14.29 Male circumcision for prevention of HIV transmission

'Circumcision is effective in reducing HIV infection rates in men without increasing high-risk behaviour. In a setting of low circumcision and high HIV prevalence, this is likely to provide an effective method for reducing HIV transmission.'

• Gray RH, et al. *Lancet* 2007; 369:657–666.

14.30 Prevention measures for HIV transmission

Sexual

- Comprehensive sex education programmes in schools
- Public awareness campaigns for HIV
- Easily accessible/discreet testing centres
- Safe sex practices (avoiding penetrative intercourse, delaying sexual debut, condom use, fewer sexual partners)
- Targeting safe sex methods to high-risk groups
- Control of STIs
- Effective treatment of HIV-infected individuals
- Post-sexual exposure prophylaxis

Parenteral

- Blood product transmission: donor questionnaire, routine screening of donated blood, blood substitute use
- Injection drug use: education, needle/syringe exchange, avoidance of 'shooting galleries', sharing and support for methadone maintenance programmes

Perinatal

- Routine 'opt-out' antenatal HIV antibody testing
- Preconception family planning if HIV-seropositive
- Measures to reduce vertical transmission (p. 407)

Occupational

- Education/training: universal precautions, needlestick avoidance
- Post-exposure prophylaxis

Sexually transmitted infections

15

Clinical examination in men 410

Clinical examination in women 411

Approach to patients with a suspected STI 412

Presenting problems in men 412

- Urethral discharge 412
- Genital itch and/or rash 413
- Genital ulceration 413
- Genital lumps 414
- Proctitis in men who have sex with men 414

Presenting problems in women 415

- Vaginal discharge 415
- Lower abdominal pain 415
- Genital ulceration 416
- Genital lumps 416
- Chronic vulval pain and/or itch 416

Prevention of STI 416

Sexually transmitted bacterial infections 417

- Syphilis 417
- Gonorrhoea 420
- Chlamydial infection 421
- Other sexually transmitted bacterial infections 421

Sexually transmitted viral infections 421

- Genital herpes simplex 421
- Human papillomavirus and anogenital warts 423
- Molluscum contagiosum 424
- Viral hepatitis 424

Investigations for STIs in heterosexual males

- Urethral swab for gonococci—either plated directly on a selective medium such as modified New York City (MNYC), or sent in appropriate transport medium for either culture or nucleic acid amplification test (NAAT) according to local laboratory protocol
- Urethral swab or first void urine (FVU) for chlamydia
- Serological test for syphilis (STS), e.g. enzyme immunoassay (EIA) for anti-treponemal IgG antibody
- HIV test (see note)

Investigations for STIs in men who have sex with men

- Pharyngeal, urethral and rectal swabs for gonococci
- Urethral swab or FVU, and rectal swab for chlamydia
- STS (repeat testing may be necessary in the event that there are negative test results in the first few weeks following exposure)
- Serological tests for hepatitis A/B (with a view to vaccination if seronegative)
- HIV test (see note)

HIV testing

It should be standard practice to offer HIV testing as part of STI screening because the benefits of early diagnosis outweigh other considerations. Extensive pre-test counselling is not required in most instances, but it is important to establish efficient pathways for referral of patients at high risk in whom the clinician wishes specialist support, and for those diagnosed HIV-positive.

Investigations for STIs in women

- Urethral and cervical swabs for gonococci
- Cervical swab for chlamydia
- Wet mount for microscopy or high vaginal swab (HVS) for culture of *Trichomonas*
- STS
- HIV test (see note)

Management goals in suspected STI

- Relief of any symptoms
- Screening for treatable STI that may not be causing symptoms
- Tracing and treatment of sexual contacts who may also be infected
- Advice to reduce risk of infection in the future

Those at particular risk from STIs*

- Sex workers, male and female
- Clients of sex workers
- Men who have sex with men
- Injecting drug users (sex for money or drugs) and their partners
- Frequent travellers

*Adapted from WHO/UNAIDS, 1997.

Sexually transmitted infections (STIs) are a group of contagious conditions whose principal mode of transmission is by intimate sexual activity involving the moist mucous membranes of the penis, vulva, vagina, cervix, anus, rectum, mouth and pharynx, along with their adjacent skin surfaces. A wide range of infections may be sexually transmitted, including syphilis, gonorrhoea, human immunodeficiency virus (HIV), genital herpes, genital warts, chlamydia and trichomoniasis. Bacterial vaginosis and genital candidiasis are not regarded as STIs, although they are common causes of vaginal discharge in sexually active women. Chancroid, lymphogranuloma venereum and granuloma inguinale are usually seen in tropical countries. Hepatitis viruses A, B, C and D (pp. 947–954) may be acquired sexually, as well as by other routes.

The World Health Organization estimates that 340 million curable STIs occur each year, including 170 million cases of *Trichomonas vaginalis*, 92 million cases of *Chlamydia trachomatis*, 62 million cases of gonorrhoea and 12 million cases of syphilis. In the UK in 2007, the most common treatable STIs diagnosed were chlamydia (more than 120 000 cases) and gonorrhoea (18 000 cases). Genital warts are the second most common complaint seen in genitourinary medicine (GUM) departments.

As coincident infection with more than one STI is frequently seen, GUM clinics routinely offer a full set of investigations at the patient's first visit (pp. 410–411), regardless of the reason for attendance. In other settings, less comprehensive investigation may be appropriate.

The extent of the examination largely reflects the likelihood of HIV infection or syphilis. Most heterosexuals in the UK are at such low risk of these infections that routine extragenital examination is unnecessary. This is not the case in parts of the world where HIV is endemic, or for men who have sex with men (MSM) in the UK. In other words, the extent of the examination is determined by the sexual history.

APPROACH TO PATIENTS WITH A SUSPECTED STI

Patients concerned about the possible acquisition of an STI are often anxious. Staff must be friendly, sympathetic and reassuring; they should have the ability to put patients at ease, whilst emphasising that clinic

attendance is confidential. The history focuses on genital symptoms, with reference to genital ulceration, rash, irritation, pain, swelling and urinary symptoms, especially dysuria. In men, the clinician should ask about urethral discharge, and in women, vaginal discharge, pelvic pain or dyspareunia. Enquiry about general health should include menstrual and obstetric history, cervical cytology, recent medication, especially with antimicrobial or antiviral agents, previous STI and allergy. Immunisation status for hepatitis A and B should be noted, as should information about recreational drug use.

A detailed sexual history is imperative, as this informs the clinician of the degree of risk for certain infections as well as specific sites that should be sampled; for example, rectal samples should be taken from men who have had unprotected anal sex with other men. Sexual partners, whether male or female, and casual or regular, should be recorded. Sexual practices—insertive or receptive vaginal, anal, orogenital or oroanal—should be noted. Choice of contraception should be recorded for women, together with condom use for both sexes.

STI in children

The presence of an STI in a child may be indicative of sexual abuse, although vertical transmission may explain some presentations in the first 2 years. In an older child, STI may be the result of voluntary sexual activity.

STI during pregnancy

Many STIs can be transmitted from mother to child in pregnancy, either transplacentally or during delivery. Possible outcomes are highlighted in Box 15.1.

PRESENTING PROBLEMS IN MEN

Urethral discharge

In the UK the most important causes of urethral discharge are gonorrhoea and chlamydia. In a significant minority of cases, tests for both of these infections are negative, a scenario often referred to as non-specific urethritis (NSU). Some of these cases may be caused by *Trichomonas vaginalis*, herpes simplex virus (HSV), mycoplasmas or ureaplasmas. A small minority seem not to have an infectious aetiology.

15.1 Possible outcomes of STI in pregnancy

Organism	Mode of transmission	Outcome for fetus/neonate	Outcome for mother
<i>Treponema pallidum</i>	Transplacental	Ranges from no effect to severe stigmata or miscarriage/stillbirth	None directly relating to the pregnancy
<i>Neisseria gonorrhoeae</i>	Intrapartum	Severe conjunctivitis	Possibility of ascending infection postpartum
<i>Chlamydia trachomatis</i>	Intrapartum	Conjunctivitis, pneumonia	Possibility of ascending infection postpartum
Herpes simplex	Usually intrapartum, but transplacental infection may occur rarely	Ranges from no effect to severe disseminated infection	Rarely, primary infection during 2nd/3rd trimesters becomes disseminated, with high maternal mortality
Human papillomaviruses	Intrapartum	Anogenital warts or laryngeal papillomas are very rare	Warts may become more florid during pregnancy, but usually regress postpartum

Gonococcal urethritis usually causes symptoms within 7 days of exposure. The discharge is typically profuse and purulent. Chlamydial urethritis has an incubation period of 1–4 weeks, and tends to result in milder symptoms than gonorrhoea; there is overlap, however, and microbiological confirmation should always be sought.

Investigations

A presumptive diagnosis of urethritis can be made from a Gram-stained smear of the urethral exudate (Fig. 15.1), which will demonstrate significant numbers of polymorphonuclear leucocytes (≥ 5 per high-power field). A working diagnosis of gonococcal urethritis is made if Gram-negative intracellular diplococci (GNDC) are seen; if no GNDC are seen, a label of non-specific urethritis is applied.

If microscopy is not available, swabs and/or urine samples should be taken and empirical antimicrobials prescribed.

A urethral swab should always be sent for culture of *Neisseria gonorrhoeae*; in addition, a first void urine (FVU) sample or a specific urethral swab should be sent for detection of chlamydial DNA by a nucleic acid amplification test (NAAT) such as polymerase chain reaction (PCR). NAATs are likely to replace the need for routine culture for gonorrhoea. Tests for other potential causes of urethritis are not performed routinely.

A swab should also be taken from the pharynx because gonococcal infection at this site is not reliably eradicated by single-dose therapy. In MSM swabs for gonorrhoea and chlamydia should be taken from the rectum.

Management

This depends upon local epidemiology and the availability of diagnostic resources. Treatment is often presumptive, with prescription of multiple antimicrobials to cover the possibility of gonorrhoea and/or chlamydia. This is likely to include a single-dose treatment for gonorrhoea, which is desirable because it eliminates the risk of non-adherence. The recommended agents for treating gonorrhoea vary according to local antimicrobial resistance patterns (p. 420). Appropriate treatment for chlamydia (p. 421) should also be prescribed because concurrent infection is present in up to 50% of men with

Fig. 15.1 A Gram-stained urethral smear from a man with gonococcal urethritis. Gram-negative diplococci are seen within polymorphonuclear leucocytes.

gonorrhoea. Non-gonococcal, non-chlamydial urethritis is treated as for chlamydia.

Patients should be advised to avoid sexual contact until it is confirmed that any infection has resolved, and whenever possible, recent sexual contacts should be traced. The task of contact tracing—also called partner notification—is best performed by trained nurses based in GUM clinics; it is standard practice in the UK to treat current sexual partners of men with gonococcal or non-specific urethritis without waiting for microbiological confirmation.

If symptoms clear, a routine test of cure is not necessary, but patients should be re-interviewed to confirm that there was no immediate vomiting or diarrhoea after treatment, that there has been no risk of re-infection, and that traceable partners have sought medical advice.

Genital itch and/or rash

Patients may present with many combinations of penile/genital symptoms that may be acute or chronic, and infectious or non-infectious. Box 15.2 provides a guide to diagnosis.

Balanitis refers to inflammation of the glans penis, often extending to the under-surface of the prepuce when it is called balanoposthitis. Tight prepuce and poor hygiene may be aggravating factors. Candidiasis is sometimes associated with immune deficiency, diabetes mellitus, and the use of broad-spectrum antimicrobials, corticosteroids or antimitotic drugs. Local saline bathing is usually helpful, especially when no cause is found.

Genital ulceration

The most common cause of ulceration is genital herpes. Classically, multiple painful ulcers affect the glans, coronal sulcus or shaft of penis (Fig. 15.2), but solitary lesions occur rarely. Perianal ulcers may be seen in MSM. The diagnosis is made by gently scraping material from lesions and sending this in an appropriate transport medium for culture or detection of HSV DNA by PCR.

In the UK, the possibility of any other ulcerating STI is remote unless the patient is an MSM and/or has had a sexual partner from a region where tropical STIs are more common. The classic lesion of primary syphilis (chancre) is single, painless and indurated; however, multiple lesions are seen rarely and anal chancres are often painful. Diagnosis is made in GUM clinics by dark-ground microscopy, but in other settings by serological tests for syphilis (p. 418). Other rare infective causes seen in the UK include varicella zoster virus (p. 313) and trauma with secondary infection. Tropical STI such as chancroid, lymphogranuloma venereum (LGV) and granuloma inguinale are described in Box 15.11 (p. 422). Inflammatory causes include Stevens–Johnson syndrome (p. 1285), Behçet’s syndrome (p. 1114) and fixed drug reactions. In older patients, malignant and pre-malignant conditions such as squamous cell carcinoma and erythroplasia of Queyrat (intra-epidermal carcinoma) should be considered.

15.2 Differential diagnosis of genital itch and/or rash in men

Likely diagnosis	Acute or chronic	Itch	Pain	Discharge (non-urethral)	Specific characteristics	Diagnostic test	Treatment
Subclinical urethritis	Either	±	–	±	Often intermittent	Gram stain and urethral swabs	As for urethral discharge
Candida	Acute	✓	–	White	Postcoital	Microscopy	Antifungal cream, e.g. clotrimazole
Anaerobic (erosive) balanitis	Acute	±	–	Yellow	Offensive	Microscopy	Saline bathing ± metronidazole
<i>Pthirus pubis</i> ('crab lice')	Either	✓	–	–	Lice and nits seen attached to pubic hairs	Can be by microscopy, but usually visual	According to local policy—often permethrin
Lichen planus (p. 1265)	Either	±	–	–	Violaceous papules ± Wickham's striae	Clinical	None or mild topical corticosteroid, e.g. hydrocortisone
Lichen sclerosus	Chronic	±	–	–	Ivory white plaques, scarring	Clinical or biopsy	Strong topical corticosteroid, e.g. clobetasol
Plasma cell balanitis of Zoon	Chronic	–	–	±	Shiny, inflamed circumscribed areas	Clinical or biopsy	Strong topical corticosteroid, e.g. clobetasol
Dermatoses, e.g. eczema or psoriasis	Either	✓	–	–	Similar to lesions elsewhere on skin	Clinical	Mild topical corticosteroid, e.g. hydrocortisone
Genital herpes	Acute	±	✓	–	Atypical ulcers are not uncommon	Swab for HSV PCR	Oral antiviral, e.g. aciclovir
Circinate balanitis	Either	–	–	–	Painless erosions with raised edges; usually as part of Reiter's syndrome (p. 1094)	Clinical	Mild topical steroid, e.g. hydrocortisone

Fig. 15.2 Penile herpes simplex (HSV-2) infection.

Genital lumps

The most common cause of genital 'lumps' is warts (p. 423). These are classically found in areas of friction during sex such as the parafoveal skin and prepuce of the penis. Warts may also be seen in the urethral meatus, and less commonly on the shaft or around the base of the penis. Perianal warts are surprisingly common in men who do not have anal sex.

The differential diagnosis includes molluscum contagiosum and skin tags. Adolescent boys may confuse normal anatomical features such as coronal papillae (p. 410), parafoveal glands or sebaceous glands (Fordyce spots) with warts.

Proctitis in men who have sex with men

STIs that may cause proctitis in MSM include gonorrhoea, chlamydia, herpes and syphilis. The subtypes of *Chlamydia trachomatis* that cause LGV (L1–3) have been associated with outbreaks of severe proctitis in the Netherlands and the UK. Symptoms include mucopurulent anal discharge, rectal bleeding, pain and tenesmus.

Examination may show mucopus and erythema with contact bleeding (Fig. 15.3). In addition to the diagnostic tests on page 410, a PCR test for HSV and a request

Fig. 15.3 Proctitis showing mucopus in the lumen of the rectum.

for identification of LGV substrain should be arranged if chlamydial infection is detected. Treatment is directed at the individual infections (see below).

MSM may also present with gastrointestinal symptoms from infection with organisms such as *Entamoeba histolytica* (p. 358), *Shigella* spp. (p. 339), *Campylobacter* spp. (p. 336) and *Cryptosporidium* spp. (p. 363).

PRESENTING PROBLEMS IN WOMEN

Vaginal discharge

The natural vaginal discharge may vary considerably, especially under differing hormonal influences such as puberty, pregnancy or prescribed contraception. A sudden or recent change in discharge, especially if associated with alteration of colour and/or smell, or vulval itch/irritation is more likely to indicate an infective cause than a gradual or long-standing change.

Local epidemiology is particularly important when assessing possible causes. In the UK, most cases of vaginal discharge are not sexually transmitted, being due to either candidal infection or bacterial vaginosis (BV). World-wide, the most common treatable STI causing vaginal discharge is trichomoniasis; other possibilities include gonorrhoea and chlamydia. HSV may cause increased discharge, although vulval pain and dysuria are usually the predominant symptoms. Non-infective causes include retained tampons, malignancy and/or fistulae.

Speculum examination often allows a relatively accurate diagnosis to be made. In BV, the discharge is characteristically homogeneous and off-white in colour. Vaginal pH is greater than 4.5, and Gram stain microscopy reveals scanty or absent lactobacilli with significant numbers of Gram-variable organisms, some of which may be coating vaginal squames (so-called Clue cells, Fig. 15.4). In candidiasis, there may be vulval and vaginal erythema, and the discharge is typically curdy

Fig. 15.4 Gram stain of a Clue cell from a patient with bacterial vaginosis. The margin of this vaginal epithelial cell is obscured by a coating of anaerobic organisms.

in nature. Vaginal pH is usually less than 4.5, and Gram stain microscopy reveals fungal spores and pseudo-hyphae. Trichomoniasis tends to cause a profuse yellow or green discharge and is usually associated with significant vulvovaginal inflammation. Diagnosis is made by observing motile flagellate protozoa on a wet-mount microscopy slide of vaginal material.

If examination reveals the discharge to be cervical in origin, the possibility of chlamydial or gonococcal infection is increased and appropriate cervical swabs should be taken (p. 411). In addition, Gram stain of cervical and urethral material may reveal GNDC, allowing presumptive treatment for gonorrhoea to be given. If gonococcal cervicitis is suspected, swabs should also be taken from the pharynx and rectum; infections at these sites are not reliably eradicated by single-dose therapy and a test of cure will therefore be required.

GUM clinics in the UK routinely offer sexually active women presenting with vaginal discharge an STI screen (p. 411). In other settings such as primary care or gynaecology, testing for chlamydia and gonorrhoea should be strongly considered in young women (< 25 years old), those who have changed partner recently, and those not using a barrier method of contraception, even if a non-STI cause of discharge is suspected clinically.

Treatment of infections causing vaginal discharge is shown in Box 15.3.

Lower abdominal pain

Pelvic inflammatory disease (PID, infection or inflammation of the Fallopian tubes and surrounding structures) is part of the extensive differential diagnosis of lower abdominal pain in women, especially those who are sexually active. The possibility of PID is increased if, in addition to acute/subacute pain, there is dyspareunia, abnormal vaginal discharge and/or bleeding. There may also be systemic features such as fever and malaise. On examination, lower abdominal pain is usually bilateral, and vaginal examination reveals adnexal tenderness with or without cervical excitation. Unfortunately, a definitive diagnosis can only be made by laparoscopy. A pregnancy test should be performed (in addition to the diagnostic tests listed on page 411) because the differential diagnosis includes ectopic pregnancy.

15.3 Infections that cause vaginal discharge

Cause	Clinical features	Treatment (in pregnancy seek specialist advice)
Candidiasis	Vulval and vaginal inflammation Curdy white discharge adherent to walls of vagina Low vaginal pH	Clotrimazole ¹ 500 mg pessary once at night and clotrimazole cream 12-hourly <i>or</i> Econazole ¹ pessary 150 mg for 3 nights and econazole cream 12-hourly (topical creams for 7 days) <i>or</i> Fluconazole ² 150 mg orally stat
Trichomoniasis	Vulval and vaginal inflammation Frothy yellow/green discharge	Metronidazole ³ 400 mg 12-hourly orally for 5–7 days <i>or</i> Metronidazole ³ 2 g orally as a single dose
Bacterial vaginosis	No inflammation White homogeneous discharge High vaginal pH	Metronidazole ³ 2 g stat <i>or</i> 400 mg 12-hourly orally for 5–7 days Metronidazole ³ vaginal gel 0.75% daily for 5 days Clindamycin ^{1,4} vaginal cream 2% daily for 7 days
Streptococcal/staphylococcal infection	Purulent vaginal discharge	Choice of antibiotic depends on sensitivity tests

¹Clotrimazole, econazole and clindamycin damage latex condoms and diaphragms.

²Avoid in pregnancy and breastfeeding.

³Avoid alcoholic drinks until 48 hours after finishing treatment. Avoid high-dose regimens in pregnancy or breastfeeding.

⁴Pseudomembranous colitis has been reported with the use of clindamycin cream.

Broad-spectrum antibiotics, including those active against gonorrhoea and chlamydia such as ofloxacin and metronidazole, should be prescribed if PID is suspected, along with appropriate analgesia. Delaying treatment increases the likelihood of adverse sequelae such as abscess formation, and tubal scarring that may lead to ectopic pregnancy or infertility. Hospital admission may be indicated in women with severe symptoms.

Genital ulceration

The most common cause of ulceration is genital herpes. Classically, multiple painful ulcers affect the introitus, labia and perineum, but solitary lesions occur rarely. Inguinal lymphadenopathy and systemic features such as fever and malaise are more common than in men. Diagnosis is made by gently scraping material from lesions and sending this in an appropriate transport medium for culture or detection of HSV DNA by PCR. In the UK, the possibility of any other ulcerating STI is unlikely unless the patient has had a sexual partner from a region where tropical STIs are more common (see Box 15.11, p. 422).

Inflammatory causes include lichen sclerosus, Stevens–Johnson syndrome (p. 1285), Behçet's syndrome (p. 1114) and fixed drug reactions. In older patients,

malignant and pre-malignant conditions such as squamous cell carcinoma should be considered.

Genital lumps

The most common cause of genital 'lumps' is warts. These are classically found in areas of friction during sex, such as the fourchette and perineum. Perianal warts are surprisingly common in women who do not have anal sex.

The differential diagnosis includes molluscum contagiosum, skin tags and normal papillae or sebaceous glands.

Chronic vulval pain and/or itch

Women may present with a range of chronic symptoms that may be intermittent or continuous (Box 15.4).

Recurrent candidiasis may lead to hypersensitivity to candidal antigens, with itch and erythema becoming more prominent than increased discharge. Effective treatment may require regular oral antifungals, e.g. fluconazole 150 g once every 2–4 weeks plus a combined antifungal/corticosteroid cream such as Daktacort or Canesten HC.

PREVENTION OF STI

Case-finding

Early diagnosis and treatment facilitated by active case-finding will help to reduce the spread of infection by limiting the period of infectivity; tracing and treating sexual partners will also reduce the risk of re-infection. Unfortunately, the majority of individuals with an STI are asymptomatic and therefore unlikely to seek medical attention. Improving access to diagnosis in primary care or non-medical settings, especially through opportunistic testing, may help. However, the impact of medical intervention through improved access alone is likely to be small.

Changing behaviour

The prevalence of STIs is driven largely by sexual behaviour. Primary prevention encompasses efforts to delay the onset of sexual activity and limit the number of sexual partners thereafter. Encouraging the use of barrier methods of contraception will also help to reduce the risk of transmitting or acquiring STIs. This is especially important in the setting of 'sexual concurrency', where sexual relationships overlap.

Unfortunately, there is contradictory evidence as to which (if any) interventions can reduce sexual activity. Knowledge alone does not translate into behaviour change, and broader issues such as poor parental role modelling, low self-esteem, peer group pressure in the context of the increased sexualisation of our societies, gender power imbalance and homophobia all need to be addressed. Throughout the world there is a critical need to enable women to protect themselves from disciplined and coercive male sexual activity. Economic collapse and the turmoil of war regularly lead to situations where women are raped or must turn to prostitution to feed themselves and their children, and an inability to negotiate safe sex increases their risk of acquiring STI, including HIV.

15.4 Chronic vulval pain and/or itch

Likely diagnosis	Itch	Pain	Specific characteristics	Diagnostic test	Treatment
Candida	✓	±	Usually cyclical	Microscopy	Oral antifungal, e.g. fluconazole 150 mg
Lichen planus	±	–	Violaceous papules ± Wickham's striae	Clinical	No treatment, or mild topical corticosteroid, e.g. hydrocortisone
Lichen sclerosis	±	–	Ivory white plaques, scarring ± labial resorption	Clinical or biopsy	Strong topical corticosteroid, e.g. clobetasol
Vestibulitis	–	✓	Dyspareunia common, pain on touching erythematous area	Clinical	Refer to specialist vulva clinic
Vulvodynia	–	✓	Pain usually neuropathic in nature	Clinical	Refer to specialist vulva clinic
Dermatoses, e.g. eczema or psoriasis	✓	–	Similar to lesions elsewhere on skin	Clinical	Mild topical corticosteroid, e.g. hydrocortisone
Genital herpes	±	✓	Atypical ulcers are not uncommon	Swab for HSV PCR	Oral antiviral, e.g. aciclovir

SEXUALLY TRANSMITTED BACTERIAL INFECTIONS

Syphilis

Syphilis is caused by infection, through abrasions in the skin or mucous membranes, with the spirochaete *Treponema pallidum*. In adults the infection is usually sexually acquired; however, transmission by kissing, blood transfusion and percutaneous injury has been reported. Transplacental infection of the fetus can occur.

The natural history of untreated syphilis is variable. Infection may remain latent throughout, or clinical features may develop at any time. The classification of syphilis is shown in Box 15.5. All infected patients should be treated. Penicillin remains the drug of choice for all stages of infection.

Acquired syphilis

Early syphilis

Primary syphilis

The incubation period is usually between 14 and 28 days with a range of 9–90 days. The primary lesion or chancre (Fig. 15.5) develops at the site of infection, usually in the genital area. A dull red macule develops, becomes

papular and then erodes to form an indurated ulcer (chancre). The draining inguinal lymph nodes may become moderately enlarged, mobile, discrete and rubbery. The chancre and the lymph nodes are both painless and non-tender, unless there is concurrent or secondary infection. Without treatment, the chancre will resolve within 2–6 weeks to leave a thin atrophic scar.

Chancres may develop on the vaginal wall and on the cervix. Extragenital chancres are found in about 10% of patients, affecting sites such as the finger, lip, tongue, tonsil, nipple, anus or rectum. Anal chancres often resemble fissures and may be painful.

Secondary syphilis

This occurs 6–8 weeks after the development of the chancre when treponemes disseminate to produce a multisystem disease. Constitutional features such as mild fever, malaise and headache are common. Over 75% of patients present with a rash on the trunk and limbs that may later involve the palms and soles; this is initially macular but evolves to maculopapular or papular forms, which are generalised, symmetrical

Fig. 15.5 Primary syphilis. A painless ulcer (chancre) is shown in the coronal sulcus of the penis. This is usually associated with inguinal lymphadenopathy.

15.5 Classification of syphilis		
Stage	Acquired	Congenital
Early	Primary Secondary Latent	Clinical and latent
Late	Latent Benign tertiary Cardiovascular Neurosyphilis	Clinical and latent

and non-irritable. Scales may form on the papules later. Without treatment, the rash may last for up to 12 weeks. Condylomata lata (papules coalescing to plaques) may develop in warm, moist sites such as the vulva or perianal area. Generalised non-tender lymphadenopathy is present in over 50% of patients. Mucosal lesions, known as mucous patches, may affect the genitalia, mouth, pharynx or larynx and are essentially modified papules, which become eroded. Rarely, confluence produces characteristic 'snail track ulcers' in the mouth.

Other features such as meningitis, cranial nerve palsies, anterior or posterior uveitis, hepatitis, gastritis, glomerulonephritis or periostitis are sometimes seen.

The differential diagnosis of secondary syphilis can be extensive, but in the context of a suspected STI, primary HIV infection is the most important alternative condition to consider (Ch. 14).

The clinical manifestations of secondary syphilis will resolve without treatment but relapse may occur, usually within the first year of infection. Thereafter, the disease enters the phase of latency.

Latent syphilis

This phase is characterised by the presence of positive syphilis serology or the diagnostic cerebrospinal fluid (CSF) abnormalities of neurosyphilis in an untreated patient with no evidence of clinical disease. It is divided into early latency (within 2 years of infection), when syphilis may be transmitted sexually, and late latency, when the patient is no longer sexually infectious. Transmission of syphilis from a pregnant woman to her fetus, and rarely by blood transfusion, is possible for several years following infection.

Late syphilis

Late latent syphilis

This may persist for many years or for life. Without treatment over 60% of patients might be expected to suffer little or no ill health. Coincidental prescription of antibiotics for other illnesses such as respiratory tract or skin infections may treat latent syphilis serendipitously.

Benign tertiary syphilis

This may develop between 3 and 10 years after infection but is now rarely seen in the UK. Skin, mucous membranes, bone, muscle or viscera can be involved. The characteristic feature is a chronic granulomatous lesion called a gumma, which may be single or multiple. Healing with scar formation may impair the function of the structure affected. Skin lesions may take the form of nodules or ulcers whilst subcutaneous lesions may ulcerate with a gummy discharge. Healing occurs slowly with the formation of characteristic tissue paper scars. Mucosal lesions may occur in the mouth, pharynx, larynx or nasal septum, appearing as punched-out ulcers. Of particular importance is gummatous involvement of the tongue, healing of which may lead to leucoplakia with the attendant risk of malignant change. Gummas of the tibia, skull, clavicle and sternum have been described, as has involvement of the brain, spinal cord, liver, testis and, rarely, other organs. Resolution of active disease should follow treatment, though some tissue damage may be permanent. Paroxysmal cold haemoglobinuria (p. 1026) may be seen.

Cardiovascular syphilis

This may present many years after initial infection. Aortitis which may involve the aortic valve and/or the coronary ostia is the key feature. Clinical features include aortic incompetence, angina and aortic aneurysm (p. 602). The condition typically affects the ascending aorta and sometimes the aortic arch; aneurysm of the descending aorta is rare. Treatment with penicillin will not correct anatomical damage and surgical intervention may be required.

Neurosyphilis

This may also take years to develop. Asymptomatic infection is associated with CSF abnormalities in the absence of clinical signs. Meningovascular disease, tabes dorsalis and general paralysis of the insane constitute the symptomatic forms (p. 1212). Neurosyphilis and cardiovascular syphilis may coexist and are sometimes referred to as quaternary syphilis.

Congenital syphilis

Congenital syphilis is rare where antenatal serological screening is practised. Antisyphilitic treatment in pregnancy treats the fetus, if infected, as well as the mother.

Treponemal infection may give rise to a variety of outcomes after 4 months of gestation when the fetus becomes immunocompetent:

- miscarriage or stillbirth, premature or at term
- birth of a syphilitic baby (a very sick baby with hepatosplenomegaly, bullous rash and perhaps pneumonia)
- birth of a baby who develops signs of early congenital syphilis during the first few weeks of life (Box 15.6)
- birth of a baby with latent infection who either remains well or develops congenital syphilis/stigmata later in life (see Box 15.6).

Investigations in adult cases

T. pallidum may be identified in serum collected from chancres, or from moist or eroded lesions in secondary syphilis using a dark-field microscope, a direct fluorescent antibody test or PCR.

The serological tests for syphilis are listed in Box 15.7. Many centres use treponemal enzyme immunoassays (EIAs) for IgG and IgM antibodies to screen for syphilis. EIA for antitreponemal IgM becomes positive at approximately 2 weeks, whilst non-treponemal tests become positive about 4 weeks after primary syphilis. All positive results in asymptomatic patients must be confirmed by repeat tests.

Biological false positive reactions occur occasionally; these are most commonly seen with Venereal Diseases Research Laboratory (VDRL) or rapid plasma reagin (RPR) tests (when treponemal tests will be negative). Acute false positive reactions may be associated with infections such as infectious mononucleosis, chikungunya and malaria, and may also occur in pregnancy. Chronic false positive reactions may be associated with autoimmune diseases. False negative results for non-treponemal tests may be found in secondary syphilis because extremely high antibody levels can prevent the formation of the antibody-antigen lattice necessary for the visualisation of the flocculation reaction (the prozone phenomenon).

15.6 Clinical features of congenital syphilis

Early congenital syphilis (neonatal period)

- Maculopapular rash
- Condylomata lata
- Mucous patches
- Fissures around mouth, nose and anus
- Rhinitis with nasal discharge (snuffles)
- Hepatosplenomegaly
- Osteochondritis/periostitis
- Generalised lymphadenopathy
- Choroiditis
- Meningitis
- Anaemia/thrombocytopenia

Late congenital syphilis

- Benign tertiary syphilis
- Periostitis
- Paroxysmal cold haemoglobinuria
- Neurosyphilis
- 8th nerve deafness
- Interstitial keratitis
- Clutton's joints (painless effusion into knee joints)

Stigmata

- Hutchinson's incisors (anterior-posterior thickening with notch on narrowed cutting edge)
- Mulberry molars (imperfectly formed cusps/deficient dental enamel)
- High arched palate
- Maxillary hypoplasia
- Saddle nose (following snuffles)
- Rhagades (radiating scars around mouth, nose and anus following rash)
- Salt and pepper scars on retina (from choroiditis)
- Corneal scars (from interstitial keratitis)
- Sabre tibia (from periostitis)
- Bossing of frontal and parietal bones (healed periosteal nodes)

In benign tertiary and cardiovascular syphilis, examination of CSF should be considered because asymptomatic neurological disease may coexist. The CSF should also be examined in patients with clinical signs of neurosyphilis (p. 1212) and in both early and late congenital syphilis. Chest X-ray, ECG and echocardiogram are useful in the investigation of cardiovascular syphilis. Biopsy may be required to diagnose gumma.

Endemic treponematoses such as yaws, endemic (non-venereal) syphilis (bejel) and pinta (pp. 327–328)

15.7 Serological tests for syphilis

Non-treponemal (non-specific) tests

- Venereal Diseases Research Laboratory (VDRL) test
- Rapid plasma reagin (RPR) test

Treponemal (specific) antibody tests

- Treponemal antigen-based enzyme immunoassay (EIA) for IgG and IgM
- *T. pallidum* haemagglutination assay (TPHA)
- *T. pallidum* particle agglutination assay (TPPA)
- Fluorescent treponemal antibody-absorbed (FTA-ABS) test

are caused by treponemes morphologically indistinguishable from *T. pallidum* that cannot be differentiated by serological tests. A VDRL or RPR test may help to elucidate the correct diagnosis because adults with late yaws usually have low titres.

Investigations in suspected congenital syphilis

Passively transferred maternal antibodies from an adequately treated mother may give rise to positive serological tests in her baby. In this situation, non-treponemal tests should become negative within 3–6 months of birth. A positive EIA test for antitreponemal IgM suggests early congenital syphilis. A diagnosis of congenital syphilis mandates investigation of the mother, her partner and any siblings.

Management

Penicillin is the drug of choice. Specific regimens depend on the stage of infection. Longer courses are required in late syphilis. Doxycycline is indicated for patients allergic to penicillin, except in pregnancy (see below). Azithromycin is a further alternative. All patients must be followed up to ensure cure, and partner notification is of particular importance. Resolution of clinical signs in early syphilis with declining titres for non-treponemal tests, usually to undetectable levels within 6 months for primary syphilis and 12–18 months for secondary syphilis, are indicators of successful treatment. Specific treponemal antibody tests may remain positive for life. In patients who have had syphilis for many years there may be little serological response following treatment.

Pregnancy

Penicillin is the treatment of choice in pregnancy. Erythromycin stearate can be given if there is penicillin hypersensitivity, but crosses the placenta poorly; the newborn baby must therefore be treated with a course of penicillin and consideration given to retreating the mother. Some specialists recommend penicillin desensitisation for pregnant mothers so that penicillin can be given during temporary tolerance. The author has successfully prescribed ceftriaxone 250 mg i.m. for 10 days in this situation. Babies should be treated in hospital with the help of a paediatrician.

Treatment reactions

- *Anaphylaxis*. Penicillin is a common cause; on-site facilities should be available for management (p. 89).
- *Jarisch-Herxheimer reaction*. This is an acute febrile reaction that follows treatment and is characterised by headache, malaise and myalgia; it resolves within 24 hours. It is common in early syphilis and rare in late syphilis. Fetal distress or premature labour can occur in pregnancy. The reaction may also cause worsening of neurological (cerebral artery occlusion) or ophthalmic (uveitis, optic neuritis) disease, myocardial ischaemia (inflammation of the coronary ostia) and laryngeal stenosis (swelling of a gumma). Prednisolone 10–20 mg orally 8-hourly for 3 days is recommended to prevent the reaction in patients with these forms of the disease; antisyphilitic treatment can be started 24 hours after introducing corticosteroids. In high-risk situations it is wise to initiate therapy in hospital.

- **Procaine reaction.** Fear of impending death occurs immediately after the accidental intravenous injection of procaine penicillin and may be associated with hallucinations or fits. Symptoms are short-lived, but verbal assurance and sometimes physical restraint are needed. The reaction can be prevented by aspiration before intramuscular injection to ensure the needle is not in a blood vessel.

Gonorrhoea

Gonorrhoea is caused by infection with *Neisseria gonorrhoeae* and may involve columnar epithelium in the lower genital tract, rectum, pharynx and eyes. Transmission is usually the result of vaginal, anal or oral sex. Gonococcal conjunctivitis may be the result of accidental infection from contaminated fingers. Untreated mothers may infect their babies during delivery, resulting in ophthalmia neonatorum (Fig. 15.6). Infection of children beyond the neonatal period is usually indicative of sexual abuse.

Clinical features

The incubation period is usually 2–10 days. In men the anterior urethra is commonly infected, causing urethral discharge and dysuria, but symptoms are absent in about 10% of cases. Examination will usually show a mucopurulent or purulent urethral discharge. Rectal infection in MSM is usually asymptomatic but may present with anal discomfort, discharge or rectal bleeding. Proctoscopy may reveal either no abnormality, or clinical evidence of proctitis (see Fig. 15.3, p. 415) such as inflamed rectal mucosa and mucus.

In women, the urethra, paraurethral glands/ducts, Bartholin's glands/ducts or endocervical canal may be infected. The rectum may also be involved either due to

contamination from a urogenital site or as a result of anal sex. Occasionally, the rectum is the only site infected. About 80% of women who have gonorrhoea are asymptomatic. There may be vaginal discharge or dysuria but these symptoms are often due to additional infections such as chlamydia (see below), trichomoniasis or candidiasis, making full investigation essential (p. 411). Lower abdominal pain, dyspareunia and intermenstrual bleeding may be indicative of PID. Clinical examination may show no abnormality or pus may be expressed from urethra, paraurethral ducts or Bartholin's ducts. The cervix may be inflamed, with mucopurulent discharge and contact bleeding.

Pharyngeal gonorrhoea is the result of receptive orogenital sex and is usually symptomless. Gonococcal conjunctivitis is an uncommon complication, presenting with purulent discharge from the eye(s), severe inflammation of the conjunctivae and oedema of the eyelids, pain and photophobia. Gonococcal ophthalmia neonatorum presents similarly with purulent conjunctivitis and oedema of the eyelids. Conjunctivitis must be treated urgently to prevent corneal damage.

Disseminated gonococcal infection (DGI) is seen rarely, and typically affects women with asymptomatic genital infection. Symptoms include arthritis of one or more joints, pustular skin lesions and fever. Gonococcal endocarditis has been described.

Investigations

GNDC may be seen on microscopy of smears from infected sites (see Fig. 15.1, p. 413). Pharyngeal smears are difficult to analyse due to the presence of other diplococci, so the diagnosis must be confirmed by culture or NAAT.

Management of adults

Uncomplicated gonorrhoea responds to a single adequate dose of a suitable antimicrobial (many UK centres

Fig. 15.6 Gonococcal ophthalmia neonatorum.

15.8 Treatment of uncomplicated anogenital gonorrhoea
Uncomplicated infection
<ul style="list-style-type: none"> • Cefixime 400 mg stat <i>or</i> • Ciprofloxacin 500 mg orally stat^{1,2} <i>or</i> • Ofloxacin 400 mg orally stat^{1,2} <i>or</i> • Amoxicillin 3 g <i>plus</i> probenecid 1 g orally stat³

15.9 Complications of delayed therapy in gonorrhoea

- Acute prostatitis
- Epididymo-orchitis
- Bartholin's gland abscess
- PID (may lead to infertility or ectopic pregnancy)
- Disseminated gonococcal infection

currently use oral cefixime 400mg, Box 15.8); cure rates should exceed 95%. Longer courses of antibiotics are required for complicated infection. Partner(s) of patients with gonorrhoea should be seen as soon as possible.

Delay in treatment may lead to complications (Box 15.9).

Chlamydial infection

Chlamydial infection in men

Chlamydia is transmitted and presents in a similar way to gonorrhoea; however, urethral symptoms are usually milder and may be absent in over 50% of cases. Conjunctivitis is also milder than in gonorrhoea; pharyngitis does not occur. The incubation period varies from 1 week to a few months. Without treatment, symptoms may resolve but the patient remains infectious for several months. Complications such as epididymo-orchitis and Reiter's syndrome, or sexually acquired reactive arthropathy (SARA, p. 1094) are rare. Sexually transmitted pathogens such as chlamydia or gonococci are usually responsible for epididymo-orchitis in men aged less than 35 years, whereas bacteria such as Gram-negative enteric organisms are more commonly implicated in older men.

Treatments for chlamydia are listed in Box 15.10. Non-specific urethritis is treated identically. The partner(s) of men with chlamydia should be treated even if laboratory tests for chlamydia are negative. Investigation is not mandatory, but serves a useful epidemiological purpose; moreover, positive results encourage further attempts at contact-tracing.

Chlamydial infection in women

The cervix and urethra are commonly involved. Infection is asymptomatic in about 80% of patients but may cause vaginal discharge, dysuria, intermenstrual and/or post-coital bleeding. Lower abdominal pain and dyspareunia are features of PID. Examination may reveal mucopurulent cervicitis, contact bleeding from cervix, evidence of PID or no obvious clinical signs. Treatment options are

15.10 Treatment of chlamydial infection

Standard regimens

- Azithromycin 1 g orally as a single dose¹ *or*
- Doxycycline 100 mg 12-hourly orally for 7 days²

Alternative regimens

- Erythromycin 500 mg 6-hourly orally for 7 days *or* 500 mg 12-hourly for 2 weeks *or*
- Ofloxacin 200 mg 12-hourly orally for 7 days²

¹Safety in pregnancy and breastfeeding has not been fully assessed.

²Contraindicated in pregnancy and breastfeeding.

listed in Box 15.10. The patient's male partner(s) should be investigated and treated.

Some infections may clear spontaneously but others persist. PID, with the risk of tubal damage and subsequent infertility or ectopic pregnancy, is an important long-term complication. Other complications include perihepatitis, chronic pelvic pain, conjunctivitis and Reiter's syndrome or SARA. Perinatal transmission may lead to ophthalmia neonatorum and/or pneumonia in the neonate.

Other sexually transmitted bacterial infections

Chancroid, granuloma inguinale and LGV as causes of genital ulcers in the tropics are described in Box 15.11. LGV is also a cause of proctitis in MSM (p. 414).

SEXUALLY TRANSMITTED VIRAL INFECTIONS

Genital herpes simplex

Infection with herpes simplex virus type 1 (HSV-1) or type 2 (HSV-2) produces a wide spectrum of clinical problems (p. 321). Transmission is usually sexual (vaginal, anal, orogenital or oroanal), but perinatal infection of the neonate may also occur. Primary infection at the site of HSV entry, which may be symptomatic or asymptomatic, establishes latency in local sensory ganglia. Recurrences, either symptomatic or asymptomatic viral shedding, are a consequence of HSV reactivation. The first symptomatic episode is usually the most severe. Although HSV-1 is classically associated with orolabial herpes and HSV-2 with anogenital herpes, HSV-1 now accounts for more than 50% of anogenital infections in the UK.

Clinical features

The first symptomatic episode presents with irritable vesicles that soon rupture to form small, tender ulcers on the external genitalia (see Figs 15.7 and 15.2, p. 414). Lesions at other sites (e.g. urethra, vagina, cervix, perianal area, anus or rectum) may cause dysuria, urethral or vaginal discharge, or anal, perianal or rectal pain. Constitutional symptoms such as fever, headache and malaise are common. Inguinal lymph nodes become enlarged and tender, and there may be nerve root pain in the 2nd and 3rd sacral dermatomes.

Extragenital lesions may develop at other sites such as the buttock, finger or eye due to auto-inoculation. Oropharyngeal infection may result from orogenital sex. Complications such as urinary retention due to autonomic neuropathy, and aseptic meningitis are occasionally seen.

First episodes usually heal within 2–4 weeks without treatment; recurrences are usually milder and of shorter duration than the initial attack. They occur more often in HSV-2 infection and their frequency tends to decrease with time. Prodromal symptoms such as irritation or burning at the subsequent site of recurrence, or neuralgic pains affecting buttocks, legs or hips are commonly seen. The first symptomatic episode may be a recurrence of a previously undiagnosed primary infection. Recurrent episodes of asymptomatic viral shedding are important in the transmission of HSV.

15.11 Salient features of lymphogranuloma venereum, chancroid and granuloma inguinale (Donovanosis)

Infection and distribution	Organism	Incubation period	Genital lesion	Lymph nodes	Diagnosis	Management
Lymphogranuloma venereum (LGV) East/West Africa, India, South-east Asia, South America, Caribbean	<i>Chlamydia trachomatis</i> types L1,2,3	3–30 days	Small, transient, painless ulcer, vesicle, papule; often unnoticed	Tender, usually unilateral, matted, adherent, multilocular, suppurative bubo; inguinal/femoral nodes involved; there may be late sequelae ¹	Serological tests for L1–3 serotypes; swab from ulcer or bubo pus for <i>Chlamydia</i>	Doxycycline ² 12-hourly orally for 21 days <i>or</i> Erythromycin 500 mg 6-hourly orally
Chancroid Africa, Asia, Central and South America	<i>Haemophilus ducreyi</i> (short Gram-negative bacillus)	3–10 days	Single or multiple painful ulcers with ragged undermined edges	As above but unilocal, suppurative bubo; inguinal nodes involved in ~50%	Microscopy and culture of scrapings from ulcer or pus from bubo	Azithromycin ³ 1 g orally once <i>or</i> Ceftriaxone 250 mg i.m. once <i>or</i> Ciprofloxacin ² 500 mg 12-hourly orally for 3 days <i>or</i> Erythromycin 500 mg 6-hourly orally for 7 days
Granuloma inguinale Australia, Caribbean, India, South Africa, South America, Papua New Guinea	<i>Klebsiella granulomatis</i> (Donovan bodies)	3–40 days	Ulcers or hypertrophic granulomatous lesions; usually painless ⁴	Initial swelling of inguinal nodes, then spread of infection to form abscess or ulceration through adjacent skin	Microscopy of cellular material for intracellular bipolar-staining Donovan bodies	Azithromycin ³ 1 g weekly orally <i>or</i> 500 mg daily orally <i>or</i> Doxycycline ² 100 mg 12-hourly orally <i>or</i> Ceftriaxone 1 g i.m. daily <i>or</i> Erythromycin 500 mg 6-hourly orally Treatment for at least 3 weeks and until lesions have healed

¹The genito-ano-rectal syndrome is a late manifestation of LGV.
²Doxycycline and ciprofloxacin are contraindicated in pregnancy and breastfeeding.
³The safety of azithromycin in pregnancy and breastfeeding has not been fully assessed.
⁴Mother-to-baby transmission of granuloma inguinale may rarely occur.
N.B. Partners of patients with LGV, chancroid and granuloma inguinale should be investigated and treated, even if asymptomatic.

Diagnosis

Swabs are taken from vesicular fluid or ulcers for detection of DNA by PCR or tissue culture and typing. Electron microscopy of such material will only give a presumptive diagnosis, as herpes group viruses appear similar. Type-specific antibody tests are available but are not sufficiently accurate for general use.

Management

First episode

The following 5-day oral regimens are all recommended and should be started within 5 days of the beginning of the episode, or whilst lesions are still forming:

- aciclovir 200 mg five times daily
- famciclovir 250 mg 8-hourly
- valaciclovir 500 mg 12-hourly.

Analgesia may be required and saline bathing can be soothing. Treatment may be continued for longer than

5 days if new lesions develop. Occasionally intravenous therapy may be indicated if oral therapy is poorly tolerated or aseptic meningitis occurs.

Catheterisation via the suprapubic route is advisable for urinary retention due to autonomic neuropathy because the transurethral route may introduce HSV into the bladder.

Recurrent genital herpes

Symptomatic recurrences are usually mild and may require no specific treatment other than saline bathing. For more severe episodes patient-initiated treatment at onset, with one of the following 5-day oral regimens, should reduce the duration of the recurrence:

- aciclovir 200 mg five times daily
- famciclovir 125–150 mg 12-hourly
- valaciclovir 500 mg 12-hourly.

In a few patients, treatment started at the onset of prodromal symptoms may abort recurrence.

Fig. 15.7 Herpetic ulceration of the vulva.

Suppressive therapy may be required for patients with frequent recurrences, especially if these occur at intervals of less than 4 weeks. Treatment should be given for a minimum of 1 year before stopping to assess recurrence rate. About 20% of patients will experience reduced attack rates thereafter, but for those whose recurrences remain unchanged, resumption of suppressive therapy is justified. Aciclovir 400 mg 12-hourly is most commonly prescribed.

Management in pregnancy

If her partner is known to be infected with HSV, a pregnant woman with no previous anogenital herpes should be advised to protect herself during sexual intercourse because the risk of disseminated infection is increased in pregnancy. Consistent condom use during pregnancy may reduce transmission of HSV. Genital herpes acquired during the first or second trimester of pregnancy is treated with aciclovir as clinically indicated. Although aciclovir is not licensed for use in pregnancy in the UK, there is considerable clinical evidence to support its safety. Third-trimester acquisition has been associated with life-threatening haematogenous dissemination and should be treated with aciclovir.

Vaginal delivery should be routine in women who are symptomless in late pregnancy. Caesarean section (CS) is sometimes considered if there is a recurrence at the beginning of labour, although the risk of neonatal herpes through vaginal transmission is very low. CS is often recommended if primary infection occurs after 34 weeks because the risk of viral shedding is very high in labour.

Human papillomavirus (HPV) and anogenital warts

HPV DNA typing has demonstrated over 90 genotypes (p. 1271), of which HPV-6, HPV-11, HPV-16 and HPV-18 most commonly infect the genital tract through sex-

ual transmission. It is important to differentiate between the benign genotypes (HPV-6 and 11) that cause anogenital warts, and genotypes such as 16 and 18 that are associated with dysplastic conditions and cancers of the genital tract but are not a cause of benign warts. All genotypes usually result in subclinical infection of the genital tract rather than clinically obvious lesions affecting penis, vulva, vagina, cervix, perineum or anus.

Clinical features

Anogenital warts caused by HPV may be single or multiple, exophytic, papular or flat. Perianal warts (p. 410), whilst being more commonly found in MSM, are also found in heterosexual men and in women. Rarely, a giant condyloma (Buschke–Lewenstein tumour) develops with local tissue destruction. Atypical warts should be biopsied. In pregnancy warts may dramatically increase in size and number, making treatment difficult. Rarely, they are large enough to obstruct labour and in this case delivery by CS will be required. Perinatal transmission of HPV rarely leads to anogenital warts, or possibly laryngeal papillomas, in the neonate.

Management

The use of condoms can help prevent the transmission of HPV to non-infected partners, but HPV may affect parts of the genital area not protected by condoms. Vaccination against HPV infection has been introduced and is in routine use in several countries. There are two types of vaccine:

- A *bivalent vaccine* offers protection against HPV types 16 and 18, which account for approximately 75% of cervical cancers in the UK.
- A *quadrivalent vaccine* offers additional protection against HPV types 6 and 11, which account for over 90% of genital warts.

Both types of vaccine have been shown to be highly effective in the prevention of cervical intraepithelial neoplasia in young women, and the quadrivalent vaccine has also been shown to be highly effective in protecting against HPV-associated genital warts (Box 15.12). It is currently recommended that HPV vaccination should be administered prior to the onset of sexual activity, typically at age 11–13, in a course of three injections. In the UK, only girls are being offered vaccination, although it should be noted that this approach will not protect HPV transmission for MSM. As neither vaccine protects against all oncogenic types of HPV, cervical screening programmes will still be necessary.

A variety of treatments are available for established disease, including the following:

- *Podophyllotoxin, 0.5% solution or 0.15% cream* (contraindicated in pregnancy) applied 12-hourly for 3 days, followed by 4 days' rest, for up to 4 weeks is suitable for home treatment of external warts.

EBM 15.12 HPV vaccination and precancerous cervical intraepithelial neoplasia

'Prophylactic HPV vaccination in women aged 15–25 years is highly effective at preventing precancerous cervical intraepithelial neoplasia in young women who have not previously been infected with HPV.'

- Garland SM, et al. *New Engl J Med* 2007; 356:1928–1943.
- Paavonen J, et al. *Lancet* 2007; 369:2161–2170.

- *Imiquimod* cream (contraindicated in pregnancy) applied 3 times weekly (and washed off after 6–10 hours) for up to 16 weeks is also suitable for home treatment of external warts.
- *Cryotherapy* using liquid nitrogen to freeze warty tissue is suitable for external and internal warts but often requires repeated clinic visits.
- *Hyfrecation* – electrofulguration that causes superficial charring – is suitable for external and internal warts. Hyfrecation results in smoke plume which contains HPV DNA and the potential to cause respiratory infection in the operator/patient. Masks should be worn during the procedure and adequate extraction of fumes should be provided.
- *Surgical removal*. Refractory warts, especially pedunculated perianal lesions, may be excised under local or general anaesthesia.

Molluscum contagiosum

Infection by molluscum contagiosum virus, both sexual and non-sexual, produces flesh-coloured umbilicated hemispherical papules usually up to 5 mm in diameter after an incubation period of 3–12 weeks (Fig. 15.8). Larger lesions may be seen in HIV infection (p. 391). Lesions are often multiple and, once established in an individual, may spread by auto-inoculation. They are found on the genitalia, lower abdomen and upper thighs when sexually acquired. Facial lesions are highly suggestive of underlying HIV infection. Diagnosis is made on clinical grounds and by expression of the central core, in which the typical pox-like viral particles can be seen on electron microscopy (differentiating molluscum contagiosum from genital warts). Typically, lesions persist for an average of 2 years before spontaneous reso-

Fig. 15.8 Molluscum contagiosum of the shaft of the penis.

lution occurs. Treatment regimens are therefore cosmetic; they include cryotherapy, hyfrecation, topical applications of 0.15% podophyllotoxin cream (contraindicated in pregnancy) or expression of the central core.

Viral hepatitis

The hepatitis viruses A–D (pp. 947–954) may be sexually transmitted:

- *Hepatitis A (HAV)*. Insertive oroanal sex, insertive digital sex, insertive anal sex and multiple sexual partners have been linked with HAV transmission in MSM. HAV transmission in heterosexual men and women is also possible through oroanal sex.
- *Hepatitis B (HBV)*. Insertive oroanal sex, anal sex and multiple sexual partners are linked with HBV infection in MSM. Heterosexual transmission of HBV is well documented and commercial sex workers are at particular risk. Hepatitis D (HDV) may also be sexually transmitted.
- *Hepatitis C*. Sexual transmission of HCV is well documented in MSM, but less so in heterosexuals. Sexual transmission is less efficient than for HBV.

The sexual partner(s) of patients with HAV and HBV should be seen as soon as possible and offered immunisation where appropriate. Patients with HAV should abstain from all forms of unprotected sex until non-infectious. Those with HBV should likewise abstain from unprotected sex until they are non-infectious or until their partners have been vaccinated successfully. No active or passive immunisation is available for protection against HCV but the consistent use of condoms is likely to protect susceptible partners. Active immunisation against HAV and HBV should be offered to susceptible people at risk of infection. Many STI clinics offer HAV immunisation to MSM along with routine HBV immunisation; a combined HAV and HBV vaccine is available.

There is a world-wide trend towards increased use of laboratory-based diagnostic investigations, and biochemical investigations in particular. In health-care systems of developed countries, it has been estimated that 60–70% of all critical decisions taken in regard to patients, and over 90% of data stored in electronic medical records systems, involve a laboratory service or result.

This chapter covers a diverse group of disorders affecting adults not considered elsewhere in this book, whose primary manifestation is in abnormalities of biochemistry laboratory results, or whose underlying pathophysiology involves disturbance in specific biochemical pathways.

BIOCHEMICAL INVESTIGATIONS

There are three broad reasons why a clinician may request a biochemical laboratory investigation:

- to screen an asymptomatic subject for the presence of disease
- to assist in diagnosis of a patient's presenting complaint
- to monitor changes in test results, as a marker of disease progression or response to treatment.

Contemporary medical practice has become increasingly reliant on laboratory investigation, and in particular, on biochemical investigation. This has been associated with extraordinary improvements in the ana-

lytical capacity and speed of laboratory instrumentation and the following operational trends:

- Large central biochemistry laboratories feature extensive use of automation and information technology. Specimens are transported from clinical areas to the laboratory using high-speed transport systems (such as pneumatic tubes), and identified with machine-readable labels (such as bar codes). Laboratory instruments have been miniaturised and integrated with robot transport systems to enable multiple rapid analyses of a single sample. Statistical process control techniques are used to assure the quality of analytical results, and increasingly to monitor other aspects of the laboratory, such as the time taken to complete the analysis ('turn-around time').
- Point-of-care testing (POCT) brings selected laboratory analytical systems into clinical areas, to the patient's bedside, or even connected to an individual patient. These systems allow the clinician to receive results almost instantaneously, although with less precision and often at greater cost than using a central laboratory.
- The diversity of analyses has widened considerably with the introduction of many techniques borrowed from the chemical or other industries (Box 16.1).

Good medical practice involves appropriate ordering of laboratory investigations and correct interpretation of test results. The key principles, including the concepts of sensitivity and specificity, are described in Chapter 1

16.1 Range of analytical modalities used in the clinical biochemistry laboratory

Analytical modality	Analyte	Typical applications
Ion-selective electrodes	Blood gases, electrolytes (e.g. Na, K, Cl)	Point-of-care testing (POCT) High-throughput analysers
Colorimetric chemical reaction or coupled enzymatic reaction	Simple mass or concentration measurement (e.g. creatinine, phosphate) Simple enzyme activity	High-throughput analysers
Ligand assay (usually immunoassay)	Specific proteins Hormones Drugs	Increasingly available for POCT or high-throughput analysers
Chromatography: gas chromatography (GC), high-pressure liquid chromatography (HPLC), thin-layer chromatography (TLC)	Organic compounds	Therapeutic drug monitoring (TDM)
Mass spectroscopy (MS)		Drug screening (e.g. drugs of misuse) Vitamins Biochemical metabolites
Spectrophotometry, turbidimetry, nephelometry, fluorimetry	Haemoglobin derivatives Specific proteins Immunoglobulins	Xanthochromia Lipoproteins Paraproteins
Electrophoresis	Proteins Some enzymes	Paraproteins Isoenzyme analysis
Atomic absorption (AA) Inductively coupled plasma/mass spectroscopy (ICP-MS)	Trace elements and metals	Quantitation of heavy metals
Molecular diagnostics	Nucleic acid quantification and/or sequence	Inherited and somatic cell mutations (Ch. 3) Genetic polymorphisms (Ch. 3) Variations in rates of drug metabolism (Ch. 2) Microbial diagnosis (Ch. 6)

(pp. 5–6). Reference ranges for laboratory results are discussed in Chapter 28. Many laboratory investigations can be subject to variability arising from incorrect patient preparation (e.g. fasting or fed state), timing of sample collection (e.g. in relation to diurnal variation of hormone levels, or dosage regimens for therapeutic agents), or analytical factors (e.g. serum vs. plasma sample, use of the correct anticoagulant, or POCT vs. central analyser). It is therefore important for clinical and laboratory staff to communicate effectively and for clinicians to follow local recommendations concerning collection and transport of samples in the appropriate container and with appropriate labelling.

INTEGRATED WATER AND ELECTROLYTE BALANCE

One of the most common uses of the clinical biochemistry laboratory is to monitor electrolyte and acid–base status. The diverse clinical consequences of these biochemical disorders are illustrated in Box 16.2. Some whole-body electrolyte disturbances (notably of sodium) result in major clinical problems with minimal disturbance in measured biochemical parameters. However, these will also be considered for convenience in this section.

Before considering individual electrolytes and acid–base balance in turn, it is important to review the relationships between them.

16.2 Manifestations of disordered water, electrolyte and acid–base status

Primary disturbance	Altered physiology	Clinical effect
Sodium	ECF volume	Circulatory changes
Water	ECF osmolality	Cerebral changes
Potassium	Action potential in excitable tissues	Neuromuscular weakness, cardiac effects
Hydrogen ion	Acid–base balance (pH)	Altered tissue function, respiratory compensation
Magnesium	Cell membrane stability	Neuromuscular, vascular and cardiac effects
Phosphate	Cellular energetics	Widespread tissue effects

(ECF = extracellular fluid)

Water and electrolyte distribution

The following basic concepts are relevant to understanding the origin, consequences and therapy of many of the fluid and electrolyte disturbances discussed in this chapter.

In a typical adult male, total body water (TBW) is approximately 60% of body weight (somewhat more for infants and less for women). Of a TBW of 40 L, more than half is located inside cells (the intracellular fluid or ICF) while the remainder, some 15 L, is in the extracellular fluid (ECF) compartment (Fig. 16.1). Of the ECF, the plasma is itself a small fraction (some 3 L) while the

Fig. 16.1 Normal distribution of body water and electrolytes.

Schematic representation of volume (L = litres) and composition (dominant ionic species only shown) of the intracellular fluid (ICF) and extracellular fluid (ECF) in a 70 kg male. The main difference in composition between the plasma and interstitial fluid (ISF) is the presence of appreciable concentrations of protein in the plasma but not the ISF.

remainder is interstitial fluid, within the tissues but outside the cells.

Figure 16.1 illustrates some of the major differences in composition between the main body fluid compartments. The dominant cation in the ICF is potassium, while the dominant cation in the ECF is sodium. Phosphates and negatively charged proteins constitute the major intracellular anions, while chloride and, to a lesser extent, bicarbonate dominate the ECF anions. An important difference between the plasma and interstitial compartments of the ECF is that only plasma contains significant concentrations of protein.

The major force maintaining the difference in cation concentration between the ICF and ECF is the activity of the sodium–potassium pump (Na,K-activated ATPase) integral to all cell membranes. Maintenance of the cation gradients across cell membranes is essential for many cell processes, including the excitability of conducting tissues such as nerve and muscle. The difference in protein content between the plasma and the interstitial fluid compartment is maintained by the impermeability of the capillary wall to protein. This protein concentration gradient (the colloid osmotic, or oncotic, pressure of the plasma) contributes to the balance of forces across the capillary wall that favour fluid retention within the circulating plasma.

Investigation of water and electrolytes

The most common biochemical test in plasma is called the urea and electrolytes ('U&Es') test in some parts of the world and the electrolytes/urea/creatinine ('EUC') test in others. A guide to its interpretation is shown in Box 16.3. Because the blood consists of both intracellular (red cell) and extracellular (plasma) components, it is important to avoid haemolysis during or after collection of the sample, which causes contamination of the plasma compartment by intracellular elements, particularly potassium. Blood should not be

16.3 How to interpret 'U&Es' (urea and electrolytes) or 'EUC' (electrolytes, urea, creatinine) results

Na⁺ (sodium)

- Largely reflects reciprocal changes in body water content
- See 'Hyponatraemia' and 'Hypernatraemia', pp. 435–437

K⁺ (potassium)

- May reflect K shifts in and out of cells
- Low levels usually mean excessive losses (gastrointestinal or renal)
- High levels usually mean renal dysfunction
- See 'Hypokalaemia' and 'Hyperkalaemia', pp. 438–440

Cl⁻ (chloride)

- Generally changes in parallel with plasma Na
- Low in metabolic alkalosis
- High in some forms of metabolic acidosis

HCO₃⁻ (bicarbonate)

- Abnormal in acid–base disorders
- See Box 16.18, p. 443

Urea

- Increased with a fall in glomerular filtration rate (GFR), reduced renal perfusion or urine flow rate, and in high protein intake or catabolic states
- See Fig. 17.3, p. 465

Creatinine

- Increased with a fall in GFR, in individuals with high muscle mass, and with some drugs
- See Fig. 17.3, p. 465

drawn from an arm into which an intravenous infusion is being given, to avoid contamination by the infused fluid. Repeated measurements of plasma electrolytes are frequently necessary when a marked abnormality has been detected and corrective therapy instituted.

Since the kidney maintains the constancy of body fluids by adjusting urine volume and composition, it is frequently helpful to obtain a sample of urine ('spot' specimen or 24-hour collection) at the time of blood analysis. An example of the use of urine biochemistry is given for the differential diagnosis of hyponatraemia in Box 16.14 (p. 436).

DISORDERS OF SODIUM BALANCE

Functional anatomy and physiology of renal sodium handling

Since the great majority of the body's sodium content is located in the ECF, where it is by far the most abundant cation, total body sodium is a principal determinant of ECF volume. Regulation of sodium excretion by the kidney is crucially important in maintaining normal ECF volume, and hence plasma volume, in the face of wide variations in sodium intake, typically in the range 50–250 mmol/day.

The functional unit for renal excretion is the nephron (Fig. 16.2). The glomerulus is the site of ultrafiltration of the blood, resulting in the generation of a cell- and protein-free fluid, resembling plasma in electrolyte composition, that is delivered into the initial part of the tubular system (more detail on the structure

Fig. 16.2 The nephron. Letters A–D refer to tubular segments shown in more detail in Figure 16.3. (aa = afferent arteriole; ea = efferent arteriole; md = macula densa)

and function of the glomerulus is given in Ch. 17). The glomerular filtration rate (GFR) is approximately 125 mL/min (equivalent to 180 L/day) in a typical adult. Over 99% of this filtered fluid is reabsorbed into the blood in the peritubular capillaries during its passage through successive segments of the nephron, largely as a result of tubular reabsorption of sodium. The processes mediating this sodium reabsorption, and the factors which regulate it, are key to understanding clinical disturbances and pharmacological interventions.

Nephron segments

At least four different functional segments of the nephron can be defined in terms of their mechanism for sodium reabsorption (Fig. 16.3).

Proximal tubule

This is responsible for the reabsorption of some 65% of the filtered sodium load. The cellular mechanism is complex but some of the key features are shown in Figure 16.3A. The basolateral membrane contains a high density of Na,K-ATPase pump units which remove sodium from the cell into the blood. The filtered sodium in the luminal fluid enters the cell via several transporters in the apical membrane. Cotransporters couple sodium to the entry of glucose, amino acid, phosphate and other organic molecules. A quantitatively more significant mechanism is the entry of sodium by countertransport with H⁺ ions, using the sodium–hydrogen exchanger (NHE-3).

Fig. 16.3 Principal transport mechanisms in segments of the nephron. See text for further details. Black circles indicate primary active transport pumps; open circles are carrier molecules without direct linkage to adenosine triphosphate (ATP) hydrolysis. *Site of diuretic action in each segment. †Peritubular forces refers to the hydrostatic and oncotic pressures in the peritubular capillaries. (ADH = antidiuretic hormone; c.a. = carbonic anhydrase)

Intracellular H^+ ions are generated from carbonic acid, the product of the enzyme carbonic anhydrase, which hydrates carbon dioxide. In addition, a large component of the transepithelial flux of sodium, water and other dissolved solutes occurs through the gaps *between* the cells (the 'shunt' pathway). Overall, fluid and electrolyte reabsorption is almost isotonic in this segment, as water reabsorption is matched very closely to sodium fluxes. A component of this water flow also passes *through* the cells, via aquaporin-1 (AQP-1) water channels, which are not sensitive to hormonal regulation.

The loop of Henle

The thick ascending limb of the loop of Henle (Fig. 16.3B) reabsorbs a further 25% of the filtered sodium but is impermeable to water, resulting in dilution of the luminal fluid. Again, the primary driving force for sodium reabsorption is the Na,K -ATPase on the basolateral cell membrane, but in this segment sodium enters the cell from the lumen via a specific carrier molecule, the $Na,K,2Cl$ cotransporter ('triple cotransporter', or $NKCC2$), which allows electroneutral entry of these ions. Some of the potassium accumulated inside the cell recirculates across the apical membrane back into the

lumen through a specific potassium channel (ROMK), providing a continuing supply of potassium to match the high concentrations of sodium and chloride available in the lumen. A small positive transepithelial potential difference exists in the lumen of this segment relative to the interstitium and this serves to drive cations such as sodium, potassium, calcium and magnesium between the cells, forming a reabsorptive shunt pathway.

Early distal tubule

Some 6% of filtered sodium is reabsorbed in the early distal (also called distal convoluted) tubule (Fig. 16.3C), again driven by the activity of the basolateral Na,K -ATPase. In this segment, entry of sodium into the cell from the luminal fluid is via a sodium-chloride cotransport carrier (NCCT). This segment is also impermeable to water, resulting in further dilution of the luminal fluid. There is no significant transepithelial flux of potassium in this segment, but calcium is reabsorbed through the mechanism shown in Figure 16.3C; a basolateral sodium-calcium exchanger leads to low intracellular concentrations of calcium, promoting calcium entry from the luminal fluid through a calcium channel.

Late distal tubule and collecting ducts

The late distal tubule and cortical collecting duct are anatomically and functionally continuous (Fig. 16.3D). Here sodium entry from the luminal fluid is via the epithelial sodium channel (ENaC) through which sodium passes alone, generating a substantial lumen-negative transepithelial potential difference. This sodium reabsorptive flux is balanced by excretion of potassium and hydrogen ions and by reabsorption of chloride ions. Potassium is accumulated in the cell by the basolateral Na,K-ATPase, and passes into the luminal fluid down its electrochemical gradient, through an apical potassium channel (ROMK). Chloride ions pass largely between cells. Hydrogen ion secretion is mediated by an H⁺-ATPase located on the luminal membrane of the intercalated cells, which constitute approximately one-third of the epithelial cells in this nephron segment. This part of the nephron has a variable permeability to water, depending on the availability of antidiuretic hormone (ADH, or vasopressin) in the circulation. All ion transport processes in this segment are stimulated by the steroid hormone aldosterone. This can increase the sodium reabsorption in this segment to a maximum of 2–3% of the filtered sodium load.

Less than 1% of sodium reabsorption occurs in the medullary collecting duct, where it is inhibited by natriuretic peptides such as ANP (atrial) and BNP (brain).

Regulation of sodium transport

A large number of interrelated mechanisms serve to maintain whole body sodium balance and hence ECF volume by matching urinary sodium excretion to sodium intake (Fig. 16.4).

Important sensing mechanisms include volume receptors in the cardiac atria and the intrathoracic veins, as well as pressure receptors located in the central arterial tree (aortic arch and carotid sinus) and the afferent arterioles within the kidney. A further afferent signal

is generated within the kidney itself; the enzyme renin is released from specialised smooth muscle cells in the walls of the afferent and efferent arterioles, at the point where they make contact with the early distal tubule (at the macula densa) to form the juxtaglomerular apparatus. Renin release is stimulated by:

- reduced perfusion pressure in the afferent arteriole
- increased sympathetic nerve activity
- decreased sodium chloride concentration in the distal tubular fluid.

Renin released into the circulation activates the effector mechanisms for sodium retention which are components of the renin–angiotensin–aldosterone (RAA) system (see Fig. 20.19, p. 769). Renin acts on the peptide substrate angiotensinogen (manufactured in the liver), producing angiotensin I in the circulation. This in turn is cleaved by angiotensin-converting enzyme (ACE) into angiotensin II, largely in the pulmonary capillary bed. Angiotensin II has multiple actions: stimulation of proximal tubular sodium reabsorption, release of aldosterone from the zona glomerulosa of the adrenal cortex, and direct vasoconstriction of small arterioles. Aldosterone acts to amplify sodium retention by its action in the cortical collecting duct. The net effect is to restore ECF volume and blood pressure towards normal, thereby correcting the initiating hypovolaemic stimulus.

The sympathetic nervous system also increases sodium retention, both through haemodynamic mechanisms (afferent arteriolar vasoconstriction and GFR reduction) and by direct stimulation of proximal tubular sodium reabsorption. Other humoral mediators, such as the natriuretic peptides, inhibit sodium reabsorption, contributing to natriuresis during periods of sodium and volume excess. Hypovolaemia also has haemodynamic effects which reduce GFR and alter the peritubular physical forces around the proximal tubule, thereby decreasing sodium excretion. Conversely, increased renal perfusion in hypervolaemia and hypertension results in a compensatory increase in sodium excretion.

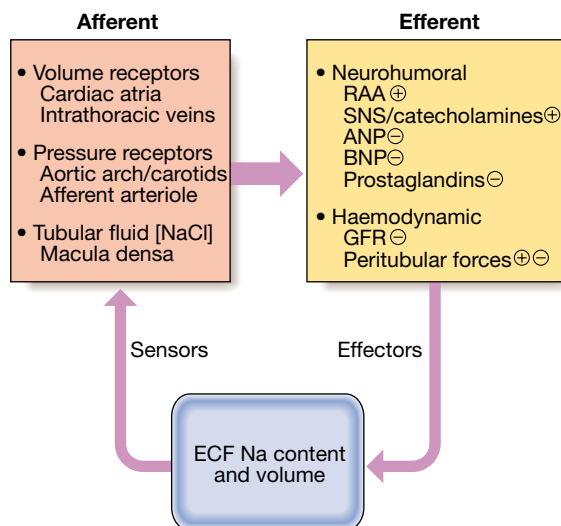

Fig. 16.4 Mechanisms involved in the regulation of sodium transport. (ANP = atrial natriuretic peptide; BNP = brain natriuretic peptide; ECF = extracellular fluid; GFR = glomerular filtration rate; RAA = renin–angiotensin–aldosterone system; SNS = sympathetic nervous system. ⊕ indicates an effect to reduce Na excretion, while ⊖ indicates an effect to increase Na excretion)

Presenting problems in disorders of sodium balance

When the balance of sodium intake and excretion is disturbed, any tendency for plasma sodium concentration to change is usually corrected by the osmotic mechanisms controlling water balance (p. 434). As a result, disorders in sodium balance present chiefly as altered ECF volume rather than altered sodium concentration. Clinical manifestations of altered volume are illustrated in Box 16.4.

Sodium depletion (usually associated with hypovolaemia)**Aetiology and clinical assessment**

Sodium depletion can occur occasionally under extreme environmental conditions as a result of inadequate intake of salt, but it is much more commonly due to pathological losses of sodium-containing fluids (Box 16.5). Loss of whole blood, as in acute haemorrhage, is also an obvious cause of hypovolaemia, and elicits the same mechanisms for the conservation of sodium and water.

Diagnosis of hypovolaemia is based on characteristic symptoms and signs (see Box 16.4) in the context of a

16.4 Clinical features of hypovolaemia and hypervolaemia

	Hypovolaemia	Hypervolaemia
Symptoms	Thirst Dizziness on standing Weakness	Ankle swelling Abdominal swelling Breathlessness
Signs	Low JVP Postural hypotension Tachycardia Dry mouth Reduced skin turgor Reduced urine output Weight loss Confusion, stupor	Peripheral oedema Raised JVP Pulmonary crepitations Pleural effusion Ascites Weight gain Hypertension (sometimes)

(JVP = jugular venous pressure)

16.5 Causes of sodium and water depletion

Mechanism	Examples
Inadequate intake	Environmental deprivation, inadequate therapeutic replacement
Gastrointestinal sodium loss	Vomiting, diarrhoea, nasogastric suction, external fistula
Skin sodium loss	Excessive sweating, burns
Renal sodium loss	Diuretic therapy, mineralocorticoid deficiency, tubulointerstitial disease (sometimes)
Internal sequestration*	Bowel obstruction, peritonitis, pancreatitis, crush injury

*A cause of circulatory volume depletion, although total body sodium and water may be normal or increased.

relevant precipitating illness. Supportive evidence may be obtained the clinical biochemistry laboratory. Although plasma sodium concentration may not be reduced if salt and water are lost in equal proportions, a number of other parameters are altered during appropriate renal, hormonal and haemodynamic responses to hypovolaemia. In early hypovolaemic states, GFR is maintained while urinary flow rate is reduced as a consequence of activation of sodium- and water-retaining mechanisms in the nephron. Thus, plasma creatinine, which reflects GFR, may be relatively normal, but the plasma urea concentration is typically elevated, since urea excretion is affected by both GFR and urine flow rate. Plasma uric acid may also rise, reflecting activation of compensatory proximal tubular reabsorption. With avid retention of sodium and water, the urine osmolality increases while the urine sodium concentration falls. Under these circumstances, sodium excretion may fall to less than 0.1% of the filtered sodium load.

Management

Management of sodium and water depletion has two main components:

- treat the cause where possible, to stop ongoing salt and water losses
- replace the salt and water deficits, and provide ongoing maintenance requirements, usually by intravenous fluid replacement when depletion is severe.

Intravenous fluid therapy

Box 16.6 shows the daily maintenance requirements for water and electrolytes in a typical adult, and Box 16.7 summarises the composition of some widely available intravenous fluids. The choice of fluid and the rate of administration depend on the clinical circumstances, as assessed at the bedside and from laboratory data, and described in Box 16.8.

16.6 Basic daily water and electrolyte requirements

	Requirement per kg	Typical 70 kg adult
Water	35–45 mL/kg	2.5–3.0 L/day
Sodium	1.5–2 mmol/kg	100–140 mmol/day
Potassium	1.0–1.5 mmol/kg	70–100 mmol/day

16.7 Composition of some isotonic intravenous fluids (mmol/L except D-glucose)

Fluid	D-glucose	Calories	Na ⁺	Cl ⁻	Other
5% dextrose	50 g	200	0	0	0
Normal (0.9%) saline	0	0	154	154	0
Hartmann's solution	0	0	131	111	K ⁺ 5 Ca ²⁺ 2 Lactate ⁻ 29

16.8 How to assess fluid and electrolyte balance in hospitalised patients

Step 1: assess clinical volume status

- Examine patient for signs of hypovolaemia or hypervolaemia (see Box 16.4)
- Check daily weight change

Step 2: review fluid balance chart

- Check total volumes IN and OUT on previous day (IN–OUT is positive ~400 mL in normal balance, reflecting insensible fluid losses of ~800 mL and metabolic water generation of ~400 mL)
- Check cumulative change in daily fluid balance over previous 3–5 days
- Correlate chart figures with weight change and clinical volume status to estimate net fluid balance

Step 3: assess ongoing pathological process

- Check losses from GI tract and surgical drains
- Estimate increased insensible losses (e.g. in fever) and internal sequestration ('third space')

Step 4: check plasma U&Es (see Box 16.3)

- Check plasma Na as marker of relative water balance
- Check plasma K as a guide to extracellular K balance
- Check HCO₃⁻ as a clue to acid–base disorder
- Check urea and creatinine to monitor renal function

Step 5: prescribe appropriate i.v. fluid replacement therapy

- Replace basic water and electrolytes each day (see Box 16.6)
- Allow for anticipated oral intake and pathological fluid loss
- Adjust amounts of water (if i.v., usually given as isotonic 5% dextrose), sodium and potassium according to plasma electrolyte results

In the absence of normal oral intake (as in a fasting or post-operative patient in hospital), maintenance quantities of fluid, sodium and potassium should be provided. If any deficits or continuing pathological losses are identified, additional fluid and electrolytes will be required. In prolonged periods of fasting (greater than a few days), attention also needs to be given to providing sufficient caloric and nutritional intake to prevent excessive catabolism of body energy stores (p. 121).

The choice of intravenous fluid therapy in the treatment of significant hypovolaemia relates to the concepts in Figure 16.1 (p. 427). If fluid containing neither sodium nor protein is given, it will distribute in the body fluid compartments in proportion to the normal distribution of total body water. Thus, giving 1 L of 5% dextrose will contribute relatively little (approximately 3/25 of the infused volume) towards expansion of the plasma volume. This makes 5% dextrose ineffective at restoring the circulation and perfusion of vital organs. Intravenous infusion of an isotonic (normal) saline solution, on the other hand, results in more effective expansion of the extracellular fluid, although again a minority of the infused volume (some 3/15) will contribute to plasma volume.

Carrying this reasoning further, it might be expected that a solution containing plasma proteins would be largely retained within the plasma, thus maximally expanding the circulating fluid volume and improving tissue perfusion. Recent clinical studies have not verified any overall advantage of infusions containing albumin (Box 16.9). Resuscitation fluids containing synthetic colloids (based on carbohydrate polymers or gelatin) may be more effective in the short-term resuscitation

EBM 16.9 Albumin infusions in hypovolaemia

'For patients with hypovolaemia there is no evidence that albumin reduces mortality when compared with cheaper alternatives such as saline.'

of volume-depleted patients than solutions containing sodium chloride alone (p. 180).

Sodium excess (usually associated with hypervolaemia)

Aetiology and clinical assessment

In the presence of normal function of the heart and kidneys, an excessive intake of salt and water is compensated for by increased excretion and so is unlikely to lead to clinically obvious features of hypervolaemia. However, diseases affecting the heart, kidneys or liver frequently set in train a sequence of events leading to hypervolaemia (Fig. 16.5). This volume expansion does not always involve an increase in circulating blood volume, since in conditions where fluid leaks out of the capillaries due to hypoproteinaemia (e.g. nephrotic syndrome and chronic liver disease), retention of sodium and water may expand the ECF predominantly in the interstitial rather than intravascular compartment. Important causes of sodium excess are given in Box 16.10.

Fig. 16.5 Secondary mechanisms causing sodium excess and oedema in cardiac failure, cirrhosis and nephrotic syndrome. Primary renal retention of Na and water may also contribute to oedema formation when GFR is significantly reduced (see Box 16.10 and p. 481).

16.10 Causes of sodium and water excess

Mechanism	Examples
Impaired renal function (Ch. 17)	Primary renal disease
Primary hyperaldosteronism* (p. 777)	e.g. Conn's syndrome
Secondary hyperaldosteronism (see Fig. 16.5)	Congestive cardiac failure Cirrhotic liver disease Nephrotic syndrome Other hypoalbuminaemic states Protein-losing enteropathy Malnutrition Idiopathic/cyclical oedema Renal artery stenosis*

*Conditions in this table *other than* primary hyperaldosteronism and renal artery stenosis are typically associated with generalised oedema.

Peripheral oedema is the most common physical sign associated with ECF volume expansion (p. 481). In the three most common systemic disorders associated with sodium and fluid overload (cardiac failure, cirrhosis and nephrotic syndrome), sodium retention is largely a secondary response to circulatory insufficiency caused by the primary disorder, as illustrated in Figure 16.5. The pathophysiology is different in renal failure, when the primary cause of volume expansion is the profound reduction in GFR impairing sodium and water excretion, and secondary tubular mechanisms are of less importance. Further detail on each of these conditions is given in other chapters of this book.

Management

The management of ECF volume overload involves a number of components:

- specific treatment (where available) directed at the cause, e.g. ACE inhibitors in heart failure, corticosteroids in minimal change nephropathy
- restriction of dietary sodium to match more closely the diminished excretory capacity, e.g. 50–80 mmol/day
- treatment with diuretic drugs.

Diuretic therapy

Diuretics are important in the treatment of conditions of ECF expansion due to salt and water retention and in hypertension (p. 609). They act by inhibiting sodium reabsorption at various locations along the nephron (see Fig. 16.3, p. 429). Their potency and adverse effects relate to their mechanism and site of action.

Mechanisms of action

In the proximal tubule, carbonic anhydrase inhibitors (e.g. acetazolamide) inhibit the intracellular production of H^+ ions, thereby reducing the fraction of sodium reabsorption which is exchanged for H^+ by the apical membrane sodium–hydrogen exchanger. These drugs have limited usefulness, however, since only a small fraction of proximal sodium reabsorption uses this mechanism, and much of the unreabsorbed sodium can be reabsorbed by downstream segments of the nephron.

In the thick ascending limb of the loop of Henle, loop diuretics (e.g. furosemide) inhibit sodium reabsorption by blocking the action of the apical membrane $Na,K,2Cl$ cotransporter. Because this segment reabsorbs a significant fraction of the filtered sodium, these drugs are potent diuretics, in common use in diseases causing significant oedema.

In the early distal (distal convoluted) tubule, thiazide drugs inhibit sodium reabsorption by blocking the sodium–chloride cotransporter in the apical membrane. Since this segment reabsorbs a much smaller fraction of the filtered sodium, thiazide drugs are less potent than loop diuretics, but are widely used in the treatment of hypertension and less severe oedema.

All diuretic drugs acting in the proximal, loop and early distal segments cause excretion not only of sodium (and with it water), but also of potassium. This occurs largely as a result of delivery of increased amounts of sodium to the late distal/cortical collecting ducts, where sodium reabsorption is associated with excretion of potassium, and is amplified if circulating aldosterone levels are high. By contrast, drugs acting to inhibit sodium reabsorption in the late distal/cortical collecting duct segment are associated with reduced potassium secretion, and are described as ‘potassium-sparing’. One target of drug action in this segment is the apical sodium channel in the principal cells (see Fig. 16.3), which is blocked by drugs such as amiloride and triamterene. Another is the mineralocorticoid receptor, to which binding of aldosterone is blocked by spironolactone and eplerenone.

An important feature of the most commonly used diuretic drugs (furosemide, thiazides and amiloride) is that they act on their target transport molecules from the luminal side of the tubular epithelium. Since they are highly protein-bound in the plasma, very little reaches the urinary fluid by glomerular filtration, but there are active transport mechanisms for secreting organic acids and bases, including these drugs, across the proximal tubular wall, resulting in adequate drug concentrations being delivered to later tubular segments. This secretory process may be impaired by certain other drugs, and also by accumulated organic anions as occurs in chronic renal failure and chronic liver failure, leading to resistance to diuretics.

Osmotic diuretics are a further class of drug which act independently of any specific transport mechanism. These substances are freely filtered but are not reabsorbed by any part of the tubular system. They thus entrain fluid osmotically within the tubular lumen and limit the extent of sodium reabsorption in multiple segments. Mannitol is the most commonly used such drug, given by intravenous infusion to achieve short-term diuresis in conditions associated with cell swelling, such as cerebral oedema.

Clinical use of diuretics

In the selection of a diuretic drug for hypertension or oedema disorders, the following principles should be observed:

- Use the minimum effective dose.
- Use for as short a period of time as necessary.
- Monitor regularly for adverse effects.

The choice of diuretic drug class will be determined by the required potency of action, the presence

16.11 Adverse effects of loop-acting and thiazide diuretics

Renal side-effects

- Hypovolaemia
- Hyponatraemia
- Hypokalaemia
- Metabolic alkalosis
- Hyperuricaemia
- Hypomagnesaemia
- Hypercalciuria (loop)
- Hypocalciuria (thiazide)

Metabolic side-effects

- Glucose intolerance/hyperglycaemia
- Hyperlipidaemia

Miscellaneous side-effects

- Hypersensitivity reactions
- Acute pancreatitis/cholecystitis (thiazides)
- Erectile dysfunction

of coexistent conditions, and the anticipated side-effect profile.

The adverse effects encountered with the most commonly used classes of diuretic (loop drugs and thiazide drugs) are summarised in Box 16.11. Volume depletion and electrolyte disorders occur, as predicted from their mechanism of action. The metabolic side-effects listed are rarely of clinical significance and may reflect effects on K^+ channels which influence insulin secretion (p. 798). Since most drugs from these classes are sulphonamides, there is a relatively high incidence of hypersensitivity reactions, and occasional idiosyncratic side-effects in a variety of organ systems.

The side-effect profile of the potassium-sparing diuretics differs in a number of important respects from other diuretics. The disturbances in potassium, magnesium and acid-base balance are in the opposite direction, so that normal or increased levels of potassium and magnesium are found in the blood, and there is a tendency to metabolic acidosis, especially when renal function is impaired.

Diuretic resistance is encountered under a variety of circumstances, including impaired renal function, activation of sodium-retaining mechanisms, impaired oral bioavailability (e.g. due to gastrointestinal disease) and decreased renal blood flow. In these circumstances short-term intravenous therapy with a loop-acting agent such as furosemide may be useful. Combinations of diuretics administered orally may also increase potency. Either a loop or a thiazide drug can be combined with a potassium-sparing drug, and all three classes can be used together for short periods, with carefully supervised clinical and laboratory monitoring.

DISORDERS OF WATER BALANCE

Daily water intake can vary over a wide range, from 500 mL to several litres a day. While a certain amount of water is lost ('insensible losses', approximately 800 mL/day) through the stool, sweat and the respiratory tract, and some water is generated by oxidative metabolism ('metabolic water', approximately 400 mL/day), the kidneys are chiefly responsible for adjusting water excretion to maintain constancy of body water content and body fluid osmolality (normal range 280–295 mmol/kg).

Functional anatomy and physiology of renal water handling

While regulation of total ECF volume is largely achieved through the kidneys' control of sodium excretion, there must also be mechanisms to allow for the excretion of a 'pure' water load when free water intake is high, and for the avid retention of water by the kidneys when access to water is restricted.

These functions are largely achieved by the properties of the loop of Henle and the collecting ducts. The counter-current configuration of flow in adjacent limbs of the loop (see Fig. 16.2, p. 428), involving osmotic water movement from the descending limbs and solute reabsorption from neighbouring ascending limbs, sets up a gradient of tissue osmolality from isotonic (like plasma) in the renal cortex through to hypertonic (around 1200 mmol/kg) in the inner part of the medulla. At the same time, the fluid emerging from the thick ascending limb is hypotonic compared to plasma, because it has been diluted by the reabsorption of sodium, but not water, from the thick ascending limb and early distal tubule. As this dilute fluid passes from the cortex through the collecting duct system to the renal pelvis, it traverses the medullary interstitial gradient of osmolality set up by the operation of the loop of Henle, and water is avidly reabsorbed.

Further changes in the urine osmolality on passage through the collecting ducts depend on the level in the plasma of the peptide ADH, which is released by the posterior pituitary gland under conditions of increased plasma osmolality or other stimuli such as hypovolaemia (Ch. 20).

- When ADH levels are minimal, such as during adequate water intake and low-normal plasma osmolality, the collecting ducts remain impermeable to water and the luminal fluid osmolality remains low, resulting in the excretion of a dilute urine (minimum osmolality approximately 50 mmol/kg in a healthy young person).
- When ADH levels are elevated (during water restriction and high plasma osmolality, or severe volume depletion), the water permeability of the collecting ducts is greatly increased through the action of ADH on its V2 receptor, which enhances collecting duct water permeability via the insertion of aquaporin AQP-2 channels into the luminal cell membrane. This results in osmotic reabsorption of water along the entire length of the collecting duct, with maximum urine osmolality approaching that in the medullary tip (up to 1200 mmol/kg).

Parallel to these changes in ADH release are changes in water-seeking behaviour triggered by the sensation of thirst, which also becomes activated as plasma osmolality rises from normal to above normal levels.

In summary, for adequate dilution of the urine there must be:

- adequate solute delivery to the loop of Henle and early distal tubule
- normal function of the loop of Henle and early distal tubule
- no ADH in the circulation.

If any of these processes is faulty, water retention and hyponatraemia may result.

Conversely, to achieve concentration of the urine there must be:

- adequate solute delivery to the loop of Henle
- normal function of the loop of Henle
- ADH release into the circulation
- ADH action on the collecting ducts.

Failure of any of these steps may result in inappropriate water loss and hypernatraemia.

Presenting problems in disorders of water balance

Disturbances in body water balance, in the absence of changes in sodium balance, alter plasma sodium concentration and hence plasma osmolality. When extracellular osmolality changes abruptly, water flows rapidly across cell membranes with resultant cell swelling (during hypo-osmolality) or shrinkage (during hyper-osmolality). Cerebral cell function is very sensitive to such volume changes, particularly during cell swelling, when an increase in intracerebral pressure occurs due to the constraints imposed by the bony skull, thereby reducing cerebral perfusion.

Hyponatraemia

Aetiology and clinical assessment

Hyponatraemia (plasma Na < 135 mmol/L) is a common electrolyte abnormality, often detected asymptotically, but it may also be associated with profound disturbances of cerebral function, manifesting as anorexia, nausea, vomiting, confusion, lethargy, seizures and coma. The degree of cerebral symptomatology depends more on the rate of development of the electrolyte abnormality than on its severity. When plasma osmolality falls rapidly, water flows into cerebral cells which become swollen and ischaemic. However, when hyponatraemia develops gradually, cerebral neurons have time to respond by reducing intracellular osmolality, through excreting potassium and reducing synthesis of intracellular organic osmolytes (Fig. 16.6). The osmotic gradient favouring water movement into the cells is thus reduced and cerebral symptomatology avoided.

The causes of hyponatraemia are best categorised according to any associated change in ECF volume status, i.e. the total body sodium (Box 16.12). In all cases, there is retention of water relative to sodium, and it is the clinical examination rather than the electrolyte test results which gives clues to the underlying cause.

Artefactual causes of apparent hyponatraemia should be remembered. This can occur in the presence of severe hyperlipidaemia or hyperproteinaemia, when the aqueous fraction of the plasma specimen is reduced because of the volume occupied by the macromolecules (although this artefact is dependent on the assay technology). Transient hyponatraemia may also occur due to osmotic shifts of water out of cells during hyperosmolar states caused by acute hyperglycaemia or by mannitol infusion.

Hyponatraemia with hypovolaemia

Patients with hyponatraemia in association with a sodium deficit ('depletional hyponatraemia') have clinical features of hypovolaemia (see Box 16.4, p. 431)

Fig. 16.6 Hyponatraemia and the brain. Numbers represent osmolality in mmol/kg. (Osmo = osmolality)

16.12 Causes of hyponatraemia

Volume status	Examples
Hypovolaemic (sodium deficit with a relatively smaller water deficit)	Renal Na losses Diuretic therapy (especially thiazides) Adrenocortical failure Gastrointestinal Na losses Vomiting Diarrhoea Skin Na losses Burns
Euvolaemic (water retention alone)	Primary polydipsia Excessive electrolyte-free water infusion SIADH* Hypothyroidism
Hypervolaemic (sodium retention with relatively greater water retention)	Congestive cardiac failure Cirrhosis Nephrotic syndrome Chronic renal failure (during free water intake)

*SIADH = syndrome of inappropriate antidiuretic hormone secretion (Box 16.13).

and supportive laboratory findings, including low urinary sodium concentration ($< 30 \text{ mmol/L}$) and elevated plasma renin activity. The cause of sodium loss is usually apparent; common examples are shown in Box 16.12.

Hyponatraemia with euvolaemia

Patients in this group ('dilutional hyponatraemia') have no major disturbance of body sodium content and are clinically euvolaemic. Excess body water may be the result of abnormally high intake, either orally (primary polydipsia) or as a result of medically infused fluids (as intravenous dextrose solutions, or by absorption of sodium-free bladder irrigation fluid after prostatectomy).

Water retention also occurs in the syndrome of inappropriate secretion of ADH (SIADH). In this condition an endogenous source of ADH (either cerebral or tumour-derived) promotes renal water retention in the absence of an appropriate physiological stimulus (Box 16.13). The clinical diagnosis requires the patient to be euvolaemic, with no evidence of organ system disease potentially associated with hyponatraemia (heart, liver, kidney). Other non-osmotic stimuli to release of ADH (pain, stress, nausea) should also be excluded. Supportive laboratory findings are shown in Box 16.13. The plasma has low concentrations of sodium, chloride, urea and uric acid, with a correspondingly low osmolality. Urine osmolality, which should physiologically be maximally dilute (approximately 50 mmol/kg) in the face of low plasma osmolality, is higher than at least 100 mmol/kg and indeed is typically higher than the plasma osmolality. The urine sodium concentration is typically high ($> 30 \text{ mmol/L}$), consistent with euvolaemia and lack of compensatory factors promoting sodium retention.

Hyponatraemia with hypervolaemia

In the third pattern of hyponatraemia, excess water retention is associated with sodium retention and volume expansion, as in heart failure and other oedematous disorders.

16.13 Syndrome of inappropriate antidiuretic hormone secretion (SIADH): causes and diagnosis

Causes

- Tumours, e.g. lung or colon cancer
- CNS disorders: stroke, trauma, infection, psychosis
- Pulmonary disorders: pneumonia, tuberculosis, obstructive lung disease
- Drugs
 - Anticonvulsants, e.g. carbamazepine
 - Psychotropics, e.g. haloperidol
 - Antidepressants, e.g. amitriptyline, fluoxetine
 - Cytotoxics, e.g. cyclophosphamide, vincristine
 - Hypoglycaemics, e.g. chlorpropamide
 - Opiates, e.g. morphine
- Idiopathic

Diagnosis

- Low plasma sodium concentration (typically $< 130 \text{ mmol/L}$)
- Low plasma osmolality ($< 270 \text{ mmol/kg}$)
- Urine osmolality not minimally low (typically $> 150 \text{ mmol/kg}$)
- Urine sodium concentration not minimally low ($> 30 \text{ mmol/L}$)
- Low-normal plasma urea, creatinine, uric acid
- Exclusion of other causes of hyponatraemia (see Box 16.12)
- Appropriate clinical context (above)

Investigations

Plasma and urine electrolytes and osmolality (Box 16.14) are usually the only tests required to classify the hyponatraemia. Doubt about clinical signs of ECF volume may be resolved with measurement of plasma renin activity.

Note that measuring plasma ADH is not generally helpful in distinguishing between these categories of hyponatraemia. This is because ADH is activated both in hypovolaemic states and in most chronic hypervolaemic states, as the impaired circulation in those disorders activates ADH release through non-osmotic mechanisms. Indeed, these disorders may have higher circulating ADH levels than patients with SIADH. The only disorders listed in Box 16.12 in which ADH is not normal or elevated are primary polydipsia and iatrogenic water intoxication, in which the hypo-osmolar plasma suppresses ADH release.

16.14 Urine Na and osmolality in the differential diagnosis of hyponatraemia*

Urine Na (mmol/L)	Urine osmolality (mmol/kg)	Possible diagnoses
Low (< 30)	Low (< 100)	Primary polydipsia Malnutrition Beer excess
Low	High (> 150)	Salt depletion Hypovolaemia
High (> 40)	Low	Diuretic action (acute phase)
High	High	SIADH Cerebral salt-wasting Adrenal insufficiency

*Note that intermediate urine results are of indeterminate significance, and diagnosis depends on a comprehensive clinical assessment.

Management

The treatment for hyponatraemia is critically dependent on the rate of development, severity and underlying cause. In general, if hyponatraemia has developed rapidly (over hours to days), morbidity due to cerebral oedema is more likely, and it is generally safe to correct the plasma sodium relatively rapidly. This can include infusion of hypertonic (3%) sodium chloride solutions, especially when the patient is obtunded or convulsing.

On the other hand, rapid correction of hyponatraemia which has developed slowly (over weeks to months) can itself be hazardous to the brain. This is because cerebral cells adapt to slowly developing hypo-osmolality by reducing the intracellular osmolality, thus maintaining normal cell volume (see Fig. 16.6). Under these conditions, an abrupt increase in extracellular osmolality can lead to water shifting out of the cerebral neurons, abruptly reducing their volume and risking detachment from their myelin sheaths. The resulting 'myelinolysis' can produce permanent structural and functional damage to mid-brain structures, and is generally fatal. The rate of correction of the plasma Na concentration in chronic asymptomatic hyponatraemia should not exceed 10 mmol/L/day , and an even slower rate is generally safer.

The underlying cause should be treated. For hypovolaemic patients, this involves controlling the source of sodium loss, and administering intravenous saline if clinically warranted. Patients with dilutional hyponatraemia will generally respond to fluid restriction in the range 600–1000 mL/day, accompanied where possible by withdrawal of the precipitating stimulus (e.g. a drug causing SIADH). If an inadequate rise in plasma Na results, treatment with demeclocycline (600–900 mg/day) may enhance water excretion, by interfering with collecting duct responsiveness to ADH. An effective alternative for subjects with persistent hyponatraemia due to prolonged SIADH is oral urea therapy (30–45 g/day), which provides a solute load to promote water excretion. Where available, oral vasopressin receptor antagonists (vaptans) may be used to block the ADH-mediated component of water retention in a range of hyponatraemic conditions. Hypervolaemic patients with hyponatraemia need optimal treatment of the underlying condition, accompanied by cautious use of diuretics in conjunction with strict fluid restriction. Potassium-sparing diuretics may be particularly useful in this context where there is significant secondary hyperaldosteronism.

Hypernatraemia

Aetiology and clinical assessment

Just as hyponatraemia represents a failure of the mechanisms for diluting the urine during free access to water, so hypernatraemia (plasma Na > 148 mmol/L) reflects inadequate concentration of the urine in the face of restricted water intake. This can be due to failure to generate an adequate medullary concentration gradient (low GFR states, loop diuretic therapy), but more commonly it is due to failure of the ADH system, either because no ADH is released from the pituitary (central or 'cranial' diabetes insipidus, p. 792) or because the collecting duct cells are unable to respond to circulating ADH (nephrogenic diabetes insipidus, either inherited or acquired).

Patients with hypernatraemia generally have reduced cerebral function, either as a primary problem or as a consequence of the hypernatraemia itself, which results in dehydration of cerebral neurons and brain shrinkage. In the presence of an intact thirst mechanism and preserved capacity to obtain and ingest water, hypernatraemia may not progress very far. If adequate water is not obtained, dizziness, confusion, weakness and ultimately coma and death can result.

Like hyponatraemia, the causes of hypernatraemia are best grouped according to the associated disturbance, if any, in total body sodium content (Box 16.15). It is important to note the risk of iatrogenic induction of hypernatraemia, and to reiterate that, whatever the underlying cause, sustained or severe hypernatraemia must reflect an impaired thirst mechanism or responsiveness to thirst, which would otherwise lead to sufficient water being ingested to prevent this disorder progressing.

Management

Treatment of hypernatraemia depends on both the rate of development and the underlying cause. If there is reason to think that the condition has developed rapidly,

16.15 Causes of hypernatraemia

Volume status	Examples
Hypovolaemic (sodium deficit with a relatively greater water deficit)	Renal Na losses Diuretic therapy (especially osmotic diuretic, or loop diuretic during water restriction) Glycosuria (HONK, p. 804) Gastrointestinal Na losses Colonic diarrhoea Skin Na losses Excessive sweating
Euvolaemic (water deficit alone)	Diabetes insipidus (central or nephrogenic) (p. 792)
Hypervolaemic (sodium retention with relatively less water retention)	Enteral or parenteral feeding I.v. or oral salt administration Chronic renal failure (during water restriction)

cerebral shrinkage may be acute, and relatively rapid correction with appropriate volumes of intravenous fluid (isotonic 5% dextrose or hypotonic 0.45% saline) may be attempted. However, in older, institutionalised patients it is more likely that the disorder has developed slowly, and extreme caution should be used to lower the plasma sodium slowly, to avoid the risk of cerebral oedema in the osmotically adapted cerebral neurons. Where possible, the underlying cause should also be addressed (see Box 16.15).

Elderly patients are predisposed, in different circumstances, to both hyponatraemia and hypernatraemia, and a high index of suspicion of these electrolyte disturbances is appropriate in aged patients with recent alterations in behaviour (Box 16.16).

16.16 Hyponatraemia and hypernatraemia in old age

- **Decline in GFR:** older patients are predisposed to both hyponatraemia and hypernatraemia, mainly because, as GFR declines with age, the capacity of the kidney to dilute or concentrate the urine is impaired.
- **Hyponatraemia:** occurs when free water intake continues in the presence of a low dietary salt intake and/or diuretic drugs (particularly thiazides).
- **ADH release:** water retention is aggravated by any condition which stimulates ADH release, especially heart failure. Moreover, the ADH response to non-osmotic stimuli may be brisker in older subjects. Appropriate water restriction may be a key part of the management.
- **Hypernatraemia:** occurs when water intake is inadequate, due to physical restrictions preventing access to drinks and/or blunted thirst. Both are frequently present in patients with advanced dementia or following a severe stroke.
- **Dietary salt:** hypernatraemia is aggravated if dietary supplements or medications with a high sodium content (especially effervescent preparations) are administered. Appropriate prescription of fluids is a key part of the management.

DISORDERS OF POTASSIUM BALANCE

Potassium is the major intracellular cation (see Fig. 16.1, p. 427), and the steep concentration gradient for potassium across the cell membrane of excitable cells plays an important part in generating the resting membrane potential and allowing the propagation of the action potential which is crucial to normal functioning of nerve, muscle and cardiac tissues. Control of body potassium balance is described below.

Factors influencing the distribution of potassium between the ICF and ECF compartments can alter plasma potassium concentration, without any overall change in total body potassium content. Potassium is driven into the cells from the plasma by extracellular alkalosis and by a number of hormones, including insulin, catecholamines (through the β_2 receptor) and aldosterone. These influences alone can produce hypokalaemia, while the contrary changes (extracellular acidosis, lack of insulin, insufficiency or blockade of catecholamines or aldosterone) can contribute to hyperkalaemia due to redistribution of potassium outside the cells.

Functional anatomy and physiology of renal potassium handling

In the steady state, the kidneys excrete some 90% of the daily intake of potassium, typically 80–100 mmol/day. Potassium is freely filtered at the glomerulus; around 65% is reabsorbed in the proximal tubule and a further 25% in the thick ascending limb of the loop of Henle. However, in the early distal tubule little potassium is transported, while in the late distal/cortical collecting duct tubule a significant secretory flux of potassium into the urine ensures that this cation is removed from the blood in proportion to the ingested load.

The mechanism for potassium secretion in the distal parts of the nephron is shown in Figure 16.3D (p. 429). Movement of potassium from blood to lumen is dependent on active uptake across the basal cell membrane by the Na,K-ATPase, followed by diffusion of potassium through a luminal membrane potassium channel (ROMK) into the tubular fluid. The electrochemical gradient for potassium movement into the lumen is contributed to both by the high intracellular potassium concentration and by the negative luminal potential difference relative to the blood.

A number of factors influence the rate of potassium secretion. Luminal influences include the rate of sodium delivery and fluid flow through the late distal/cortical collecting ducts, and this is a major factor in the increased potassium loss during therapy with diuretics acting earlier in the nephron. Agents interfering with the generation of the negative luminal potential impair potassium secretion, and this is the basis of reduced potassium secretion during therapy with potassium-sparing diuretics such as amiloride. Factors acting from the blood side of this tubule segment include plasma potassium and pH, such that hyperkalaemia and alkalosis stimulate potassium secretion directly. However, the most important factor in the acute and chronic adjustment of potassium secretion to match metabolic potassium load is the corticosteroid hormone aldosterone.

Fig. 16.7 Feedback control of plasma potassium concentration.

As shown in Figure 16.7, a negative feedback relationship exists between the plasma potassium concentration and aldosterone. In addition to its regulation by the renin–angiotensin system (see Fig. 20.19, p. 769), aldosterone is released from the adrenal cortex in direct response to an elevated plasma potassium, and aldosterone acts on the kidney to stimulate potassium secretion, as well as hydrogen secretion and sodium reabsorption, in the late distal/cortical collecting duct segment. The resulting increased potassium excretion serves to dampen the accumulation of potassium in the plasma, keeping plasma concentrations tightly controlled within a narrow normal range (3.3–4.7 mmol/L). Since the plasma aldosterone concentration is the net effect of two different stimuli, factors reducing angiotensin II levels may indirectly impair potassium balance by blunting the rise in aldosterone which would otherwise be provoked by hyperkalaemia. This is the basis for the risk of hyperkalaemia during therapy with ACE inhibitors and related drugs.

Presenting problems in disorders of potassium balance

Hypokalaemia

Aetiology and clinical assessment

Patients with mild hypokalaemia (plasma K 3.0–3.5 mmol/L) are generally asymptomatic, but with more severe falls in the plasma potassium there is often muscular weakness and associated tiredness. Cardiac effects include ventricular ectopic beats or more serious arrhythmias, and potentiation of the adverse effects of digoxin. Typical ECG changes occur, affecting the T wave in particular (Fig. 16.8). Functional bowel obstruction may occur due to paralytic ileus. Long-standing hypokalaemia damages renal tubular structures (hypokalaemic nephropathy) and interferes with the tubular response to

Fig. 16.8 The ECG in hypokalaemia and hyperkalaemia.

ADH (acquired nephrogenic diabetes insipidus), resulting in polyuria and polydipsia.

The main causes of hypokalaemia and an approach to the differential diagnosis are shown in Figure 16.9. Redistribution of potassium into cells should be considered, since correction of the factors involved (see above) may be sufficient to correct the plasma concentration. An inadequate intake of potassium can contribute to hypokalaemia but is unlikely to be the only cause, except in extreme cases. Generally, hypokalaemia implies abnormal potassium loss from the body, through either the kidney or the gastrointestinal tract. When there is no obvious

clinical clue to which pathway is involved, measurement of urinary potassium may be helpful; if the kidney is the route of potassium loss, the urine potassium is relatively high ($> 30 \text{ mmol/day}$), whereas potassium loss through the gastrointestinal tract is usually associated with renal potassium retention, resulting in a lower urinary potassium (generally $< 20 \text{ mmol/day}$, although paradoxically, if gastrointestinal fluid loss is also associated with hypovolaemia, activation of the renin-angiotensin-aldosterone system may cause loss of potassium through the kidney as well).

The renal causes can be divided into those with or without hypertension. Hypertensive disorders with hypokalaemia may be due to excess mineralocorticoid activity such as aldosterone oversecretion in Conn's syndrome (p. 778). Apparent mineralocorticoid excess can be produced by excess liquorice intake or treatment with carbenoxolone, which inhibit the renal $11\beta\text{HSD2}$ enzyme which normally inactivates cortisol and prevents inappropriate activation of mineralocorticoid receptors. Liddle's syndrome produces a similar phenotype, due to a genetic defect causing overactivity of epithelial sodium channels in the distal nephron.

If blood pressure is normal or low, renal potassium loss can be classified according to the associated acid-base change. If hypokalaemia is associated with alkalosis and diuretic use has been excluded, an inherited tubular transport defect may be suspected. In Bartter's syndrome there is a defect in sodium reabsorption in the thick ascending limb of Henle, usually due to a mutation causing malfunction of the NKCC2 transporter. The clinical and biochemical features are similar to chronic treatment with furosemide. In Gitelman's syndrome there is a mutation causing malfunction of

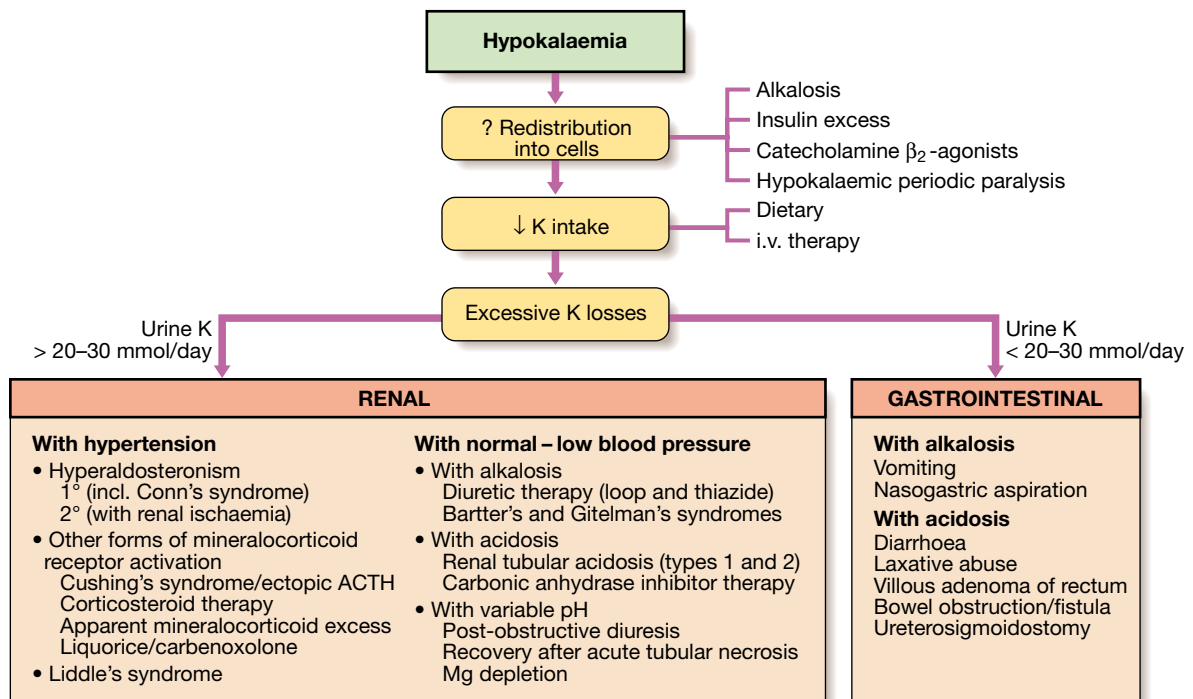

Fig. 16.9 Diagnostic decision tree for hypokalaemia. (ACTH = adrenocorticotrophic hormone)

the NCCT carrier in the early distal tubule. The clinical and biochemical features are similar to chronic thiazide treatment. Note that while both Bartter's and Gitelman's syndromes are characterised by hypokalaemia and hypomagnesaemia, urinary calcium excretion is increased in Bartter's syndrome but decreased in Gitelman's syndrome, analogous to the effects of the loop and thiazide diuretics, respectively, on calcium transport (see Box 16.11, p. 434).

If hypokalaemia is associated with a normal blood pressure but with metabolic acidosis, renal tubular acidosis (proximal or 'classical' distal) should be suspected (p. 444).

When hypokalaemia is due to potassium wasting through the gastrointestinal tract, the cause is usually obvious clinically. In some cases, when there is occult induction of vomiting or surreptitious use of aperients, a useful generalisation is that upper gastrointestinal losses (above the pylorus) are characteristically associated with metabolic alkalosis, whereas losses below the pylorus are associated with metabolic acidosis. In both cases, the urinary potassium excretion would be expected to be low (but see the qualification mentioned above regarding high aldosterone states).

Investigations

Measurement of plasma electrolytes, bicarbonate, urine potassium and sometimes of plasma calcium and magnesium is usually sufficient to establish the diagnosis. Plasma renin activity is low in patients with primary hyperaldosteronism (p. 777) and other forms of mineralocorticoid excess; in other causes of hypokalaemia renin is elevated.

Occasionally the cause of hypokalaemia is obscure, especially when the history is incomplete or unreliable, and the urine potassium is indeterminate. Many such cases are associated with metabolic alkalosis, and in this setting the measurement of urine chloride concentration can be helpful. A low urine chloride ($< 30 \text{ mmol/L}$) is characteristic of vomiting (spontaneous or self-induced, in which chloride is lost in HCl in the vomit), while a urine chloride $> 40 \text{ mmol/L}$ suggests diuretic therapy (acute phase) or a tubular disorder such as Bartter's or Gitelman's syndrome. Differentiation between these latter possibilities can be assisted by performing a screen of urine for diuretic drugs.

Management

Treatment of hypokalaemia involves first determining the cause and then correcting this where possible. If the problem is mainly one of redistribution of potassium into cells, reversal of this influence (e.g. correction of alkalosis) may be sufficient to restore plasma potassium without providing potassium supplements. In most cases, however, a form of potassium replacement will be required. This can generally be achieved with slow-release KCl tablets, but in more acute circumstances intravenous potassium chloride is necessary. The rate of administration depends on the severity of hypokalaemia and the presence of cardiac or neuromuscular complications, but should generally not exceed 10 mmol of potassium per hour. If higher rates of administration are needed, the concentration of potassium in the infused fluid may be increased to 40 mmol/L if a peripheral vein is used, but higher concentrations must be infused into a large 'central' vein with continuous cardiac monitoring.

In the less common situation of hypokalaemia being associated with systemic acidosis, alkaline salts of potassium, such as potassium bicarbonate, can be given by mouth. If magnesium depletion is also present, replacement of magnesium may be necessary to allow correction of hypokalaemia to occur. In appropriate circumstances, use of a potassium-sparing diuretic such as amiloride can assist in the correction of hypokalaemia, hypomagnesaemia and metabolic alkalosis, especially when these are due to use of a loop or thiazide diuretic.

Hyperkalaemia

Aetiology and clinical assessment

Significant hyperkalaemia can be dangerous, because of the risk of cardiac arrest caused by the marked slowing of action potential conduction in the presence of potassium levels above 7 mmol/L . Patients typically present with progressive muscular weakness, but sometimes there are no symptoms until cardiac arrest occurs. Typical ECG changes are shown in Figure 16.8. Peaking of the T wave is an early ECG sign, but widening of the QRS complex presages a dangerous cardiac arrhythmia.

An approach to defining the cause of hyperkalaemia is shown in Figure 16.10. It is important to exclude artefacts due to in vitro haemolysis of blood specimens, but if there is doubt about this and there are consistent changes present in the ECG, treatment for hyperkalaemia should be initiated. Redistribution of potassium from the ICF to the ECF may occur in the presence of systemic acidosis, or when the relevant hormones (insulin, catecholamines and aldosterone) are reduced or blocked (p. 438). While a high potassium intake may contribute to hyperkalaemia, it is unlikely to be the only explanation if renal excretion mechanisms are intact.

Impaired excretion of potassium into the urine may be associated with a reduced GFR, as in acute or chronic renal failure. Acute renal failure is associated with particularly severe hyperkalaemia when there is a concomitant potassium load, such as in rhabdomyolysis or in sepsis, particularly when acidosis is also present. In chronic renal failure, adaptation to a moderately elevated plasma potassium commonly develops, but a further rise can occur during intercurrent events which destabilise the new steady state, e.g. a dietary load of potassium, hypovolaemia or drugs (see below).

Hyperkalaemia can also develop when tubular potassium secretory processes are impaired, even if the GFR is well maintained. In some cases, this is due to inadequate circulating aldosterone, as in Addison's disease, ACE inhibitor therapy, or other situations where the renin-angiotensin-aldosterone system is inactivated (e.g. hyporeninaemic hypoaldosteronism, which typically occurs in association with neuropathy in diabetes and is thought to reflect impaired β -adrenergic stimulation of renin release; or therapy with angiotensin receptor antagonists, non-steroidal anti-inflammatory drugs (NSAIDs) or β -blocking drugs). In another group of conditions, tubular potassium secretion is impaired, even in the presence of high aldosterone levels. Such aldosterone resistance can occur in a variety of diseases involving inflammation in the tubulointerstitium (e.g. systemic lupus erythematosus (SLE), renal transplant), during therapy with potassium-sparing diuretics, and in a number of inherited disorders of tubular transport.

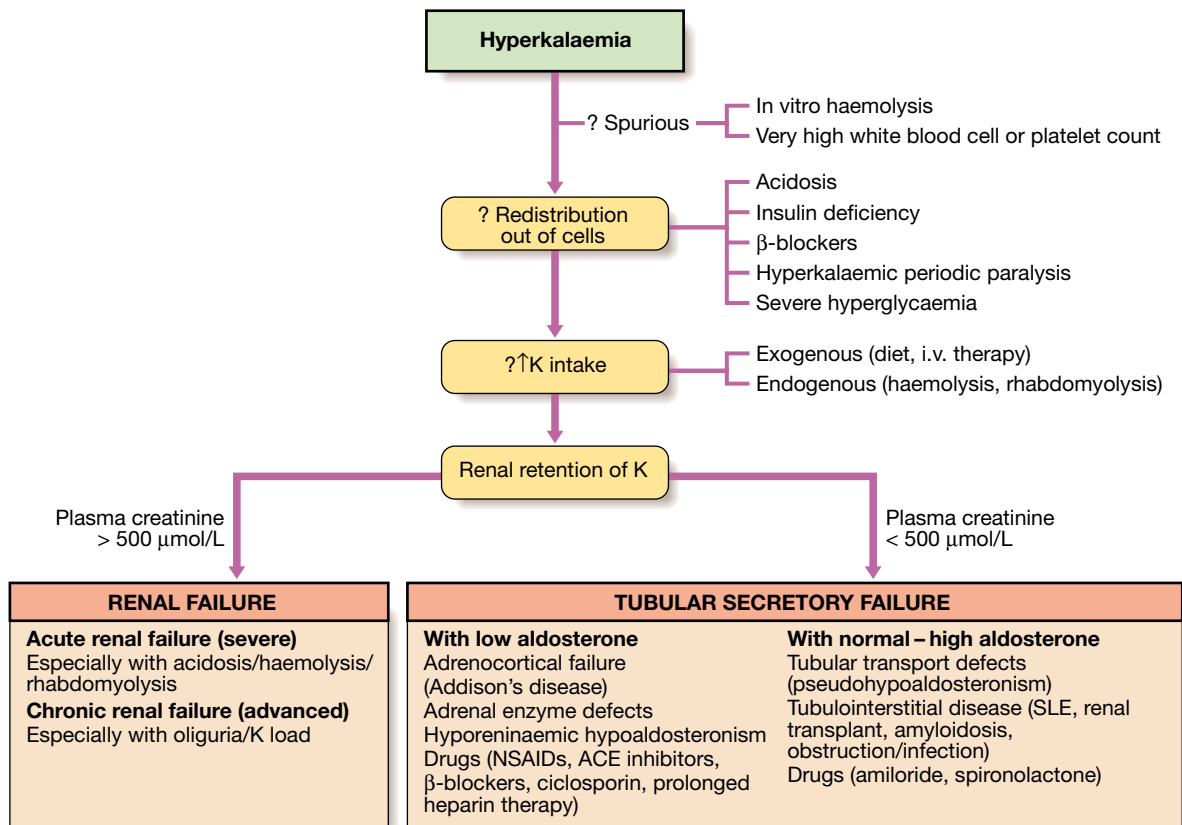

Fig. 16.10 Diagnostic decision tree for hyperkalaemia. Creatinine of 500 μ mol/L = 5.67 mg/dL.

In all conditions of aldosterone deficiency or aldosterone resistance, hyperkalaemia may be associated with acid retention, giving rise to the pattern of hyperkalaemic distal ('type 4') renal tubular acidosis (p. 444).

Investigations

Results for plasma electrolytes, creatinine and bicarbonate, together with consideration of the clinical scenario, will usually provide the explanation for hyperkalaemia. In aldosterone deficiency, plasma sodium concentration is characteristically low, although this can occur in many causes of hyperkalaemia. Addison's disease should be excluded unless there is an obvious alternative diagnosis, as described on page 775.

Management

Treatment of hyperkalaemia depends on the severity and the rate of development. In the absence of neuromuscular symptoms or ECG changes, reduction of potassium intake and correction of underlying abnormalities may be sufficient. However, in acute and/or severe hyperkalaemia (plasma K > 6.5–7.0 mmol/L) more urgent measures must be taken (Box 16.17).

If ECG changes are present, the first step should be infusion of calcium gluconate to stabilise conductive tissue membranes (calcium has the opposite effect to potassium on conduction of an action potential). Measures to shift potassium from the ECF to the ICF should also be taken, as they generally act rapidly and may avert arrhythmia. Ultimately, a means of removing potassium from the body is generally necessary. When renal function

16.17 Treatment of severe hyperkalaemia

Mechanism	Therapy
Stabilise cell membrane potential¹	I.v. calcium gluconate (10 mL of 10% solution)
Shift K into cells	Inhaled β_2 agonist, e.g. salbutamol I.v. glucose (50 mL of 50% solution) and insulin (5 U Actrapid) Intravenous sodium bicarbonate ²
Remove K from body	I.v. furosemide and normal saline ³ Ion-exchange resin (e.g. Resonium) orally or rectally Dialysis

¹If ECG changes suggestive of hyperkalaemia (K typically > 7 mmol/L).

²If acidosis present.

³If adequate residual renal function.

is reasonably preserved, loop diuretics (accompanied by intravenous saline if hypovolaemia is present) may be effective; in established renal failure, ion-exchange resins acting through the gastrointestinal tract and urgent dialysis may be required.

DISORDERS OF ACID–BASE BALANCE

The pH of the arterial plasma is normally 7.40, corresponding to a H^+ concentration of 40 nmol/L. An increase in H^+ concentration corresponds to a decrease in pH. To

preserve function of many pH-sensitive enzymes, this parameter is under tight homeostatic regulation, such that the H^+ concentration does not vary outside the range 36–44 nmol/L (pH 7.44–7.36) under normal circumstances. Abnormal acid–base balance occurs in a wide range of diseases.

Functional anatomy and physiology of acid–base homeostasis

A variety of physiological mechanisms maintain the pH of the ECF. The first is the action of blood and tissue buffers, of which the most important involves reaction of H^+ ions with bicarbonate to form carbonic acid, which, under the influence of the enzyme carbonic anhydrase (c.a.), dissociates to form CO_2 and water:

This buffer system is important because bicarbonate is present in relatively high concentration in the ECF (21–28 mmol/L), and two of its key components are under physiological control: the CO_2 by the lungs, and the bicarbonate by the kidneys. These relationships are illustrated in Figure 16.11 (a form of the Henderson–Hasselbalch equation).

Respiratory compensation for acid–base disturbances can occur quickly. In response to acid accumulation, pH changes in the brain stem stimulate ventilatory drive, serving to reduce the PCO_2 and hence drive up the pH (p. 651). Conversely, systemic alkalosis leads to inhibition of ventilation (although this is limited because hypoxia provides an alternative stimulus to ventilation).

The kidney provides a third line of defence against disturbances of arterial pH. When acid accumulates due to chronic respiratory or metabolic (non-renal) causes,

Fig. 16.11 Relationship between pH, PCO_2 (in mmHg) and plasma bicarbonate concentration (in mmol/L). *Note that changes in HCO_3^- concentration are also part of the renal correction for sustained metabolic acid–base disturbances as long as the kidney itself is not the cause of the primary disturbance.

the kidney has the long-term capacity to enhance urinary excretion of acid, effectively increasing the plasma bicarbonate.

Renal control of acid–base balance

There are several components to the kidneys' contribution to maintaining acid–base balance. First, the proximal tubule reabsorbs some 85% of the filtered bicarbonate ions, through the mechanism for H^+ secretion illustrated in Figure 16.3A (p. 429). This is dependent on the enzyme carbonic anhydrase both in the cytoplasm of the proximal tubular cells and on the luminal surface of the brush border membranes. The system has a high capacity but does not lead to significant acidification of the luminal fluid.

Distal nephron segments have an important role in determining net acid excretion by the kidney. In the intercalated cells of the cortical collecting duct and the outer medullary collecting duct cells, acid is secreted into the lumen by an H^+ -ATPase. This excreted acid is generated in the tubular cell from the hydration of CO_2 to form carbonic acid, which dissociates into an H^+ ion secreted luminally, and a bicarbonate ion which passes across the basolateral membrane into the blood. The secreted H^+ ions contribute to the reabsorption of any residual bicarbonate present in the luminal fluid, but also contribute net acid for removal from the body, bound to a variety of urinary buffers. The first is filtered non-bicarbonate buffer, such as phosphate (HPO_4^{2-}) which is titrated in the distal lumen to dihydrogen phosphate ($H_2PO_4^-$), excreted in the urine with sodium. The second significant buffer is ammonia, which is generated within tubular cells by the action of the enzyme glutaminase on glutamine. NH_3 reacts with secreted acid to form ammonium (NH_4^+), which becomes trapped in the luminal fluid and is excreted with chloride ions.

The net removal of acid by the kidney, using these latter two mechanisms, amounts to some 1 mmol/kg/day of hydrogen ions, which equals the non-volatile acid load arising from the metabolism of dietary protein. Thus a slightly alkaline plasma pH of 7.4 (H^+ 40 nmol/L) is maintained by the kidney's capacity to generate an acidic urine (pH typically 5–6) in which the net daily excess of metabolic acid can be excreted.

Presenting problems in disorders of acid–base balance

Patients with disturbances of acid–base balance may present clinically either with the effects of tissue malfunction due to disturbed pH (such as altered cardiac and central nervous system function), or with secondary changes in respiration as a response to the underlying metabolic change (e.g. Kussmaul respiration during metabolic acidosis). The clinical picture is often dominated by the cause of the acid–base change, such as uncontrolled diabetes mellitus or primary lung disease. Frequently the acid–base disturbance only becomes evident when the venous plasma bicarbonate concentration is noted to be abnormal, or when a full arterial blood gas analysis shows abnormalities in the pH, PCO_2 or bicarbonate. The 'base excess' or 'base deficit' may also be provided with these data; this is the difference

16.18 Principal patterns of acid–base disturbance

Disturbance	Blood H ⁺	Primary change	Compensatory response	Predicted compensation
Metabolic acidosis	> 40 ¹	HCO ₃ < 24 mmol/L	PCO ₂ < 5.33 kPa ²	PCO ₂ fall in kPa = 0.16 × HCO ₃ fall in mmol/L
Metabolic alkalosis	< 40 ¹	HCO ₃ > 24 mmol/L	PCO ₂ > 5.33 kPa ^{2,3}	PCO ₂ rise in kPa = 0.08 × HCO ₃ rise in mmol/L
Respiratory acidosis	> 40 ¹	PCO ₂ > 5.33 kPa ²	HCO ₃ > 24 mmol/L	Acute: HCO ₃ rise in mmol/L = 0.75 × PCO ₂ rise in kPa Chronic: HCO ₃ rise in mmol/L = 2.62 × PCO ₂ rise in kPa
Respiratory alkalosis	< 40 ¹	PCO ₂ < 5.33 kPa ²	HCO ₃ < 24 mmol/L	Acute: HCO ₃ fall in mmol/L = 1.50 × PCO ₂ fall in kPa Chronic: HCO ₃ fall in mmol/L = 3.75 × PCO ₂ fall in kPa

¹H⁺ of 40 nmol/L = pH of 7.40.

²PCO₂ of 5.33 kPa = 40 mmHg.

³PCO₂ does not rise above 7.33 kPa (55 mmHg) because hypoxia then intervenes to drive respiration.

between the patient's bicarbonate level and the normal bicarbonate, measured in vitro with the PCO₂ adjusted to 5.33 kPa (40 mmHg), and is particularly useful in patients with combined respiratory and metabolic disorders (p. 192).

The common patterns of abnormality in the blood gas parameters in acid–base disturbances are shown in Box 16.18. (Note that the terms acidosis and alkalosis strictly refer to the underlying direction of the acid–base change, while acidaemia and alkalaemia more correctly refer to the net change present in the blood.) Interpretation of arterial blood gases is also described on page 651.

In metabolic disturbances, respiratory compensation is almost immediate, so that the predicted compensatory change in PCO₂ is achieved soon after the onset of the metabolic disturbance. In respiratory disorders, on the other hand, a small initial change in bicarbonate occurs as a result of chemical buffering of CO₂, largely within red blood cells, but over days and weeks the kidney achieves further compensatory changes in bicarbonate concentration as a result of long-term adjustments in acid secretory capacity. When clinically obtained acid–base parameters do not accord with the predicted compensation shown, a mixed acid–base disturbance should be suspected (p. 445).

Metabolic acidosis

Aetiology and assessment

Metabolic acidosis occurs when an acid other than carbonic acid (due to CO₂ retention) accumulates in the body, resulting in a fall in the plasma bicarbonate. The pH fall which would otherwise occur is blunted by hyperventilation, resulting in a reduced PCO₂. If the kidneys are intact (i.e. not the cause of the initial disturbance), renal excretion of acid can be gradually increased over days to weeks, raising the plasma bicarbonate and hence the pH towards normal in the new steady state.

Two patterns of metabolic acidosis can be defined (Box 16.19), depending on the nature of the accumulating acid:

- In pattern A, when a mineral acid (HCl) accumulates, or when there is a primary loss of bicarbonate buffer from the ECF, there is no addition to the plasma of a new acidic anion. In this case, the 'anion gap' (calculated as the difference between the

16.19 Causes of metabolic acidosis

Disorder	Mechanism
A. Normal anion gap	
Inorganic acid addition	Therapeutic infusion of or poisoning with NH ₄ Cl, HCl
Gastrointestinal base loss	Loss of HCO ₃ in diarrhoea, small bowel fistula, urinary diversion procedure
Renal tubular acidosis (RTA)	Urinary loss of HCO ₃ in proximal RTA; impaired tubular acid secretion in distal RTA
B. Increased anion gap	
Endogenous acid load	
Diabetic ketoacidosis	Accumulation of ketones ¹ with hyperglycaemia
Starvation ketosis	Accumulation of ketones without hyperglycaemia
Lactic acidosis	Tissue hypoxia (e.g. shock) or liver disease
Renal failure	Accumulation of organic acids
Exogenous acid load	
Aspirin poisoning	Accumulation of salicylate ²
Methanol poisoning	Accumulation of formate
Ethylene glycol poisoning	Accumulation of glycolate, oxalate

¹Ketones include the acid anions acetoacetate and β-hydroxybutyrate (p. 805).

²Salicylate poisoning is also associated with respiratory alkalosis due to direct ventilatory stimulation.

main measured cations (Na⁺ + K⁺) and the anions (Cl⁻ + HCO₃⁻) is normal, since the plasma chloride increases to replace the depleted bicarbonate levels. This 'gap', normally around 15 mmol/L, is made up of anions such as phosphate, sulphate and multiple negative charges on plasma protein molecules. Normal anion gap metabolic acidosis (pattern A) is usually due either to diarrhoea, where the clinical diagnosis is generally obvious, or to renal tubular acidosis (see below).

- In pattern B, an accumulating acid is accompanied by its corresponding anion, which adds to the unmeasured anion gap, while the chloride concentration remains normal. The cause is usually apparent from associated clinical features such as

uncontrolled diabetes mellitus, renal failure or shock, or may be suggested by associated symptoms, such as visual complaints in methanol poisoning (p. 220). It is noteworthy that a number of causes of increased anion gap acidosis are associated with alcoholism, including starvation ketosis, lactic acidosis and intoxication by methanol or ethylene glycol.

Lactic acidosis

Lactic acidosis may be confirmed by the measurement of plasma lactate, which will be increased over the normal maximal level of 2 mmol/L by as much as tenfold. Two types of lactic acidosis have been defined:

- Type 1, due to tissue hypoxia and peripheral generation of lactate, as in patients with circulatory failure and shock.
- Type 2, due to impaired metabolism of lactate as in liver disease. A number of drugs and toxins also impair lactate metabolism, including metformin.

Renal tubular acidosis (RTA)

This condition should be suspected when there is a hyperchloraemic (normal anion gap) acidosis with no evidence of gastrointestinal disturbance, and the urine pH is inappropriately high (i.e. > 5.5 in the presence of systemic acidosis). The defect can affect one of three tubular processes: reabsorption of bicarbonate in the proximal tubule (proximal RTA), acid secretion in the late distal/cortical collecting duct intercalated cells (classical distal RTA), or sodium reabsorption in the principal cells of this nephron segment, with secondary effects to reduce secretion of both potassium and acid (hyperkalaemic distal RTA).

Typical causes of each type of RTA are shown in Box 16.20. Inherited causes are due to defects in the molecular mechanisms mediating acid or bicarbonate transport in the respective tubular segments (see Fig. 16.3, p. 429). However, many causes are acquired, and the metabolic acidosis may serve as an early clue to their diagnosis.

16.20 Causes of renal tubular acidosis (RTA)

Proximal RTA ('type 2')

- Congenital, e.g. Fanconi's syndrome, cystinosis, Wilson's disease
- Paraproteinaemia, e.g. myeloma
- Amyloidosis
- Hyperparathyroidism
- Heavy metal toxicity, e.g. Pb, Cd, Hg
- Drugs, e.g. carbonic anhydrase inhibitors, ifosfamide

Classical distal RTA ('type 1')

- Congenital
- Hyperglobulinaemia
- Autoimmune connective tissue diseases, e.g. SLE
- Toxins and drugs, e.g. toluene, lithium, amphotericin

Hyperkalaemic distal RTA ('type 4')

- Hypoaldosteronism (primary or secondary)
- Obstructive nephropathy
- Drugs, e.g. amiloride, spironolactone
- Renal transplant rejection

Sometimes distal RTA is 'incomplete' and the plasma bicarbonate concentration is normal under resting conditions. However, in incomplete distal RTA the urine pH fails to fall below 5.3 after an acid challenge test, involving the ingestion of ammonium chloride sufficient to lower the plasma bicarbonate.

A number of features allow differentiation of types of RTA. The proximal form is frequently associated with urinary wasting of amino acids, phosphate and glucose (Fanconi's syndrome), as well as bicarbonate and potassium. In severe acidosis, patients with proximal RTA can lower the urine pH once the plasma bicarbonate has fallen below 16 mmol/L and leakage of bicarbonate has subsided, since distal H^+ secretion mechanisms are intact. In classical distal RTA, by contrast, acid accumulation is relentless and progressive, resulting in mobilisation of calcium from bone and consequent osteomalacia with hypercalciuria, stone formation and nephrocalcinosis. Potassium is also lost in classical distal RTA, while it is retained in hyperkalaemic distal RTA.

Management

The first step in management of metabolic acidosis is to identify and correct the cause when possible (see Box 16.19). This may involve control of diarrhoea, treatment of diabetes mellitus, correction of shock, cessation of drug administration, or dialysis to remove toxins. Since metabolic acidosis is frequently associated with sodium and water depletion, resuscitation with appropriate intravenous fluids is often needed. Use of intravenous bicarbonate in this setting is controversial. Because rapid correction of acidosis has some inherent risks (e.g. induction of hypokalaemia or reduced plasma ionised calcium), use of bicarbonate infusions is best reserved for situations where the underlying disorder cannot be readily corrected and the acidosis is critical ($H^+ > 100 \text{ nmol/L}$, $\text{pH} < 7.00$) and associated with evidence of tissue dysfunction.

In RTA, the acidosis can sometimes be controlled by treating the underlying cause (see Box 16.20). Usually, however, supplements of sodium and potassium bicarbonate are necessary to achieve the target of a plasma bicarbonate level above 18 mmol/L with normokalaemia in types 1 and 2 RTA, while diuretics of the loop or thiazide classes or fludrocortisone (as appropriate to the underlying diagnosis) may be effective in increasing acid secretion in type 4 RTA.

Metabolic alkalosis

Aetiology and clinical assessment

Metabolic alkalosis is characterised by an increase in the plasma bicarbonate concentration and the plasma pH (see Box 16.18). There is a compensatory rise in PCO_2 due to hypoventilation, but this is limited by the need to avoid hypoxia. The causes are best classified by the accompanying disturbance of ECF volume.

Hypovolaemic metabolic alkalosis is the most common pattern, typified by disorders such as sustained vomiting in which acid-rich fluid is lost directly from the body. This pattern also occurs during treatment with most diuretic drugs (other than carbonic anhydrase inhibitors and potassium-sparing drugs), since the diuretic action involves increased acid loss into the urine. In the case of sustained vomiting, the loss of acid is the immediate trigger for generating metabolic alkalosis, but several factors act to sustain or amplify

metabolic alkalosis in the context of volume depletion (Fig. 16.12). Loss of sodium and fluid leads to hypovolaemia and secondary hyperaldosteronism, triggering both proximal sodium bicarbonate reabsorption and further distal acid secretion. Hypokalaemia, due to potassium loss in the vomitus as well as through the kidney under the influence of aldosterone, itself stimulates distal acid excretion. Additionally, the compensatory rise in PCO_2 enhances tubular acid secretion. The net result is an inappropriately acid urine and a failure of the kidney to effect long-term correction of the systemic pH disturbance, at least until adequate replenishment of the circulating volume and hence reversal of secondary hyperaldosteronism.

Normovolaemic (or hypervolaemic) metabolic alkalosis occurs when both bicarbonate retention and volume expansion occur simultaneously. Classical causes include corticosteroid excess states such as primary hyperaldosteronism (Conn's syndrome, p. 778), Cushing's syndrome (p. 770) and corticosteroid therapy (p. 774). Occasionally, overuse of antacid salts for treatment of dyspepsia produces a similar pattern.

Clinically, apart from manifestations of the underlying cause, there may be few symptoms or signs related to alkalosis itself. When the rise in systemic pH is abrupt, plasma ionised calcium falls and signs of increased neuromuscular irritability such as tetany may develop (p. 765).

Management

In metabolic alkalosis with hypovolaemia, treatment involves provision of adequate intravenous fluid,

specifically isotonic sodium chloride and sufficient potassium to correct the hypokalaemia, which interrupts the volume-conserving mechanisms and allows the kidney to excrete the excess alkali in the urine.

In metabolic alkalosis with normal or increased volume, treatment should focus on the underlying endocrine cause (Ch. 20).

Respiratory acidosis

Respiratory acidosis occurs when there is accumulation of CO_2 due to reduced effective alveolar ventilation (type II respiratory failure, p. 660). This results in a rise in the PCO_2 , with a compensatory increase in plasma bicarbonate concentration, particularly when the disorder is of long duration and the kidney has fully developed its capacity for increased acid excretion.

This acid–base disturbance can arise from lesions anywhere along the neuromuscular pathways from the brain to the respiratory muscles that result in impaired ventilation. It can also arise during intrinsic lung disease if there is significant mismatching of ventilation and perfusion.

Clinical features of respiratory acidosis are dominated by the cause of hypoventilation (e.g. obtundation, paralysis, chest wall injury, chronic obstructive lung disease), but the CO_2 accumulation itself leads to drowsiness which itself further depresses respiratory drive.

Management involves correction of causative factors where possible, but ultimately external ventilatory support may be necessary.

Respiratory alkalosis

Respiratory alkalosis develops when there is a period of sustained hyperventilation resulting in a reduction of PCO_2 and increase in plasma pH. If the condition is sustained, renal compensation occurs such that tubular acid secretion is reduced and the plasma bicarbonate falls.

This acid–base disturbance is frequently of short duration, as in anxiety states or over-vigorous assisted ventilation. It can be prolonged in the context of pregnancy, pulmonary embolism, chronic liver disease, and ingestion of certain drugs which stimulate the brain-stem respiratory centre (e.g. salicylates).

Clinical features are those associated with the cause, but there is frequently also agitation associated with perioral and digital tingling, due to a reduction in ionised calcium concentration caused by increased binding of calcium to albumin in the alkalotic ECF. In severe cases, Trousseau's sign and Chvostek's sign may be positive, and tetany or seizures may develop (p. 766).

Management involves correction of identifiable causes, reduction of anxiety, and sometimes a period of rebreathing into a closed bag to allow CO_2 levels to rise.

Mixed acid–base disorders

In patients with complex illnesses, it is not uncommon for more than one independent disturbance of acid–base metabolism to be present at the same time. In these situations, the arterial pH will represent the net effect of all primary and compensatory changes. Indeed, the pH may be normal, but the presence of underlying acid–base disturbances can be gauged from concomitant abnormalities in the PCO_2 and bicarbonate concentration.

In assessing these disorders, all clinical influences on the patient's acid–base status should be identified, and reference should be made to the table of predicted

Fig. 16.12 Generation and maintenance of metabolic alkalosis during prolonged vomiting. Loss of H^+Cl^- generates metabolic alkalosis which is maintained by renal changes.

compensation given in Box 16.18 (p. 443). If the compensatory change is discrepant from the rules of thumb provided, the presence of more than one disturbance of acid-base metabolism may be suspected.

DISORDERS OF DIVALENT ION METABOLISM

The present section excludes discussion of calcium disorders, which are considered in Chapters 20 (pp. 764–765) and 25 (p. 1121).

Functional anatomy and physiology of magnesium metabolism

Like potassium, magnesium is mainly an intracellular cation. It is important to the function of many enzymes, including the Na,K-ATPase, and can regulate both potassium and calcium channels. Its overall effect is to stabilise excitable cell membranes.

Renal handling of magnesium involves filtration of free plasma magnesium (about 70% of the total) with extensive reabsorption (50–70%) in the loop of Henle, although significant reabsorption also occurs in the proximal and distal tubules. Reabsorption is enhanced by parathyroid hormone (PTH).

Presenting problems in disorders of magnesium metabolism

Hypomagnesaemia

Aetiology and clinical assessment

A plasma magnesium concentration below the normal range (0.75–1.0 mmol/L; 1.5–2.0 meq/L) is usually a reflection of magnesium depletion (Box 16.21). Reduced

16.21 Causes of hypomagnesaemia

Mechanism	Examples
Inadequate intake	Starvation, malnutrition (esp. alcoholism), parenteral alimentation
Excessive losses	
Gastrointestinal	Prolonged vomiting/nasogastric aspiration, chronic diarrhoea/laxative abuse, malabsorption, small bowel bypass surgery, fistulas
Urinary	Diuretic therapy (loop, thiazide), alcohol, tubulotoxic drugs (gentamicin, cisplatin), volume expansion (e.g. primary hyperaldosteronism), diabetic ketoacidosis, post-obstructive diuresis, recovery from acute tubular necrosis, inherited tubular transport defect (Bartter's syndrome, Gitelman's syndrome, primary renal magnesium wasting)
Miscellaneous	Acute pancreatitis, foscarnet therapy, hungry bone syndrome, diabetes mellitus

intake alone is rarely sufficient to cause magnesium depletion, and generally there is excessive loss from either the gastrointestinal tract (notably in chronic diarrhoea) or the kidney (during prolonged use of loop diuretics). Excessive alcohol ingestion can cause magnesium depletion through both gut and renal losses. Some inherited tubular transport disorders result in urinary magnesium wasting, notably Gitelman's syndrome (p. 439).

Hypomagnesaemia is frequently associated with hypocalcaemia, probably because magnesium is required for the normal secretion of PTH in response to a fall in serum calcium, and because hypomagnesaemia induces resistance to PTH in bone. Clinical features of hypomagnesaemia and hypocalcaemia are similar; there may be tetany, cardiac arrhythmias (notably torsades de pointes, p. 567), central nervous excitation and seizures, as well as vasoconstriction and hypertension. Magnesium depletion is also associated (through uncertain mechanisms) with hyponatraemia and hypokalaemia, which may mediate some of the clinical manifestations.

Management

Treatment involves identification and correction of the cause where possible. Oral magnesium salts have limited effectiveness due to poor absorption and may cause diarrhoea. When symptoms are present, treatment should be with intravenous magnesium chloride at a rate not exceeding 0.5 mmol/kg in the first 24 hours. When intravenous access is not available, magnesium sulphate can be given intramuscularly. If hypomagnesaemia is due to diuretic treatment, adjunctive use of a potassium-sparing agent will also reduce magnesium loss into the urine.

Hypermagnesaemia

This is a much less common abnormality than hypomagnesaemia. The cause nearly always involves acute or chronic renal failure, but adrenocortical insufficiency also predisposes to magnesium retention. An increased intake, either through medications containing magnesium (antacids, laxatives, enemas) or through iatrogenic parenteral therapy, greatly increases the risk of hypermagnesaemia in patients with renal impairment.

Clinical features include bradycardia, hypotension, reduced consciousness and respiratory depression.

Management involves ceasing all magnesium intake, improving renal function if possible, and promoting urinary magnesium excretion using a loop diuretic with intravenous hydration, if residual renal function allows. Calcium gluconate may be given intravenously to reverse overt cardiac effects. Ultimately, if renal function is minimal, dialysis may be necessary to remove the magnesium load.

Functional anatomy and physiology of phosphate metabolism

Inorganic phosphate (mainly present as HPO_4^{2-}) is intimately involved in cell energy metabolism, intracellular signalling and bone and mineral balance (Ch. 25). The normal plasma concentration is 0.8–1.4 mmol/L (2.48–4.34 mg/dL). It is freely filtered at the glomerulus and approximately 65% is reabsorbed by the proximal tubule, via an apical sodium-phosphate cotransport carrier.

A further 10–20% is reabsorbed in the distal tubules, leaving a fractional excretion of some 10% to pass into the urine, usually as H_2PO_4^- . Proximal reabsorption is decreased by PTH, volume expansion and glucose infusion.

Presenting problems in disorders of phosphate metabolism

Hypophosphataemia

The causes of a reduced plasma phosphate concentration are shown in Box 16.22. Phosphate may redistribute into cells during periods of increased energy utilisation (as in refeeding after a period of starvation) and during systemic alkalosis. However, severe hypophosphataemia usually represents an overall body deficit due either to inadequate intake or absorption through the gut, or to excessive renal losses, notably in primary hyperparathyroidism (p. 766) or in diuresis involving inhibition of proximal tubular reabsorption (e.g. acute volume expansion, osmotic diuresis and proximally acting diuretics). An inherited defect of proximal sodium-phosphate cotransport causes familial hypophosphataemic rickets.

Clinical manifestations of phosphate depletion reflect the widespread involvement of phosphate in tissue metabolism. Defects appear in the blood (impaired function and survival of all cell lines), skeletal muscle (weakness, respiratory failure), cardiac muscle (congestive cardiac failure), smooth muscle (ileus), central nervous system (decreased consciousness, seizures and coma) and bone (osteomalacia in severe prolonged hypophosphataemia, p. 1121).

Management involves administering oral phosphate supplements and high-protein/high-dairy dietary supplements which are rich in naturally occurring phosphate. Intravenous treatment with sodium or potassium phosphate salts can be used in critical situations, but there is a risk of precipitating hypocalcaemia and metastatic calcification.

16.22 Causes of hypophosphataemia

Mechanism	Examples
Redistribution into cells	Refeeding after starvation, respiratory alkalosis, treatment for diabetic ketoacidosis
Inadequate intake or absorption	Malnutrition, malabsorption, chronic diarrhoea, phosphate binders (antacids), vitamin D deficiency or resistance
Increased renal excretion	Hyperparathyroidism, ECF volume expansion with diuresis, osmotic diuresis, proximal tubular transport defect (Fanconi's syndrome, familial hypophosphataemic rickets, cancer-induced hypophosphataemia)

Hyperphosphataemia

Phosphate accumulation is usually the result of acute or chronic renal failure (pp. 482–492, and p. 765). Phosphate excretion is also reduced in hypoparathyroidism and

pseudohypoparathyroidism (p. 768). Redistribution of phosphate from cells into the plasma can be a contributing factor to hyperphosphataemia in the 'tumour lysis' syndrome and in catabolic states. Phosphate accumulation is aggravated in any of these conditions if the patient takes phosphate-containing preparations or inappropriate vitamin D therapy.

The clinical features relate to hypocalcaemia and metastatic calcification, particularly in chronic renal failure with tertiary hyperparathyroidism (when a high calcium-phosphate product occurs).

Management involves volume expansion with intravenous normal saline which promotes phosphate excretion if renal function is normal. In the presence of renal failure, dietary phosphate restriction and the use of oral phosphate binders (such as calcium carbonate) are important (p. 490).

DISORDERS OF AMINO ACID METABOLISM

Congenital disorders of amino acid metabolism usually present in the neonatal period and may involve life-long treatment regimens. However, some disorders, particularly those involved in amino acid transport, may not present until later in life.

Phenylketonuria

Phenylketonuria (PKU) is inherited as an autosomal recessive disorder which causes deficiency of enzymatic activity of phenylalanine hydroxylase. As a result, phenylalanine accumulates to high levels in the neonate's blood, causing mental retardation.

Diagnosis of PKU is almost always made by routine neonatal screening. Treatment involves life-long adherence to a low-phenylalanine diet. Early and adequate dietary treatment prevents major mental retardation, although there may still be a slight reduction in IQ.

Homocystinuria

Homocystinuria is caused by cystathionine β -synthase deficiency and inherited as an autosomal recessive trait. This results in increased urinary excretion of homocystine and methionine. Many cases of homocystinuria are diagnosed through newborn screening programmes.

There is a wide spectrum of clinical manifestations, involving the eyes (ectopia lentis—displacement of the lens), central nervous system (mental retardation, delayed developmental milestones, seizures, psychiatric disturbances), skeleton (resembling Marfan's syndrome, and also with generalised osteoporosis), vascular system (thrombotic lesions of arteries and veins) and skin (hypopigmentation).

Treatment is dietary, involving a methionine-restricted, cystine-supplemented diet, as well as large doses of pyridoxine.

DISORDERS OF CARBOHYDRATE METABOLISM

The most common disorder of carbohydrate metabolism is diabetes mellitus, which is discussed in Chapter 21. There are also some rare inherited defects.

Galactosaemia

Galactosaemia is caused by a mutation in the gene encoding galactose-1-phosphate uridylyltransferase (*GALT*) and is usually inherited as an autosomal recessive disorder. The neonate is unable to metabolise galactose, one of the hexose sugars contained in lactose.

Vomiting or diarrhoea usually begins within a few days of ingestion of milk, and the neonate may become jaundiced. Failure to thrive is the most common clinical presentation. The classic form of the disease results in hepatomegaly, cataracts and mental retardation, and fulminant infection with *Escherichia coli* is a frequent complication. Treatment involves life-long avoidance of galactose- and lactose-containing foods.

The widespread inclusion of galactosaemia in newborn screening programmes has resulted in the identification of a number of milder variants (e.g. 'Duarte' variant).

Glycogen storage diseases

Glycogen provides a rapidly mobilisable storage form of glucose, enabling glucose to be released as needed during exercise or between meals. Glycogen storage diseases (GSD, or glycogenoses) result from an inherited defect in one of the many enzymes responsible for the formation or breakdown of glycogen.

There are about eleven major types of GSD which are classified by a number, by the name of the defective enzyme or eponymously after the physician who first described the condition (Box 16.23). Most forms of GSD are inherited as autosomal recessive disorders.

A diagnosis of GSD is made on the basis of the patient's symptoms, a physical examination and the results of biochemical tests. Occasionally, a muscle or liver biopsy is required to confirm the enzyme defect. Different types of GSD present at different ages, and some may require life-long modifications of diet and lifestyle.

16.23 Glycogen storage diseases (GSD)			
GSD	Eponym	Enzyme deficiency	Clinical features and complications
I	Von Gierke	Glucose-6-phosphatase	Childhood presentation, hypoglycaemia, hepatomegaly
II	Pompe	α -glucosidase (acid maltase)	Classical presentation in infancy, muscle weakness (may be severe)
III	Cori	Debrancher enzyme	Childhood presentation, hepatomegaly, mild hypoglycaemia
IV	Andersen	Brancher enzyme	Presentation in infancy, severe muscle weakness (may affect heart), cirrhosis
V	McArdle	Muscle glycogen phosphorylase	Exercise-induced fatigue and myalgia
VI	Hers	Liver phosphorylase	Mild hepatomegaly
VII	Tarui	Muscle phosphofructokinase	Exercise-induced fatigue and myalgia
VIII		Liver phosphorylase kinase	Very mild disease; hepatomegaly, growth retardation, elevated hepatic enzymes, hyperlipidaemia, fasting hyperketosis
IX		Liver glycogen phosphorylase kinase	Mild hepatomegaly. Inheritance can be autosomal or X-linked recessive
0		Hepatic glycogen synthase	Fasting hypoglycaemia, post-prandial hyperglycaemia

16.24 Lysosomal storage diseases			
Lysosomal storage disease	Clinical features	Enzyme deficiency	Human enzyme replacement therapy
Fabry disease	Variable age of onset Neurological (pain in extremities) Dermatological (hypohidrosis, angiokeratomas) Cerebrovascular (renal, cardiac, CNS)	α -galactosidase A	In clinical practice
Gaucher disease (various types)	Splenic and liver enlargement, with variable severity of disease Some types also have neurological involvement	Glucocerebrosidase	In clinical practice for some types
Mucopolysaccharidosis (MPS) (various types, including Hurler's, Hunter's, Sanfilippo's, Morquio's syndromes)	Vary with syndrome. Can cause mental retardation, skeletal and joint abnormalities, abnormal facies, obstructive respiratory diseases and recurrent respiratory infections	Each MPS type has a different enzyme deficiency	In clinical practice for some types; clinical trials underway for other types
Niemann-Pick disease	Most common presentation is as a progressive neurological disorder, accompanied by organomegaly Some variants do not have neurological symptoms	Acid sphingomyelinase	Clinical trials planned for some types
GM2-gangliosidosis (various types, including Tay-Sachs, Sandhoff's diseases)	Severe progressive neurological disorder. Sandhoff's disease also characterised by organomegaly	Hexosaminidase A, B	

DISORDERS OF COMPLEX LIPID METABOLISM

Complex lipids are key components of the cell membrane (p. 44). They are normally catabolised in organelles called lysosomes. The lysosomal storage diseases are a heterogeneous group of disorders in which there is a missing enzyme in the lysosomes (Box 16.24), resulting in an inability to break down complex glycolipids or other intracellular macromolecules. These disorders have diverse clinical manifestations, typically including mental retardation. Some are becoming treatable using human enzyme replacement therapy, while others (such as Tay–Sachs disease) can be prevented through community participation in genetic carrier screening programmes.

DISORDERS OF BLOOD LIPIDS AND LIPOPROTEINS

The term ‘lipid’ refers to substances with poor water solubility. Biologically important lipids include sterols (including cholesterol), which are composed of hydrocarbon rings, and glycerides (including triglyceride (TG) and phospholipid), which are chiefly composed of hydrocarbon chains (including fatty acids). Despite their poor water solubility, these materials must be assimilated from the diet and transported in the body; this is achieved by incorporating lipids within lipoproteins. Plasma cholesterol and TG are clinically important mainly because they are major treatable risk factors for cardiovascular disease, whilst severe hypertriglyceridaemia also predisposes to acute pancreatitis.

Functional anatomy, physiology and investigation of lipid metabolism

Lipids can be transported and metabolised *in vivo* by virtue of the detergent-like properties of apolipoproteins. The laws of physical chemistry dictate that in the aqueous *in vivo* environment of the blood and tissue fluids, apolipoproteins combine with lipids to form spherical or disc-shaped lipoproteins, which consist of a hydrophobic core and a less hydrophobic coat (Fig. 16.13). The structure of some apolipoproteins also enables them to act as enzyme co-factors or cell receptor ligands. Variations in lipid and apolipoprotein composition result in distinct classes of lipoprotein that perform specific metabolic functions.

Dietary lipid

The intestinal absorption of dietary lipid is described on page 838 (see also Fig. 16.14). Enterocytes lining the gut extract monoglyceride and free fatty acids from micelles and re-esterify them into TG. TG is combined with a truncated form of apolipoprotein B (Apo B48) as it is synthesised. Intestinal cholesterol derived from dietary and biliary sources is also absorbed via a specific intestinal membrane transporter (NPC1L1). These processes produce chylomicrons containing TG and cholesterol

Fig. 16.13 Structure of lipoproteins.

ester that are secreted basolaterally into lymphatic lacteals then carried to the circulation via the thoracic duct. Newly secreted chylomicrons are remodelled by the transfer of additional apolipoproteins. Chylomicron TG is hydrolysed by lipoprotein lipase located on the endothelium of tissue capillary beds. This releases fatty acids that may be used locally for energy or stored in tissues such as muscle or adipose tissue. The residual ‘remnant’ chylomicron particle is avidly cleared by low-density lipoprotein (LDL)-receptors in the liver which recognise Apo E on the remnant lipoproteins. Complete absorption of dietary lipids takes about 6–10 hours, so chylomicrons are undetectable in the plasma after a 12-hour fast.

The main dietary determinants of plasma cholesterol concentrations are the intakes of saturated and trans-unsaturated fatty acids, which reduce LDL receptor activity (see below). Dietary cholesterol has surprisingly little effect on fasting cholesterol levels. Plant sterols and drugs that inhibit cholesterol absorption are effective because they also reduce the re-utilisation of biliary cholesterol. Dietary determinants of plasma TG concentrations are complex. Excessive intakes of carbohydrate, fat or alcohol may each contribute to increased plasma TG by different mechanisms.

Endogenous lipid

In the fasting state, the liver is the major source of plasma lipids (see Fig. 16.14). The liver may acquire lipids by uptake, synthesis or conversion from other macronutrients. These lipids are transported to other tissues by secretion of TG-rich very low-density lipoproteins (VLDL), which differ from chylomicrons in that they contain full-length Apo B100. Following secretion into the circulation, VLDL undergo a metabolic process similar to that of chylomicrons. Hydrolysis of VLDL TG releases fatty acids to tissues and converts VLDL into ‘remnant’ particles, referred to as intermediate-density lipoproteins (IDL). Most IDL are rapidly cleared by LDL receptors in the liver, but some are processed by hepatic lipase, which converts the particle to an LDL by removing most materials other than Apo B100, and free and esterified cholesterol.

LDL is a source of cholesterol for cells and tissues (see Fig. 16.14). LDL cholesterol is internalised by receptor-mediated endocytosis via the LDL receptor. Delivery

Fig. 16.14 Absorption, transport and storage of lipids. Pathways of lipid transport are shown; in addition cholesterol ester transfer protein exchanges triglyceride and cholesterol ester between VLDL/chylomicrons and HDL/LDL, and free fatty acids released from peripheral lipolysis can be taken up in the liver. (ABCA1, ABCG1 = ATP-binding cassette A1, G1; Apo = apolipoprotein; BA = bile acids; C = cholesterol; CE = cholesterol ester; FFA = free fatty acids; HDL = mature high-density lipoprotein; iHDL = immature high-density lipoprotein; HL = hepatic lipase; HMGCoAR = hydroxy-methyl-glutaryl-coenzyme A reductase; IDL = intermediate-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor (Apo B100 receptor); LPL = lipoprotein lipase; SRB1 = scavenger receptor B1; TG = triglyceride; VLDL = very low-density lipoprotein)

of cholesterol via this pathway down-regulates further expression of the LDL receptor gene and reduces the synthesis and activity of the rate-limiting enzyme for cholesterol synthesis, HMGCoA reductase. These negative feedback pathways, together with the modulation of cholesterol esterification, control the intracellular free cholesterol level within a narrow range.

Reverse cholesterol transport

Peripheral tissues are further guarded against excessive cholesterol accumulation by high-density lipoproteins (HDL; see Fig. 16.14). Lipid-poor Apo A1 (derived from the liver, intestine and the outer layer of chylomicrons and VLDL) accepts cellular cholesterol and phospholipid from a specific membrane transporter known as the ATP-binding cassette A1 transporter (ABC A1). This produces small HDLs that are able to accept more free cholesterol from cholesterol-rich regions of the cell

membrane via another membrane transporter (ABC G1). The cholesterol that has been accepted by these small HDLs is esterified by lecithin cholesterol acyl transferase (LCAT), thus maintaining an uptake gradient and remodelling the particle into a mature spherical HDL. These HDL release their cholesterol to the liver and other cholesterol-requiring tissues via the scavenger receptor B1 (SRB1).

The cholesterol ester transfer protein (CETP) in plasma allows transfer of cholesterol from HDL or LDL to VLDL or chylomicrons in exchange for TG. When TG is elevated, the action of CETP may reduce HDL cholesterol and remodel LDL into 'small, dense' LDL particles that appear to be more atherogenic in the blood vessel wall. Animal species that lack CETP are resistant to atherosclerosis, suggesting that this process may have a detrimental effect on progression of cardiovascular disease.

Lipids and cardiovascular disease

Plasma lipoprotein levels are major modifiable risk factors for cardiovascular disease. Increased levels of atherogenic lipoproteins (especially LDL, but also IDL, lipoprotein (a) and possibly chylomicron remnants) contribute to the development of atherosclerosis (p. 577). Increased plasma concentration and reduced diameter favour subendothelial accumulation of these lipoproteins. Following chemical modifications such as oxidation, these Apo B-containing lipoproteins are no longer cleared by normal mechanisms. They trigger a self-perpetuating inflammatory response during which they are taken up by macrophages to form foam cells, a hallmark of atherosclerotic lesions. These processes also have an adverse effect on endothelial function.

Conversely, HDL removes cholesterol from the tissues to the liver, where it is metabolised and excreted in bile. HDL may also counteract some components of the inflammatory response, such as the expression of vascular adhesion molecules by the endothelium. Consequently, low HDL cholesterol levels, which are often associated with triglyceride elevation, also predispose to atherosclerosis.

Lipid measurement

Abnormalities of lipid metabolism most commonly come to light following routine blood testing. Measurement of plasma cholesterol alone is not sufficient for comprehensive assessment. Levels of total cholesterol (TC), triglyceride (TG) and HDL cholesterol (HDL-C) need to be obtained after a 12-hour fast to permit accurate calculation of LDL cholesterol (LDL-C) according to the Friedewald formula ($\text{LDL-C} = \text{TC} - \text{HDL-C} - (\text{TG}/2.2) \text{ mmol/L}$). (Before the formula is applied, lipid levels in mg/dL can be converted to mmol/L by dividing by 38 for cholesterol and 88 for triglycerides.) The formula becomes unreliable when TG levels exceed 4 mmol/L (350 mg/dL). However, non-fasting samples are often used to guide therapeutic decisions since they are unaffected in terms of TC and measured LDL-C, albeit that they differ from fasting samples in terms of TG, HDL-C and, to some extent, calculated LDL-C. Consideration must be given to confounding factors, such as recent illness, after which cholesterol levels temporarily decrease in proportion to severity. Results that will affect major decisions, such as initiation of drug therapy, should be confirmed with a repeat measurement.

Elevated TG is common in obesity, diabetes and insulin resistance (Chs 5 and 21), and is frequently associated with low HDL and increased 'small, dense' LDL. Under these circumstances, LDL-C may underestimate risk. This is one situation in which measurement of Apo B may provide additional useful information.

Presenting problems in disorders of lipids

Lipid measurements are usually performed for the following reasons:

- screening for primary or secondary prevention of cardiovascular disease

- investigation of patients with clinical features of lipid disorders (Fig. 16.15)
- testing relatives of patients with one of the single gene defects causing dyslipidaemia.

Aetiology and clinical assessment

The first step is to consider the effect of other diseases and drugs (Box 16.25). Overt or subclinical hypothyroidism (p. 741) may cause hypercholesterolaemia, so measurement of thyroid-stimulating hormone is warranted in most cases, even in the absence of typical symptoms and signs.

16.25 Causes of secondary hyperlipidaemia

Secondary hypercholesterolaemia

Moderately common

- Hypothyroidism
- Pregnancy
- Cholestatic liver disease
- Drugs (diuretics, ciclosporin, corticosteroids, androgens)

Less common

- Nephrotic syndrome
- Anorexia nervosa
- Porphyria
- Hyperparathyroidism

Secondary hypertriglyceridaemia

Common

- Diabetes mellitus (type 2)
- Chronic renal disease
- Abdominal obesity
- Excess alcohol
- Hepatocellular disease
- Drugs (β -blockers, retinoids, corticosteroids)

Once secondary causes are excluded, primary lipid abnormalities may be diagnosed. The Fredrickson classification (types I–V) adds little to clinical decision-making. Alternatively, primary lipid abnormalities can be classified according to the predominant lipid problem: hypercholesterolaemia, hypertriglyceridaemia or mixed hyperlipidaemia (Box 16.26). Although single gene disorders are encountered in all three categories, the most common cause is an interaction between numerous genetic and environmental factors (i.e. 'polygenic'). Clinical consequences of dyslipidaemia vary somewhat between these categories (see Fig. 16.15).

Predominant hypercholesterolaemia

Polygenic hypercholesterolaemia is the most common cause of a mild to moderate increase in LDL-C (see Box 16.26). Physical signs such as corneal arcus and xanthelasma may be found in this as well as other forms of lipid disturbance (see Fig. 16.15). The risk of cardiovascular disease is proportional to the degree of LDL-C elevation, but is modified by other major risk factors, particularly low HDL-C.

Familial hypercholesterolaemia (FH) causes moderate to severe hypercholesterolaemia with a prevalence of at least 0.2% in most populations. It is usually due to an autosomal dominantly inherited mutation of the LDL receptor gene, but a similar syndrome can arise with defects in Apo B100 or a sterol-sensitive protease known as PCSK-9. Most patients with these abnormalities exhibit LDL levels that are approximately twice as high as in unaffected subjects of the same age and gender.

16.26 Classification of hyperlipidaemia

Disease	Elevated lipid results	Elevated lipoprotein	CHD risk	Pancreatitis risk
Predominant hypercholesterolaemia				
Polygenic (majority)	TC \pm TG	LDL \pm VLDL	+	–
Familial hypercholesterolaemia (LDL receptor defect, defective Apo B100, increased function of PCSK-9)	TC \pm TG	LDL \pm VLDL	+++	–
Hyperalphalipoproteinaemia	TC \pm TG	HDL	–	–
Predominant hypertriglyceridaemia				
Polygenic (majority)	TG	VLDL \pm LDL	Variable	+
Lipoprotein lipase deficiency	TG > TC	Chylo	?	+++
Familial hypertriglyceridaemia	TG \pm TC	VLDL \pm Chylo	?	++
Mixed hyperlipidaemia				
Polygenic (majority)	TC + TG	VLDL + LDL	Variable	+
Familial combined hyperlipidaemia*	TC and/or TG	LDL and VLDL	++	+
Dysbetalipoproteinaemia*	TC and/or TG	IDL	+++	+

*Familial combined hyperlipidaemia and dysbetalipoproteinaemia may also present as predominant hypercholesterolaemia or predominant hypertriglyceridaemia. (Chylo = chylomicrons; CHD = coronary heart disease; TC = total cholesterol; TG = triglycerides)

Fig. 16.15 Clinical manifestations of hyperlipidaemia. *Note that xanthelasma and corneal arcus may be non-specific, especially in later life.

Family history reveals that approximately 50% of each generation suffers hypercholesterolaemia, often with very premature cardiovascular disease. FH may be accompanied by xanthomas of the Achilles or extensor digitorum tendons (see Fig. 16.15), which are strongly suggestive of (but not pathognomonic for) FH. The onset of corneal arcus before age 40 is also suggestive of this condition.

In populations in which there is a 'founder gene' effect or consanguineous marriage, homozygous FH occasionally occurs, resulting in more extensive xanthomas and precocious cardiovascular disease in childhood. A recessive form of this condition has also been described recently.

Hyperalphalipoproteinaemia refers to increased levels of HDL-C. In the absence of an increase in LDL-C, this condition does not cause cardiovascular disease, so it should not be regarded as pathological.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypercholesterolaemia (see 'mixed hyperlipidaemia' below).

Predominant hypertriglyceridaemia

Polygenic hypertriglyceridaemia is the most common primary cause of TG elevation (see Box 16.26). It also commonly occurs secondary to excess alcohol, medications, type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of the insulin resistance syndrome (p. 802). It is often accompanied by post-prandial hyperlipidaemia and reduced HDL-C, both of which may contribute to cardiovascular risk. Excessive dietary fat intake or other exacerbating factors may precipitate a massive increase in TG levels, which, if they exceed 10 mmol/L (880 mg/dL), may pose a risk of acute pancreatitis.

Lipoprotein lipase deficiency is an infrequent autosomal recessive disorder due to hereditary deficiency of this enzyme or of its co-factor Apo C2. It causes massive hypertriglyceridaemia that is not amenable to drug treatment. It may commence in childhood and is associated with episodes of acute abdominal pain and pancreatitis. In common with other causes of severe hypertriglyceridaemia, it may result in hepatosplenomegaly, lipaemia retinalis and eruptive xanthomas (see Fig. 16.15).

Familial hypertriglyceridaemia refers to dominant inheritance of pure hypertriglyceridaemia. Some cases may be due to a secondary response to impaired bile acid resorption which may not be associated with increased risk of cardiovascular disease, or deficiency of Apo A5. Familial hypertriglyceridaemia also predisposes to levels of hypertriglyceridaemia that are sufficient to pose a risk of pancreatitis.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypertriglyceridaemia (see 'mixed hyperlipidaemia', below).

Mixed hyperlipidaemia

It is difficult to define quantitatively the distinction between predominant hyperlipidaemias and mixed hyperlipidaemia. The term 'mixed' usually implies the presence of hypertriglyceridaemia as well as an increase in LDL or IDL. Treatment of massive hypertriglyceridaemia may improve TG faster than cholesterol, thus temporarily mimicking mixed hyperlipidaemia.

Primary mixed hyperlipidaemia is usually polygenic and, like predominant hypertriglyceridaemia, often

occurs in association with type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of the insulin resistance syndrome (p. 802). Both components of mixed hyperlipidaemia may contribute to the risk of cardiovascular disease.

Familial combined hyperlipidaemia is a dominantly inherited disorder caused by overproduction of atherogenic Apo B-containing lipoproteins. It results in elevation of cholesterol, TG or both in different family members at different times. It is associated with an increased risk of cardiovascular disease but it does not produce any pathognomonic physical signs. In practice, this relatively common condition is substantially modified by factors such as age and weight. It may not be a monogenic condition, but rather one end of a heterogeneous spectrum that overlaps with the insulin resistance syndrome.

Dysbetalipoproteinaemia (also referred to as type 3 hyperlipidaemia, broad-beta dyslipoproteinaemia or remnant hyperlipidaemia) involves accumulation of roughly equimolar levels of cholesterol and TG. It is caused by homozygous inheritance of the Apo E2 allele, which is the isoform least avidly recognised by the LDL receptor. In conjunction with other exacerbating factors, such as obesity and diabetes, it leads to accumulation of atherogenic IDL and chylomicron remnants. Premature cardiovascular disease is common and it may also result in the formation of palmar xanthomas, tuberous xanthomas or tendon xanthomas.

Rare dyslipidaemias

Several rare disturbances of lipid metabolism have been described (Box 16.27). They provide important insights into lipid metabolism and its impact on risk of cardiovascular disease.

Fish eye disease and Apo A1 Milano demonstrate that very low HDL levels do not necessarily cause cardiovascular disease, but Apo A1 deficiency, Tangier disease and LCAT deficiency demonstrate that low HDL-C can be atherogenic under some circumstances. Sitosterolaemia and cerebrotendinous xanthomatosis demonstrate that sterols other than cholesterol can cause xanthomas and cardiovascular disease, while abetalipoproteinaemia and hypobetalipoproteinaemia suggest that low levels of Apo B-containing lipoproteins reduce the risk of cardiovascular

i 16.27 Miscellaneous and rare forms of hyperlipidaemia

Condition	Lipoprotein pattern	CVD risk
Tangier disease	Very low HDL, low TC	+
Apo A1 deficiency	Very low HDL	++
Apo A1 Milano	Very low HDL	–
Fish eye disease	Very low HDL, high TG	–
LCAT deficiency	Very low HDL, high TG	?
Sitosterolaemia	High plant sterols including sitosterol	+
Cerebrotendinous xanthomatosis	Bile acid defect (cholestanol accumulation)	+

(CVD = cardiovascular disease; HDL = high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; TC = total cholesterol; TG = triglycerides)

disease at the expense of fat-soluble vitamin deficiency, leading to retinal lesions and peripheral neuropathy.

Management of dyslipidaemia

Lipid-lowering therapies have a key role in the secondary and primary prevention of cardiovascular diseases (p. 578). Assessment of absolute risk, treatment of all modifiable risk factors and optimisation of lifestyle, especially diet and exercise, are central to management in all cases.

Patients with the greatest absolute risk of cardiovascular disease will derive the greatest benefit from treatment. Public health organisations recommend thresholds for the introduction of lipid-lowering therapy based on the identification of patients in very high-risk categories, or those calculated to be at high absolute risk according to algorithms or tables such as the Joint British Societies Coronary Risk Prediction Chart (see Fig. 18.61, p. 580). These tables, which are based on large epidemiological studies, should be recalibrated for the local population, if possible. In general, patients who already have cardiovascular disease, diabetes mellitus, chronic renal impairment or an absolute risk of cardiovascular disease of greater than 20% in the ensuing 10 years are arbitrarily regarded as having sufficient risk to justify drug treatment.

Public health organisations also recommend target levels for patients receiving drug treatment. High-risk patients should aim for HDL-C > 1 mmol/L (38 mg/dL) and fasting TG < 2 mmol/L (approximately 180 mg/dL), whilst target levels for LDL-C have been reduced from 2.5 to 2.0 mmol/L (76 mg/dL) or less. In general, total cholesterol should be < 5 mmol/L (190 mg/dL) during treatment, and < 4 mmol/L (approximately 150 mg/dL) in high-risk patients and in secondary prevention of cardiovascular disease.

Non-pharmacological management

Patients with lipid abnormalities should receive medical advice and, if necessary, dietary counselling to:

- reduce intake of saturated and trans-unsaturated fat to less than 7–10% of total energy

- reduce intake of cholesterol to < 250 mg/day
- replace sources of saturated fat and cholesterol with alternative foods such as lean meat, low-fat dairy products, polyunsaturated spreads and low glycaemic index carbohydrates
- reduce energy-dense foods such as fats and soft drinks, whilst increasing activity and exercise to maintain or lose weight
- increase consumption of cardioprotective and nutrient-dense foods such as vegetables, unrefined carbohydrates, fish, pulses, nuts, legumes, fruit etc.
- adjust alcohol consumption, reducing intake if excessive or if associated with hypertension, hypertriglyceridaemia or central obesity
- achieve additional benefits with supplementary intake of foods containing lipid-lowering nutrients such as n-3 fatty acids, dietary fibre and plant sterols.

Response to diet is usually apparent within 3–4 weeks but dietary adjustment may need to be introduced gradually. Although hyperlipidaemia in general, and hypertriglyceridaemia in particular, can be very responsive to these measures, LDL-C reductions are often only modest in routine practice. Explanation, encouragement and persistence are often required to induce patient compliance. Even minor weight loss can substantially reduce cardiovascular risk, especially in centrally obese patients (p. 117).

All other modifiable cardiovascular risk factors should be assessed and treated. If possible, intercurrent drug treatments that adversely affect the lipid profile should be replaced.

Pharmacological management

The main diagnostic categories provide a useful framework for management and the selection of first-line pharmacological treatment (Fig. 16.16).

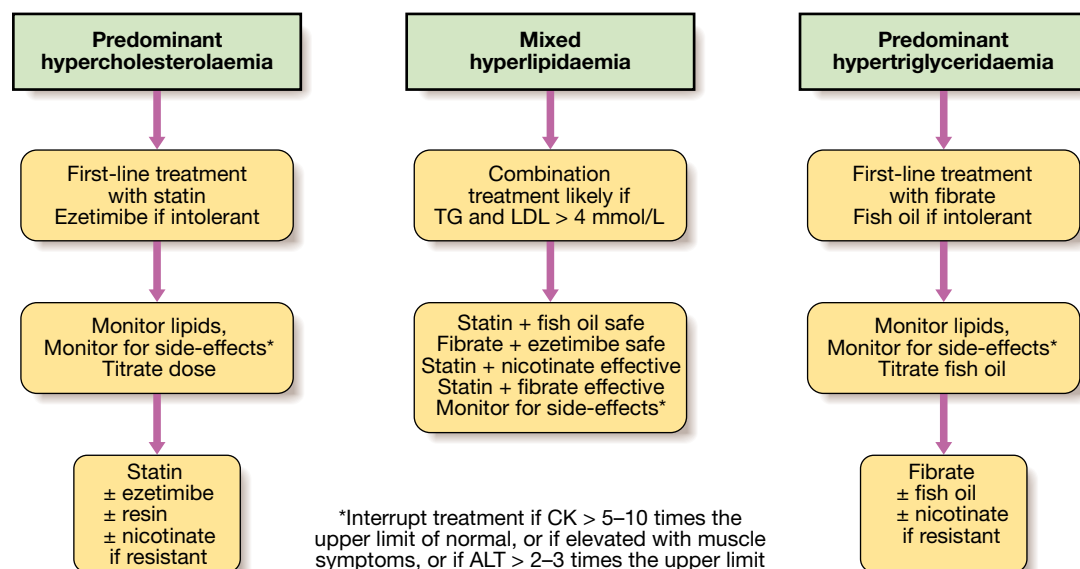

Fig. 16.16 Flow chart for the drug treatment of hyperlipidaemia. To convert TG in mmol/L to mg/dL, multiply by 88. To convert LDL-C in mmol/L to mg/dL, multiply by 38. (ALT = alanine aminotransferase; CK = creatinine kinase)

Predominant hypercholesterolaemia

Predominant hypercholesterolaemia is treated with one or more of the cholesterol-lowering drugs.

HMGCoA reductase inhibitors (statins). Statins inhibit cholesterol synthesis, thereby up-regulating activity of the LDL receptor. This increases clearance of LDL and its precursor, IDL, resulting in a secondary reduction in LDL synthesis. Statins reduce LDL-C by up to 60%, reduce TG by up to 40% and increase HDL-C by up to 10%. They also reduce the concentration of intermediate metabolites such as isoprenes, which may lead to other effects such as suppression of the inflammatory response. There is clear evidence of protection against total and coronary mortality, stroke and cardiovascular events in high-risk patients (Box 16.28).

Statins are generally well tolerated and serious side-effects are rare (well below 2%). Liver function test abnormalities and muscle problems such as myalgia, asymptomatic increase in creatine kinase (CK), myositis and, infrequently, rhabdomyolysis are the most common. Side-effects are more likely in patients who are elderly, debilitated or receiving other drugs that interfere with statin degradation, which usually involves cytochrome P450 3A4 or glucuronidation.

EBM 16.28 Benefits of treating patients with hypercholesterolaemia with statins

'Meta-analysis of major RCTs involving over 90 000 subjects receiving statins for an average of 5 years showed reduced mortality from coronary artery disease, 19% (95% confidence interval 15–24%), stroke, 17% (12–22%) and all causes, 12% (9–16%) per 1 mmol/L reduction in LDL-C.'

• Baigent C, et al. *Lancet* 2005; 366:1267–1278.

Cholesterol absorption inhibitors, such as ezetimibe.

These inhibit the intestinal mucosal transporter NPC1L1 that absorbs dietary and biliary cholesterol. Depletion of hepatic cholesterol up-regulates hepatic LDL receptor activity. This mechanism of action is synergistic with the effect of statins. Monotherapy with the standard 10mg/day dose reduces LDL-C by 15–20%. Slightly greater (17–25%) incremental LDL-C reduction occurs when ezetimibe is added to statins. Ezetimibe is well tolerated, but its effect on cardiovascular disease endpoints is yet to be determined. Plant sterol-supplemented foods, which also reduce cholesterol absorption, lower LDL-C by 7–15%.

Bile acid sequestering resins, such as colestyramine, colestipol and colesevalam. These prevent the reabsorption of bile acids, thereby increasing de novo bile acid synthesis from hepatic cholesterol. As with ezetimibe, the resultant depletion of hepatic cholesterol up-regulates LDL receptor activity and reduces LDL-C in a manner that is synergistic with the action of statins. High doses (24g/day colestyramine) can achieve substantial reductions in LDL-C and modest increases in HDL-C, but TG may rise. Resins are safe, but they may interfere with bioavailability of other drugs. Colesevalam may cause fewer gastrointestinal effects than older preparations. Development of specific inhibitors of the intestinal bile acid transporter may further improve tolerability of this class of agent.

Nicotinic acid (vitamin B3). In pharmacological doses, this reduces peripheral fatty acid release with

the result that cholesterol and TG decline whilst HDL-C increases. Randomised clinical trials suggest a beneficial effect on atherosclerosis and cardiovascular events. Side-effects include flushing, gastric irritation, liver function disturbances, and exacerbation of gout and hyperglycaemia. Slow-release formulations and low-dose aspirin may reduce flushing. Combination therapy with the prostaglandin D2 receptor inhibitor laropiprant to further reduce flushing is being evaluated.

Routine treatment of predominant hypercholesterolaemia generally requires continuation of diet plus the use of a statin in sufficient doses to achieve target LDL-C levels. Patients who do not reach LDL targets on the highest tolerated statin dose, or who are intolerant of statins, may receive ezetimibe, plant sterols, nicotinic acid or resins. Nicotinic acid is very effective in combination with a statin, but caution is required because the risk of side-effects is increased.

Predominant hypertriglyceridaemia

Predominant hypertriglyceridaemia is treated with one of the triglyceride-lowering drugs (see Fig. 16.16).

Fibrates. These stimulate peroxisome proliferator activated receptor (PPAR) alpha, which controls the expression of gene products that mediate the metabolism of triglyceride and HDL. As a result, synthesis of fatty acids, triglyceride and VLDL is reduced, whilst that of lipoprotein lipase, which catabolises TG, is enhanced. In addition, production of Apo A1 and ATP binding cassette A1 is up-regulated, leading to increased reverse cholesterol transport via HDL. Consequently, fibrates reduce TG by up to 50% and increase HDL-C by up to 20%, but LDL-C changes are variable.

Fewer large-scale trials have been conducted with fibrates than with statins and the results are less conclusive, but reduced rates of cardiovascular disease have been reported with fibrate therapy in patients with low HDL-C levels and in subgroups of patients with the clinical picture of insulin resistance (e.g. TG > 2.3 mmol/L (200 mg/dL)). Fibrates are usually well tolerated, but share a similar side-effect profile to statins, including myalgia, myopathy and abnormal liver function tests. In addition, they may increase the risk of cholelithiasis and prolong the action of anticoagulants.

Highly polyunsaturated long-chain n-3 fatty acids. Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) comprise approximately 30% of the fatty acids in fish oil. EPA and DHA are potent inhibitors of VLDL TG formation. Intakes of greater than 2g n-3 fatty acid (equivalent to 6g of most forms of fish oil) per day lower TG in a dose-dependent fashion. Up to 50% reduction in TG may be achieved with 15g fish oil per day. Changes in LDL-C and HDL-C are variable. Fish oil fatty acids have also been shown to inhibit platelet aggregation and improve cardiac arrhythmia in animal models. Dietary and pharmacological trials indicate that n-3 fatty acids reduce mortality from coronary heart disease. Fish oils appear to be safe and well tolerated.

Patients with predominant hypertriglyceridaemia who do not respond to lifestyle intervention can be treated with fibrates, fish oil or nicotinic acid, depending on individual response and tolerance. If target levels are not achieved, the fibrates or nicotinic acid and fish oil can be combined. Massive hypertriglyceridaemia may require more aggressive limitation of dietary fat intake

16.29 Management of hyperlipidaemia in the elderly

- **Prevalence of atherosclerotic cardiovascular disease:** greatest in old age.
- **Associated cardiovascular risk:** lipid levels become less predictive, as do other risk factors apart from age itself.
- **Benefit of statin therapy:** maintained up to the age of 80 years but evidence is lacking beyond this.
- **Life expectancy and statin therapy:** lives saved by intervention are associated with shorter life expectancy than in younger patients, and so the impact of statins on quality-adjusted life years is smaller in old age.

16.30 Dyslipidaemia in pregnancy

- **Lipid metabolism:** lipid and lipoprotein levels increase during pregnancy. This includes an increase in LDL-C which resolves post-partum. Remnant dyslipidaemia and hypertriglyceridaemia may be exacerbated during pregnancy.
- **Treatment:** dyslipidaemia is rarely thought to warrant urgent treatment so pharmacological therapy is usually contraindicated when conception or pregnancy is anticipated. Teratogenicity has been reported with systemically absorbed agents, and non-absorbed agents may interfere with nutrient bioavailability.
- **Monitoring:** cardiovascular disease is very unlikely amongst women of child-bearing age, but is possible in women with severe risk factor profiles or familial hypercholesterolaemia, when pre-conception cardiovascular review can be considered to ensure that the patient will be able to withstand the demands of pregnancy and labour.

(< 10–20% energy as fat). Any degree of insulin deficiency should be corrected because insulin is required for optimal activity of lipoprotein lipase. The initial target for patients with massive hypertriglyceridaemia is TG < 10 mmol/L (880 mg/dL), to reduce the risk of acute pancreatitis.

Mixed hyperlipidaemia

Mixed hyperlipidaemia can be difficult to treat. Statins alone are less effective first-line therapy once fasting TG exceeds around 4 mmol/L (350 mg/dL). Fibrates alone are first-line therapy for dysbetalipoproteinaemia, but they may not control the cholesterol component in other forms of mixed hyperlipidaemia. Combination therapy is often required. Effective combinations include: statin plus fish oil when TG is not too high; fibrate plus ezetimibe; statin plus nicotinic acid; or statin plus fibrate. Fibrates are effective in combination with statins but the risk of myopathy is increased. There is some evidence that fenofibrate is safer than gemfibrozil in this regard.

Monitoring of therapy

The effect of drug therapy can be assessed after 6 weeks (12 weeks for fibrates), and it is prudent to review side-effects, lipid response (see target levels above), CK and liver function tests at this stage. Follow-up should encourage continued compliance (especially diet and

exercise), and include monitoring for side-effects and cardiovascular symptoms or signs, and measurement of weight, blood pressure and lipids, as well as review of absolute cardiovascular disease risk status. Further assessment of CK and liver function tests is required only if relevant symptoms occur, or if statins are used in combination with fibrates, nicotinic acid or other drugs that may interfere with their clearance. If myalgia or weakness is associated with CK elevation > 5–10 times the upper limit of normal, or if sustained alanine aminotransferase (ALT) elevation > 2–3 times the upper limit of normal (and not accounted for by fatty liver, p. 956) is detected, treatment should be interrupted and alternative therapy sought.

DISORDERS OF HAEM METABOLISM—THE PORPHYRIAS

The porphyrias are rare disorders of the haem biosynthetic pathway (Fig. 16.17). Most of the described forms are due to partial enzyme deficiencies with a dominant mode of inheritance and mutations in the relevant genes. They are commonly classified as either hepatic or erythropoietic, depending on whether the major site of excess porphyrin production is in the liver or the red cell.

The porphyrias show a low penetrance in the order of 25%. Environmental factors are important in modifying disease expression in some forms. In the most common of these conditions, porphyria cutanea tarda (PCT), these include alcohol, excess iron, exogenous oestrogens and exposure to various chemicals. Many cases are now associated with hepatitis C infection.

Clinical features

The clinical features of porphyria fall into two broad categories, causes of which are shown in Figure 16.17.

Photosensitive skin manifestations, attributable to excess production and accumulation of porphyrins in the skin, cause pain, erythema, bullae, erosions, hirsutism and hyperpigmentation, and occur predominantly on areas of the skin that are exposed to sunlight (see Fig. 27.6, p. 1250). The skin also becomes especially sensitive to damage from minimal trauma.

The other pattern of presentation is with an acute relapsing and remitting neurological syndrome. This presents invariably with acute abdominal pain together with features of autonomic dysfunction such as tachycardia, hypertension and constipation. Other frequent associations include neuropsychiatric manifestations, hyponatraemia due to inappropriate ADH release (p. 436), and acute neuropathy (p. 1225), which is usually motor and sometimes causes respiratory failure.

There is no proven explanation for the episodic pattern of these attacks. However, they are often precipitated by alcohol, fasting, or drugs such as anticonvulsants, sulphonamides, oestrogen and progesterone, especially the oral contraceptive pill. In a significant number of cases, no precipitant can be identified.

Diagnosis

The diagnosis of porphyria and categorisation into various forms have traditionally relied on the pattern of the porphyrins and porphyrin precursors found in blood, urine and faeces (Box 16.31). This is straightforward

Fig. 16.17 Haem biosynthetic pathway and enzyme defects responsible for the porphyrias. (N = neurovisceral; P = photosensitive)

ward when the metabolites are significantly elevated, but this is not always the case.

More recently, measurement of the enzymes that are deficient in the various porphyrias has provided further important diagnostic information (e.g. PBG deaminase activity in red blood cells to diagnose acute intermittent porphyria). However, there is often considerable overlap between enzyme activities in normal and abnormal populations. Furthermore, some of the enzymes occur in the cell mitochondria, for which it is more difficult to obtain suitable specimens for analysis.

All the genes of the haem biosynthetic pathway have now been characterised. This has made it possible to identify affected individuals in families with known mutations, a significant advance considering that penetrance of porphyria is low and the majority of attacks do not occur without an identified precipitant. At this time, well over 150 mutations have been found to cause acute intermittent porphyria alone.

In the clinical situation if there are active cutaneous manifestations of porphyria, or when a subject pres-

ents in an acute attack, metabolite excretory patterns are always grossly abnormal and diagnostic of the particular porphyria. A normal metabolite profile in this circumstance effectively excludes porphyria. Furthermore, metabolites usually remain abnormal for long periods after an acute attack, and in some individuals never return to normal. The diagnosis may not be so straightforward in patients in remission, and investigation can be very difficult in patients with a positive family history but no clinical or metabolite manifestations. Porphyria rarely manifests before puberty, nor can it be readily diagnosed from metabolite patterns after menopause. In those circumstances, demonstration of a disease-specific mutation can now clarify the situation.

Management

For patients predisposed to neurovisceral attacks, general management includes avoidance of any agents known to precipitate acute porphyria. Specific management includes intravenous glucose, as provision of 5000 kilojoules per day can terminate acute attacks

16.31 Diagnostic biochemical findings in the porphyrias

Condition	Elevated porphyrins and precursors		
	Blood	Urine	Faeces
ALA dehydratase deficiency (plumboporphyria)	Proto IX*	ALA, Copro III*	
Acute intermittent porphyria (AIP)		ALA, PBG	
Congenital erythropoietic porphyria (CEP)	Uro I	Uro I	Copro I
Porphyria cutanea tarda (PCT)		Uro I	Isocopro
Hereditary coproporphyria (HCP)		ALA, PBG, Copro III	Copro III
Variegate porphyria (VP)		ALA, PBG, Copro III	Proto IX
Erythropoietic protoporphyria (EPP)	Proto IX		Proto IX

*The paradoxical rise in coproporphyrin III (Copro III) and protoporphyrin (Proto) in this very rare condition is poorly understood. Refer to Figure 16.17 for metabolic pathways.
