through a reduction in ALA synthetase activity. More recently, administration of haem (in various forms such as haematin or haem arginate) has been shown to reduce metabolite excretory rates, relieve pain and accelerate recovery. Cyclical acute attacks in women sometimes respond to suppression of the menstrual cycle using gonadotrophin-releasing hormone analogues.

There are few specific or effective measures to treat the photosensitive manifestations. The primary goal is to avoid sun exposure and skin trauma. Barrier sun creams containing zinc or titanium oxide are the most effective products. New colourless zinc creams have improved patient acceptance. Beta-carotene is used in some patients with erythropoietic porphyria with some efficacy. In porphyria cutanea tarda, a course of venesections to remove iron can result in long-lasting clinical and biochemical remission, especially if exposure to identified precipitants such as alcohol or oestrogens

is reduced. Alternatively, a prolonged course of chloroquine therapy may be effective.

Drugs and the kidney 519

Diseases of the kidneys and urinary tract are often clinically 'silent' and may be detected by biochemical testing, e.g. measurement of plasma creatinine or testing of urine. Severe renal disease may present with non-specific symptoms, e.g. tiredness or breathlessness due to renal failure and associated anaemia, or oedema due to fluid retention. In end-stage kidney disease, a wide range of physical signs may be present, as seen opposite.

Cardinal features of kidney and urinary tract disease

Lower urinary tract symptoms

- *Dysuria, frequency, urgency*: lower urinary tract infection
- *Impaired urinary flow, hesitancy, dribbling of urine, incomplete emptying of bladder*: bladder outflow obstruction
- *Urinary retention, incontinence/enuresis*: sphincter or bladder wall dysfunction

Upper urinary tract symptoms

- *Loin pain/tenderness*: renal infection, renal infarction or rarely obstruction and glomerulonephritis
- *Severe loin pain (renal or ureteric colic) ± radiation to iliac fossa, groin and genitalia*: acute obstruction of the renal pelvis and ureter by calculus or blood clot

Abnormal urine volume

- *Anuria or oliguria*: acute renal failure or obstruction to urine flow
- *Polyuria or nocturia*: failure to concentrate urine (e.g. diabetes insipidus, chronic kidney disease)

Abnormal urinary constituents

- *Proteinuria*: suggests glomerular disease; massive proteinuria causes oedema
- *Haematuria*: disease anywhere in the urinary tract

Hypertension

- Acute or chronic parenchymal disease or renovascular disease

Uraemia

- A group of symptoms and signs of advanced kidney disease

Diseases of the testes and epididymis

- Local swelling, pain and tenderness sometimes causing abdominal pain, inflammation and torsion

8 Abdomen

Technique for palpating the kidneys

- Lie the patient flat with abdominal muscles relaxed
- Place one hand posteriorly just below the lower ribs and the other anteriorly over the upper quadrant
- Push the hands towards each other as the patient breathes out; feel for the lower pole of the kidney moving down between the hands as the patient breathes in
- To confirm a palpable kidney, push the kidney backwards and forwards between the hands ('ballotting')
- Assess the size, surface and consistency of a palpable kidney; e.g. polycystic kidneys are often massively enlarged with an irregular, nodular surface

Possible findings

- Normal findings: the right kidney and lower pole of the left kidney may be palpable in normal slim adults
- Enlarged kidneys: polycystic kidney disease, hydronephrosis/pyonephrosis, solitary cyst, compensatory hypertrophy in a single kidney, renal tumours and renal amyloid
- Tender kidneys: may reflect infection or inflammation
- Transplanted kidney: palpable in the iliac fossa, with an overlying scar
- Distended bladder: smooth midline mass arising from the pelvis, dull to percussion
- Arterial bruits: on either side of the epigastrium, may indicate renal artery stenosis
- Testicular mass
- Prostate enlargement on rectal examination: benign enlargement is characteristically smooth and regular; an enlarged, hard, irregular prostate suggests prostatic cancer

14 Urine microscopy

Urine microscopy. **A** Phase contrast images of red blood cells ($\times 400$) showing on the right glomerular bleeding with many dysmorphic forms including acanthocytes (teardrop forms), and on the left bleeding from lower in the urinary tract. **B** On the left, phase contrast images show hyaline casts, a normal feature of urine ($\times 160$). On the right, numerous red cells and a large red cell cast in acute glomerular inflammation ($\times 100$, not phase contrast).

Renal medicine ranges from the management of common conditions (e.g. urinary tract infection) to the use of complex technology to replace renal function (e.g. dialysis and transplantation). There are close links with the surgical specialties of urology and transplantation. This chapter describes the common disorders of the kidneys and urinary tract which are encountered in everyday practice, as well as giving an overview of the highly specialised field of renal replacement therapy. Selective disorders of renal tubular function, which cause alterations in electrolyte and acid-base balance, are described in Chapter 16.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Functions of the kidneys

The kidneys are largely responsible for regulating the volume and composition of body fluids. This is achieved by making large volumes of an ultrafiltrate of plasma (120 mL/min, 170 L/day) at the glomerulus, and selectively reabsorbing components of this ultrafiltrate at points along the nephron. The rates of filtration and reabsorption are controlled by many hormonal and haemodynamic signals.

The kidney is primarily responsible for excretion of many metabolic breakdown products (including ammonia, urea and creatinine from protein, and uric acid from nucleic acids), drugs and toxins. These metabolites either are not reabsorbed from the filtrate, or are actively secreted into it.

In addition, the kidney has a number of hormonal functions. Three of these are particularly important:

- Erythropoietin is produced by interstitial peritubular cells in response to hypoxia. Replacement of erythropoietin reverses the anaemia of chronic kidney disease (p. 490).
- In vitamin D metabolism, the kidneys hydroxylate 25-hydroxycholecalciferol to the active form, 1,25-dihydroxycholecalciferol. Failure of this process contributes to the hypocalcaemia and bone disease of chronic kidney disease (p. 490).
- Renin is secreted from the juxtaglomerular apparatus in response to reduced afferent arteriolar pressure, stimulation of sympathetic nerves, and changes in sodium content of fluid in the distal convoluted tubule at the macula densa. Renin generates angiotensin II (see Fig. 20.19, p. 769), which causes aldosterone release from the adrenal cortex, constricts the efferent arteriole of the glomerulus and thereby increases glomerular filtration pressure (Fig. 17.1D). Angiotensin II also induces systemic vasoconstriction. By these mechanisms, the kidneys 'defend' circulating blood volume, blood pressure and glomerular filtration during circulatory shock. However, the same mechanisms lead to systemic hypertension in renal ischaemia.

Anatomy of the kidneys

Adult kidneys are 11–14 cm (three lumbar vertebral bodies) in length, and are located retroperitoneally on either side of the aorta and inferior vena cava. The right kidney is usually a few centimetres lower because the liver lies above it. Both kidneys rise and descend several centimetres with respiration.

Each kidney contains approximately 1 million functional units, or 'nephrons'. These consist of the glomerulus (where filtration of plasma occurs), proximal convoluted tubule, loop of Henle and distal convoluted tubule (where selective reabsorption of fluid and solutes from the filtrate occurs), and the collecting duct (see Fig. 16.2, p. 428). Of the daily filtrate of over 150 L, typically 99% is reabsorbed in the tubules. The collecting ducts of multiple nephrons drain into the renal pelvis and ureter (Fig. 17.1B). There is a rich blood supply (20–25% of cardiac output). Intralobular branches of the renal artery give rise to the glomerular afferent arterioles which supply the capillaries within the glomerulus. The efferent arteriole, leading from the glomerulus, supplies the distal nephron and medulla in a 'portal' circulation.

Glomeruli

Filtration occurs across the glomerular basement membrane (GBM), produced by fusion of the basement membranes of epithelial and endothelial cells (Fig. 17.1D). The glomerular capillary endothelial cells contain pores (fenestrae) which allow access of circulating molecules to the underlying GBM. On the outer side of the GBM, glomerular epithelial cells (podocytes) put out multiple long foot processes which interdigitate with those of adjacent epithelial cells (Fig. 17.1E). As well as maintaining the filtration barrier, podocytes are involved in the regulation of filtration and of GBM turnover. The third cell type, mesangial cells, lie in the central region of the glomerulus. They have similarities to vascular smooth muscle cells (e.g. contractility), but also some macrophage-like properties.

The filtration barrier at the glomerulus is normally almost absolute to proteins the size of albumin (67 kDa) or larger, while proteins of 20 kDa or smaller are able to filter freely. Between these sizes the ability of individual molecules to cross the GBM varies, e.g. according to charge. Little lipid is filtered.

Filtration pressure at the GBM is controlled by afferent and efferent arteriolar tone. Autoregulation maintains a constant glomerular filtration rate (GFR) by altering arteriolar tone over a wide range of systemic blood pressure and renal perfusion pressure. In response to a reduction in perfusion pressure, angiotensin II mediates constriction of the efferent arteriole, which restores filtration pressure as above.

Tubules and interstitium

Tubular cells are polarised, with a brush border (proximal tubular cells) and specialised functions at both basal and apical surfaces. As described on pages 428–429, different parts of the tubule serve distinct functions and carry a specific complement of transporter, channel and receptor molecules. Interstitial cells between tubules are less well understood. Fibroblast-like cells in the cortex produce erythropoietin in response to hypoxia.

Collecting system and lower urinary tract

The key functions of this part of the urinary system (Fig. 17.2) are to allow free passage of urine to the bladder, and to store urine in the bladder for controlled voiding (i.e. to maintain urinary continence).

Fig. 17.1 Functional anatomy of the kidney. **A** Anatomical relationships of the kidney. **B** A single nephron. For the functions of different segments, see Figures 16.2 and 16.3 (pp. 428–429). **C** Histology of a normal glomerulus. **D** Schematic cross-section of a glomerulus showing five capillary loops, to illustrate structure and show cell types. **E** Electron micrograph of the filtration barrier. (GBM = glomerular basement membrane)

Fig. 17.2 Endoscopic views of the male urinary tract.

Mechanisms of micturition and urinary continence

Continence is dependent on anatomical structures (see Fig. 17.2) and on neurological and muscle (sphincter and detrusor) function. Parasympathetic nerves arising from S2–4 stimulate detrusor contraction, resulting in micturition. Sympathetic nerves arising from T10–L2 relay in the pelvic ganglia and produce detrusor relaxation and contraction of the bladder neck (both via α -adrenoceptors). The distal sphincter mechanism is innervated by somatic motor fibres from sacral segments S2–4 which reach the sphincter either by the pelvic plexus or via the pudendal nerves. Afferent sensory impulses pass to the cerebral cortex, from where reflex-increased sphincter tone and associated suppression of detrusor contraction inhibit micturition until it is appropriate.

These factors operate in a coordinated fashion in the micturition cycle, which has a 'storage' (or 'filling') phase and a 'voiding' (or 'micturition') phase (see Fig. 17.11, p. 476). During the filling phase, the high compliance of the detrusor muscle allows the bladder to fill steadily without a rise in intravesical pressure. As bladder volume increases, stretch receptors in its wall cause reflex bladder relaxation and increased sphincter tone. At approximately 75% bladder capacity there is a desire to void. Voluntary control is now exerted over the desire to void, which disappears temporarily. Compliance of the detrusor allows further increase in capacity until the next desire to void. Just how often this desire needs to be inhibited depends on many factors, not the least of which is finding a suitable place in which to void.

The act of micturition is initiated first by voluntary and then by reflex relaxation of the pelvic floor and distal sphincter mechanism, followed by reflex detrusor contraction. These actions are coordinated by the pontine micturition centre. Intravesical pressure remains greater than urethral pressure until the bladder is empty.

Erectile function

Blood inflow into the corpus cavernosum of the penis is under tonic sympathetic control via nerves from the thoracolumbar plexus which maintain smooth muscle contraction. In response to afferent input from the glans penis and from higher centres, pelvic splanchnic parasympathetic nerves actively relax the cavernosal smooth muscle via neurotransmitters such as nitric oxide, acetylcholine, vasoactive intestinal polypeptide (VIP) and prostacyclin, with consequent dilatation of the lacunar space. At the same time, draining venules are compressed, and possibly actively constricted, trapping blood in the lacunar space with consequent elevation of pressure and tumescence of the penis.

Prostate function

Exocrine glands within the prostate produce fluid which comprises about 20% of the volume of ejaculated seminal fluid and is rich in lipids and phospholipids. Seminal vesicle secretions account for about 60% and contain fructose and prostaglandins. The remainder of the ejaculate is formed in the testes.

Smooth muscle fibres within the prostate, under sympathetic control, contract at orgasm to move seminal fluid via ejaculatory ducts into the bulbar urethra (emission). Contraction of the bulbocavernosus muscle (via a spinal muscle reflex) then ejaculates the semen out of the urethra. These smooth muscle fibres can also effect some control over urine flow through the bulbar urethra.

INVESTIGATION OF RENAL AND URINARY TRACT DISEASE

Tests of function

Glomerular filtration rate (GFR)

GFR is the rate at which fluid passes into nephrons after filtration and measures renal excretory function. GFR is proportionate to body size so the reference range is usually expressed after correction for body surface area as $120 \pm 25 \text{ mL/min/1.73 m}^2$. Direct measurement of GFR (Box 17.1) by injecting and measuring the clearance of compounds that are completely filtered and not reabsorbed by the nephron (inulin, radiolabelled ethylenediamine-tetraacetic acid (EDTA)) is inconvenient and is usually reserved for special circumstances (e.g. for potential live kidney donors).

Serum levels of endogenous compounds excreted by the kidney give useful information. Blood urea is not the best test, as it increases with high protein intake (including absorption of blood from the gut after a gastrointestinal haemorrhage) and in catabolic states, and is reduced in liver failure (low production from protein) and anorexia or malnutrition (low protein intake). Furthermore, tubular reabsorption of urea is increased when concentrated urine is produced, elevating blood levels. However, variations in blood urea can be useful when combined with other estimates of renal function.

Serum creatinine reflects GFR more reliably than urea, as it is produced from muscle at a constant rate and almost completely filtered at the glomerulus. If muscle mass remains constant, changes in creatinine concentration reflect changes in GFR (Fig. 17.3). However, the reference range for creatinine values is wide because of variations in muscle mass; in patients with low muscle mass (e.g. the elderly) serum creatinine may not be above the reference range until GFR is reduced by > 50%.

A more accurate measurement of GFR can be obtained by creatinine clearance measurements, in which serum level is related to 24-hour urinary creatinine excretion, but 24-hour urine collections are difficult and often inaccurate. Alternatively, equations that estimate creatinine clearance or GFR from serum creatinine are available (see Box 17.1). The MDRD equation has now become the accepted standard for 'estimated GFR' (eGFR). Although eGFR has important limitations (Box 17.2), its routine reporting by laboratories has enhanced recognition of moderate kidney damage, encouraged early deployment of protective therapies, and facilitated widespread adoption of the staging of chronic kidney disease (CKD), as shown in Box 17.3. This CKD staging recognises lesser degrees of renal damage than would previously have been labelled chronic renal failure (CRF). However, the advanced stages

Fig. 17.3 Serum creatinine and the glomerular filtration rate (GFR). The inverse reciprocal relationship between GFR and serum creatinine is shown for a group of patients with renal disease. The red band indicates the range of values obtained. Note that some individuals have a GFR as low as 30–40 mL/min without serum creatinine rising out of the reference range.

of CKD are still often referred to as CRF despite the wide acceptance of CKD stages and terminology.

Urinalysis

Examination of an aliquot of urine provides important information on kidney function. Dipsticks may be used to screen for blood and protein semi-quantitatively (p. 479). Urine microscopy (p. 461) can detect red cells of glomerular origin and red cell casts, indicative of intrinsic renal disease. Flow cytometry can also be used to screen for white blood cells and bacteria. Crystals

17.1 How to estimate glomerular filtration rate (GFR)

Measuring GFR

- Direct measurement using labelled EDTA or inulin
- Creatinine clearance (CrCl)
 - Minor tubular secretion of creatinine causes CrCl to exaggerate GFR when renal function is poor, and can be affected by drugs (e.g. trimethoprim, cimetidine)
 - Needs 24-hr urine collection (inconvenient and often unreliable)

$$\text{CrCl (mL/min)} = \frac{\text{urine creatinine concentration } (\mu\text{mol/L}) \times \text{volume (mL)}}{\text{plasma creatinine concentration } (\mu\text{mol/L}) \times \text{time (min)}}$$

Estimating GFR with equations

- Cockcroft and Gault (C&G) equation
 - Reasonably accurate at normal to moderately impaired renal function
 - Estimates CrCl, not GFR
 - Requires patient weight
$$\text{CrCl (C\&G)} = \frac{(140 - \text{age in yrs}) \times \text{lean body weight (kg)} \times (1.22 \text{ males or } 1.04 \text{ females})}{\text{serum creatinine } (\mu\text{mol/L})}$$
- The Modification of Diet in Renal Disease (MDRD) study equation (see www.renal.org/eGFR)
 - Performs better than C&G at reduced GFR
 - Requires knowledge of age and sex only
 - Can be reported automatically by laboratories
 - For limitations, see Box 17.2
$$\text{eGFR} = 186 \times (\text{creatinine in } \mu\text{mol/L}/88.4)^{-1.154} \times (\text{age in yrs})^{-0.203} \times (0.742 \text{ if female}) \times (1.21 \text{ if black})$$
- No equations perform well in unusual circumstances, such as extremes of body (and muscle) mass, or in acutely unwell patients (see Box 17.2)

*A correction factor, either a value recommended by the laboratory/assay manufacturer or a default value of 186; see www.renal.org/ckd. To convert creatinine in mg/dL to $\mu\text{mol/L}$, multiply by 88.4.

17.2 Limitations of eGFR

- It is only an estimate, least reliable at extremes of body composition (e.g. malnourished, amputees etc.) and in hospital inpatients (as it was derived from outpatients)
- Confidence intervals are wide (e.g. 90% of patients will have eGFR within 30% of their measured GFR, and 98% within 50%)
- Values are consistent in individuals, so changes mean more than absolute values
- Creatinine level must be stable over days; eGFR is not valid in assessing acute renal failure
- It tends to underestimate normal or near-normal function, so slightly low values should not be over-interpreted. Many laboratories report only up to > 60 mL/min/1.73 m² for this reason
- In the elderly, who constitute the majority of those with low eGFR, there is controversy about categorising people as having chronic kidney disease (CKD; Box 17.3) on the basis of eGFR alone, particularly at stage 3A, since there is little evidence of adverse outcomes when eGFR is > 50 unless there is also proteinuria
- eGFR is not valid in under-18s or during pregnancy
- The equation was originally validated in US patients and eGFR for any given creatinine was 21% higher in blacks. Performance in other racial groups is under investigation

i

17.3 Stages of chronic kidney disease (CKD)

Stage ¹	Definition ²	Description	Prevalence ³	Clinical presentation ⁴
1	Kidney damage with normal or high GFR (> 90)	Mild CKD	6.5%	Asymptomatic
2	Kidney damage and GFR 60–89			
3A ⁵ 3B ⁵	GFR 45–59 GFR 30–44	Moderate CKD	4.5%	Usually asymptomatic Anaemia in some patients at 3B Most are non-progressive or progress very slowly
4	GFR 15–29	Severe CKD	0.4%	First symptoms often at GFR < 20 Electrolyte problems likely as GFR falls
5	GFR < 15 or on dialysis	Kidney failure		Significant symptoms and complications usually present Dialysis initiation varies but usually at GFR < 10

¹ Stages of CKD 1–5 were originally defined by the US National Kidney Foundation Kidney Disease Quality Outcomes Initiative 2002.
² Kidney damage means pathological abnormalities or markers of damage, including abnormalities in urine tests or imaging studies. Two GFR values 3 mths apart are required to assign a stage. All GFR values are mL/min/1.73 m².
³ From the NHANES III study of > 15 000 US adults (Am J Kid Dis 2003; 41:1–12).
⁴ For further information, see page 487.
⁵ 3A/3B split recommended for UK in 2007/8, plus a suffix indicating presence of proteinuria (Albumin:creatinine ratio (ACR) > 30 or protein:creatinine ratio (PCR) > 50 mg/mmol), e.g. 3Ap, in view of the prognostic importance of proteinuria.

(e.g. of calcium oxalate, cysteine or urate) may be seen in renal calculus disease, although calcium oxalate and urate crystals are also sometimes found in normal urine that has been left to stand. Urine pH can provide diagnostic information in the assessment of renal tubular acidosis (p. 444), and a persistently low specific gravity may be found in diabetes insipidus (p. 792).

Timed (usually 24-hour) urine collections are now used less often to measure GFR or protein excretion (p. 480), but are still required to measure excretion rates of sodium and of solutes that can form renal calculi such as calcium, oxalate and urate (p. 510).

Other dynamic tests of tubular function, including concentrating ability (p. 792), ability to excrete a water load (p. 436) and ability to excrete acid (p. 426), are valuable in some circumstances.

Simple measurement of tubular excretory function can be made by comparison of blood and urine ratios of electrolytes to creatinine. Fractional excretion of sodium

(= urinary Na/plasma Na × plasma creatinine/urine creatinine) is reduced in volume depletion when the tubules are avidly conserving sodium, and increased in the tubular damage associated with acute tubular necrosis.

Imaging techniques

Plain X-rays may show the renal outlines (if perinephric fat and bowel gas shadows permit), opaque calculi and calcification within the renal tract.

Ultrasound

This quick, non-invasive technique is the first and often the only method required for renal imaging. It can show renal size and position, detect dilatation of the collecting system (suggesting obstruction, Fig. 17.4), distinguish tumours and cysts, and show other abdominal, pelvic and retroperitoneal pathology. In addition, it can image the prostate and bladder, and estimate completeness

Fig. 17.4 Renal ultrasound. [A] Normal kidney. The normal cortex is less echo-dense (blackier) than the adjacent liver. [B] A simple cyst occupies the upper pole of an otherwise normal kidney. [C] The renal pelvis and calyces are dilated by a chronic obstruction to urinary outflow. The thinness and increased density of the remaining renal cortex indicate chronic changes.

Fig. 17.5 Intravenous urography (IVU). [A] Normal nephrogram phase at 1 minute. [B] Normal collecting system at 5 minutes. [C] Bilateral reflux nephropathy (and chronic pyelonephritis) showing clubbing of the calyces which is particularly marked in the upper right pole.

of emptying in suspected bladder outflow obstruction. In CKD ultrasonographic density of the renal cortex is increased and corticomedullary differentiation is lost.

Doppler techniques can show blood flow in extra-renal and larger intrarenal vessels. The resistivity index is the ratio of peak systolic and diastolic velocities, and is influenced by the resistance to flow through small intrarenal arteries. It may be elevated in various diseases, including acute glomerulonephritis and rejection of a renal transplant. High peak velocities can also occur in severe renal artery stenosis.

However, renal ultrasound is operator-dependent, its stored images convey only a fraction of the information gained during the investigation, and it is often less clear in obese patients.

Intravenous urography (IVU)

While intravenous urography has been largely replaced by ultrasound and/or CT urography for routine renal imaging, the technique provides excellent definition of the collecting system and ureters, and remains superior to ultrasound for examining renal papillae, stones and urothelial malignancy (Fig. 17.5). X-rays are taken at intervals following administration of an intravenous bolus of an iodine-containing compound that is excreted by the kidney. An early image (1 minute after injection) demonstrates the nephrogram phase of renal perfusion in patients with an adequate renal arterial supply. This is followed by contrast filling the collecting system, ureters and bladder. The disadvantages of this technique are the need for an injection, time requirement, dependence on adequate renal function, and exposure to irradiation and contrast medium (Box 17.4).

Pyelography

Pyelography involves direct injection of contrast medium into the collecting system from above or below. It offers the best views of the collecting system and upper tract, and is commonly used to identify the cause of urinary tract obstruction (p. 475). Antegrade pyelography requires the insertion of a fine needle into the pelvicalyceal system under ultrasound or radiographic control. This approach is much more difficult and hazardous in a non-obstructed kidney. In the presence of

17.4 Renal complications of radiological investigations

Contrast nephrotoxicity

- An acute deterioration in renal function, sometimes life-threatening, commencing < 48 hrs after administration of i.v. radiographic contrast media

Risk factors

- Pre-existing renal impairment
- Use of high-osmolality, ionic contrast media and repetitive dosing in short time periods
- Diabetes mellitus
- Myeloma

Prevention

- Hydration, e.g. free oral fluids plus i.v. isotonic saline 500 mL then 250 mL/hr during procedure
- Avoid nephrotoxic drugs; withhold non-steroidal anti-inflammatory drugs (NSAIDs). Omit metformin for 48 hrs after procedure in case renal impairment occurs
- *N*-acetyl cysteine may provide weak additional protection (Box 17.5)
- If the risks are high, consider alternative methods of imaging

Cholesterol atheroembolism

- Typically follows days to weeks after intra-arterial investigations or interventions (p. 499)

Nephrogenic sclerosing fibrosis after MRI contrast agents

- Chronic progressive sclerosis of skin, deeper tissues and other organs, associated with gadolinium-based contrast agents
- Only reported in patients with renal impairment, typically on dialysis or with GFR < 15 mL/min/1.73m², but caution is advised in patients with GFR < 30 mL/min/1.73m²

EBM

17.5 *N*-acetylcysteine and radiocontrast-induced nephropathy

'Despite multiple randomised controlled trials and meta-analyses, the issue of whether *N*-acetylcysteine can prevent radiocontrast-induced nephropathy is still not resolved.'

- Bagshaw SM. Arch Int Med 2006; 166(2):161–166.

Fig. 17.6 Retrograde pyelography. The best views of the normal collecting system are shown by pyelography. A catheter has been passed into the left renal pelvis at cystoscopy. The anemone-like calyces are sharp-edged and normal. (Compare with the obstructed system shown in Fig. 17.9.)

obstruction, percutaneous nephrostomy drainage can be established, and often stents can be passed through any obstruction. Retrograde pyelography can be performed by inserting catheters into the ureteric orifices at cystoscopy (Fig. 17.6).

Renal arteriography and venography

The main indication for renal arteriography is to investigate suspected renal artery stenosis (p. 496) or haemorrhage. Therapeutic balloon dilatation and stenting of the renal artery may be undertaken, and bleeding vessels or arteriovenous fistulae occluded.

Computed tomography (CT)

CT is particularly useful for characterising mass lesions within the kidney (see Fig. 17.38A, p. 514), or combinations of cysts with masses. It gives clear definition of retroperitoneal anatomy regardless of obesity. Even without contrast medium it is better than IVU for demonstrating renal stones. In CT urography, after a first scan without contrast, scans are repeated during nephrogram and excretory phases. This gives more information but entails a substantially larger radiation dose than IVU.

CT arteriograms are reconstructed using a rapid-sequence technique in which images are obtained immediately following a large bolus injection of intravenous contrast medium. This produces high-quality images of the main renal vessels and is of value in trauma, renal haemorrhage and the investigation of possible renal artery stenosis. The speed of image acquisition also enables functional assessment and enhancement of vascular structures, e.g. angiomyolipomas. However, relatively large doses of contrast medium (see Box 17.4) are required.

Magnetic resonance imaging (MRI)

MRI offers excellent resolution and distinction between different tissues (see Fig. 17.32, p. 507). Magnetic resonance angiography (MRA) uses gadolinium-based contrast media, which may carry risks for patients with very low GFR (see Box 17.4). MRA can produce good images of main renal vessels but may miss branch artery stenoses.

Other tests

Radionuclide studies

These are functional studies requiring the injection of gamma ray-emitting radiopharmaceuticals which are taken up and excreted by the kidney, a process which can be monitored by an external gamma camera.

Diethylenetriamine-pentaacetic acid labelled with technetium (^{99m}Tc -DTPA) is excreted by glomerular filtration. DTPA injection and analysis of uptake and excretion provides information regarding the arterial perfusion of each kidney. Delayed peak activity and reduced excretion is seen in renal artery stenosis but the test is insufficiently reliable to use as a screening technique. In patients with significant obstruction of the outflow tract, DTPA persists in the renal pelvis (see Fig. 17.9, p. 473), and a loop diuretic fails to accelerate its disappearance. This can be useful in determining the functional significance of a 'baggy' or equivocally obstructed collecting system without undertaking pyelography.

Dimercaptosuccinic acid labelled with technetium (^{99m}Tc -DMSA) is filtered by glomeruli and partially bound to proximal tubular cells. Following intravenous injection, images of the renal cortex show the shape, size and relative function of each kidney (Fig. 17.7). This is a sensitive method for showing cortical scarring that is of particular value in children with vesico-ureteric reflux and pyelonephritis.

Fig. 17.7 DMSA isotope renogram. A posterior view is shown of a normal left kidney and a small right kidney (with evidence of cortical scarring at upper and lower poles) that contributes only 39% of total renal function.

Renal biopsy

Renal biopsy is used to establish the nature and extent of renal disease in order to judge the prognosis and need for treatment (Box 17.6). The procedure is performed transcutaneously with ultrasound or contrast radiography

17.6 Renal biopsy

Indications

- Acute renal failure that is not adequately explained
- CKD with normal-sized kidneys
- Nephrotic syndrome or glomerular proteinuria in adults
- Nephrotic syndrome in children that has atypical features or is not responding to treatment
- Isolated haematuria or proteinuria with renal characteristics or associated abnormalities

Contraindications

- Disordered coagulation or thrombocytopenia. Aspirin and other antiplatelet agents increase bleeding risk
- Uncontrolled hypertension
- Kidneys < 60% predicted size
- Solitary kidney (except transplants) (relative contraindication)

Complications

- Pain, usually mild
- Bleeding into urine, usually minor but may produce clot colic and obstruction
- Bleeding around the kidney, occasionally massive and requiring angiography with intervention, or surgery
- Arteriovenous fistula, rarely significant clinically

guidance to ensure accurate needle placement into a renal pole. Light microscopy, electron microscopy and immunohistological assessment of the specimen may all be required.

PRESENTING PROBLEMS IN RENAL AND URINARY TRACT DISEASE

The broad categories of renal and urinary tract disease, and their typical manifestations, are shown in Figure 17.8. It is convenient to divide these into pre-renal, renal and post-renal disorders.

Urinary tract infection (UTI)

In health, bacterial colonisation is confined to the lower end of the urethra and the remainder of the urinary tract is sterile (see Ch. 6). UTI is the most common bacterial infection managed in general medical practice and accounts for 1–3% of consultations. Up to 50% of women have a UTI at some time. The prevalence of UTI in women is about 3% at the age of 20, increasing by about 1% in each subsequent decade. In males UTI is uncommon, except in the first year of life and in men over 60, in

PRE-RENAL

Effects of pre-renal conditions

Loss of renal function, e.g. from hypoperfusion
Effects on other organs, e.g. 'shock' liver

Renal vasculature

Hypertension
Loss of renal function

RENAL

Glomerular disorders

Haematuria
Proteinuria
Oedema (nephrotic syndrome)
Hypertension
Loss of renal function

Interstitial disorders

Leucocyturia
Haematuria
Proteinuria] less than glomerular disorders
Loss of renal function—especially tubular/medullary
Loin pain, e.g. infection—pyelonephritis

POST-RENAL

Ureter

Haematuria
Loin pain:] e.g. from renal calculus or tumour
'renal colic'
Loss of renal function (on the side of an obstruction)

Penis

Erectile dysfunction

Urethra

Haematuria
Urinary retention—obstruction
Infection (urethritis)*

Bladder

Haematuria
Acute retention—obstruction—suprapubic pain/discomfort—oliguria/anuria
Incontinence
Infection (cystitis)*

Prostate

'Prostatism' (obstruction)—hesitancy, dribbling, poor stream, frequency, urinary retention
Infection (prostatitis)*

17

Fig. 17.8 Classification and manifestations of renal and urinary tract disease. Consequences of loss of renal function and effects on other organs are described on pages 482–492. (*Lower urinary tract infection: haematuria, dysuria, frequency, urgency, cloudy and smelly urine.)

whom urinary tract obstruction due to prostatic hypertrophy may occur. The most common presentation is with acute urethritis and cystitis, although this is part of a spectrum of severity (Box 17.7).

Aetiology and risk factors

Urine is an excellent culture medium for bacteria; in addition, the urothelium of susceptible persons may have more receptors to which virulent strains of *Escherichia coli* become adherent. In women, the ascent of organisms into the bladder is easier than in men; the urethra is shorter and absence of bactericidal prostatic secretions may be relevant. Sexual intercourse may cause minor urethral trauma and transfer bacteria from the perineum into the bladder. Instrumentation of the bladder may also introduce organisms. Multiplication of organisms then depends on a number of factors, including the size of the inoculum and virulence of the bacteria. Conditions which predispose to UTI are shown in Box 17.8.

Clinical assessment

Typical features of cystitis and urethritis include:

- abrupt onset of frequency of micturition and urgency
- scalding pain in the urethra during micturition (dysuria)
- suprapubic pain during and after voiding
- intense desire to pass more urine after micturition, due to spasm of the inflamed bladder wall (strangury)
- urine that may appear cloudy and have an unpleasant odour
- microscopic or visible haematuria.

Systemic symptoms are usually slight or absent. However, infection in the lower urinary tract can spread (see Box 17.7); acute pyelonephritis is suggested by prominent systemic symptoms with fever, rigors, vomiting, hypotension and loin pain, guarding or tenderness, and may be an indication for hospitalisation. Only about

30% of patients with acute pyelonephritis have associated symptoms of cystitis or urethritis. Prostatitis is suggested by systemic symptoms and prostatic tenderness on rectal examination.

The differential diagnosis of lower urinary tract symptoms includes urethritis due to sexually transmitted disease, notably chlamydia (p. 412) or Reiter's syndrome. Some patients, usually female, have symptoms suggestive of urethritis and cystitis but no bacteria are cultured from the urine (the 'urethral syndrome'). Possible explanations include infection with organisms not readily cultured by ordinary methods (e.g. *Chlamydia*, certain anaerobes), intermittent or low-count bacteriuria, reaction to toiletries or disinfectants, symptoms related to sexual intercourse, or post-menopausal atrophic vaginitis.

The differential diagnosis of acute pyelonephritis includes acute appendicitis, diverticulitis, cholecystitis, salpingitis, ruptured ovarian cyst or ectopic pregnancy. In perinephric abscess, there is marked pain and tenderness, and often bulging of the loin on the affected side. Patients are extremely ill, with fever, leucocytosis and positive blood cultures, but urinary symptoms are absent and urine contains neither pus cells nor organisms.

Investigations

An approach to investigation is shown in Box 17.9.

In an otherwise healthy woman with a single lower urinary tract infection, urine culture prior to treatment is not mandatory. It is necessary, however, in patients with recurrent infection or after failure of initial treatment, during pregnancy, or in patients susceptible to serious infection (e.g. the immunocompromised, those with diabetes or an indwelling catheter, or older people – Box 17.10).

Definitive diagnosis rests on the combination of typical clinical features with findings in the urine. Most urinary pathogens can reduce nitrate to nitrite, and neutrophils and nitrites can usually be detected in symptomatic infections by urine dipstick tests for leucocyte esterase and nitrite, respectively. The absence of both nitrites and leucocyte esterase in the urine makes UTI unlikely. Interpretation of bacterial counts in the urine, and of what

17.7 The spectrum of presentations of urinary tract infection

- Asymptomatic bacteriuria
- Symptomatic acute urethritis and cystitis
- Acute pyelonephritis (p. 472)
- Acute prostatitis (p. 514)
- Septicaemia (usually Gram-negative bacteria)

17.8 Risk factors for urinary tract infection

Incomplete bladder emptying

- Bladder outflow obstruction
- Neurological problems (e.g. multiple sclerosis, diabetic neuropathy)
- Gynaecological abnormalities (e.g. uterine prolapse)
- Vesico-ureteric reflux (p. 509)

Foreign bodies

- Urethral catheter or ureteric stent

Loss of host defences

- Atrophic urethritis and vaginitis in post-menopausal women
- Diabetes mellitus

17.9 Investigation of patients with urinary tract infection

All patients

- Dipstick* estimation of nitrite, leucocyte esterase and glucose
- Microscopy/cytometry of urine for white blood cells, organisms
- Urine culture

Infants, children, and anyone with fever or complicated infection

- Full blood count; urea, electrolytes, creatinine
- Blood cultures

Pyelonephritis; males; children; women with recurrent infections

- Renal tract ultrasound or CT
- Pelvic examination in women, rectal examination in men

Continuing haematuria or other suspicion of bladder lesion

- Cystoscopy

*May substitute for microscopy and culture in simple uncomplicated infection.

17.10 Urinary infection in old age

- **Prevalence of asymptomatic bacteriuria:** rises with age. Amongst the most frail in institutional care it rises to 40% in women and 30% in men.
- **Contributory factors:** include an increased prevalence of underlying structural abnormalities, post-menopausal oestrogen deficiency and increased residual urine in women, and prostatic hypertrophy with reduced bactericidal activity of prostatic secretions in men.
- **Decision to treat:** there is little evidence of benefit from treating asymptomatic bacteriuria in old age. It does not improve chronic incontinence or decrease mortality or morbidity from symptomatic urinary infection. It risks adverse effects from the antibiotic and promoting the emergence of resistant organisms.
- **Source of infection:** the urinary tract is the most frequent source of bacteraemia in older patients admitted to hospital.
- **Incontinence:** new or increased incontinence is a common presentation of UTI in older women.
- **Treatment:** post-menopausal women with acute lower urinary tract symptoms may require longer than 3 days' therapy.

is a 'significant' culture result, is based on probabilities. Urine taken by suprapubic aspiration should be sterile, so the presence of any organisms is significant. If the patient has symptoms and there are neutrophils in the urine, a small number of organisms is significant. In asymptomatic patients, $> 10^5$ organisms/mL is usually regarded as significant (asymptomatic bacteriuria, see below).

Typical organisms causing UTI in the community include *E. coli* derived from the gastrointestinal tract (about 75% of infections), *Proteus* spp., *Pseudomonas* spp., streptococci and *Staphylococcus epidermidis*. In hospital, *E. coli* still predominates, but *Klebsiella* or streptococci are more common. Certain strains of *E. coli* have a particular propensity to invade the urinary tract.

Investigations to detect underlying predisposing factors for UTI are used selectively, most commonly in patients with recurrent infections (see Box 17.9).

Management

Antibiotics are recommended in all cases of proven UTI (Box 17.11). If urine culture has been performed, treatment may be started while awaiting the result. For infection of the lower urinary tract treatment for 3 days

17.11 Antibiotic regimens for urinary tract infection (UTI) in adults

Scenario	Drug	Regimen	Duration
Cystitis and uncomplicated UTI			
First choice	Trimethoprim	200 mg 12-hourly	3 days in women, 10 days in men
Second choices*	Amoxicillin	250 mg 8-hourly	
	Nitrofurantoin	50 mg 6-hourly	
	Cefalexin	250 mg 6-hourly	
	Ciprofloxacin	100 mg 12-hourly	
In pregnancy	Co-amoxiclav	250/125 mg 8-hourly	7 days
	Cephalexin	250 mg 6-hourly	
	Amoxicillin	250 mg 8-hourly	
	(Avoid trimethoprim and quinolones)		
Prophylactic therapy			
First choice	Trimethoprim	100 mg at night	Continuous
Second choices	Nitrofurantoin	50 mg at night	
	Co-amoxiclav	250/125 mg at night	
Pyelonephritis and complicated UTI (i.e. with associated systemic toxicity)			
First choices	Co-amoxiclav	500/125mg 8-hourly	10 days
	Ciprofloxacin	500 mg 12-hourly	
Second choices*	In seriously ill patients start i.v. treatment, e.g.		7–14 days
	Cefuroxime	750 mg 8-hourly	
	Gentamicin	Dose adjusted to renal function and plasma gentamicin levels	
Epididymo-orchitis			
First choice	Ciprofloxacin	500 mg 12-hourly	14 days
Second choice	Consider screening and treatment for chlamydia (p. 421) in young men		
Acute prostatitis			
First choice	Trimethoprim	200 mg 12-hourly	28 days
Second choice*	Ciprofloxacin	500 mg 12-hourly	

*Guided by sensitivities of organism on culture.

*Guided by sensitivities of organism on culture.

is the norm and is less likely to induce significant alterations in bowel flora than more prolonged therapy. Trimethoprim is the usual choice for initial treatment; however, between 10% and 40% of organisms causing UTI are resistant to trimethoprim, the lower rates being seen in community-based practice. Nitrofurantoin, quinolone antibiotics such as ciprofloxacin and norfloxacin, and cefalexin are also generally effective. Co-amoxiclav or amoxicillin should only be used when the organism is known to be sensitive. Penicillins and cephalosporins are safe to use in pregnancy but trimethoprim, sulphonamides, quinolones and tetracyclines should be avoided.

In more severe infection, antibiotics are continued for 7–14 days and may require intravenous therapy with a cephalosporin, quinolone or gentamicin (see Box 17.11), later switching to an oral agent.

A fluid intake of at least 2L/day is usually recommended, although this is not based on evidence and may make matters worse for patients with severe dysuria. Urinary alkalinising agents such as potassium citrate may help symptomatically but are not of proven efficacy.

Persistent or recurrent UTI

If the causative organism persists on repeat culture despite treatment, or if there is reinfection with any organism after an interval, then an underlying cause is more likely to be present (see Box 17.8) and more detailed investigation is justified (see Box 17.9). In women, recurrent infections are common and further investigation is only justified if infections are frequent (three or more per year) or unusually severe. Recurrent UTI, particularly in the presence of an underlying cause, may result in permanent renal damage, whereas uncomplicated infections rarely (if ever) do so (see chronic pyelonephritis, p. 509).

If an underlying cause cannot be removed, suppressive antibiotic therapy (see Box 17.11) can be used to prevent recurrence and reduce the risk of septicaemia and renal damage. Urine is cultured at regular intervals; a regime of two or three antibiotics in sequence, rotating every 6 months, is often used in an attempt to reduce the emergence of resistant organisms. Other simple measures may help to prevent recurrence (Box 17.12).

17.12 Prophylactic measures to be adopted by women with recurrent urinary infections

- Fluid intake of at least 2L/day
- Regular complete emptying of bladder
- Good personal hygiene
- Emptying of the bladder before and after sexual intercourse
- Cranberry juice may be effective

Asymptomatic bacteriuria

This is defined as $> 10^5$ organisms/mL in the urine of apparently healthy asymptomatic patients. Approximately 1% of children under the age of 1, 1% of schoolgirls, 0.03% of schoolboys and men, 3% of non-pregnant adult women and 5% of pregnant women have asymptomatic bacteriuria. It is increasingly common in those aged over 65. There is no evidence that this condition causes renal scarring in adults who are

not pregnant and have a normal urinary tract, and in general, treatment is not indicated. However, up to 30% will develop symptomatic infection within 1 year. Treatment is required in infants, pregnant women and those with urinary tract abnormalities.

Catheter-related bacteriuria

In patients with a urethral catheter, bacteriuria increases the risk of Gram-negative bacteraemia fivefold. However, bacteriuria is common, and almost universal during long-term catheterisation. Treatment is usually avoided in asymptomatic patients, as this may promote antibiotic resistance. Careful sterile insertion technique is important, and the catheter should be removed as soon as it is not required.

Acute pyelonephritis

The kidneys are infected in a minority of patients with UTI. Acute renal infection (pyelonephritis) presents as a classic triad of loin pain, fever and tenderness over the kidneys. The renal pelvis is inflamed and small abscesses are often evident in the renal parenchyma (see Fig. 17.31C, p. 505).

Renal infection is almost always caused by organisms ascending from the bladder, and the bacterial profile is the same as for lower urinary tract infection (p. 471). Rarely, bacteraemia may give rise to renal or perinephric abscesses, most commonly due to staphylococci. Predisposing factors such as cysts or renal scarring facilitate infection.

Rarely, acute pyelonephritis is associated with papillary necrosis. Fragments of renal papillary tissue are passed per urethra and can be identified histologically. They may cause ureteric obstruction and, if this occurs bilaterally or in a single kidney, may cause acute renal failure. Predisposing factors include diabetes mellitus, chronic urinary obstruction, analgesic nephropathy and sickle-cell disease. A necrotising form of pyelonephritis with gas formation, 'emphysematous pyelonephritis', is occasionally seen in patients with diabetes mellitus. Xanthogranulomatous pyelonephritis is a chronic infection that can resemble a tumour. It is usually associated with obstruction, is characterised by accumulation of foamy macrophages and generally requires nephrectomy. Infection of cysts in polycystic kidney disease (p. 506) requires prolonged antibiotic treatment.

Appropriate investigations are shown in Box 17.9 and management is described above and in Box 17.11. Intravenous rehydration may be required in severe cases. If complicated infection is suspected or response to treatment is not prompt, urine should be recultured and renal tract ultrasound performed to exclude urinary tract obstruction or a perinephric collection. If obstruction is present, drainage by a percutaneous nephrostomy should be considered.

Loin pain

Dull ache in the loin is rarely due to renal disease but the differential diagnosis includes renal stone, renal tumour, acute pyelonephritis or urinary tract obstruction. Causes of obstruction are shown in Figure 17.9. Upper urinary tract obstruction is most commonly caused by a congenital abnormality of the pelvi-ureteric junction (PUJ),

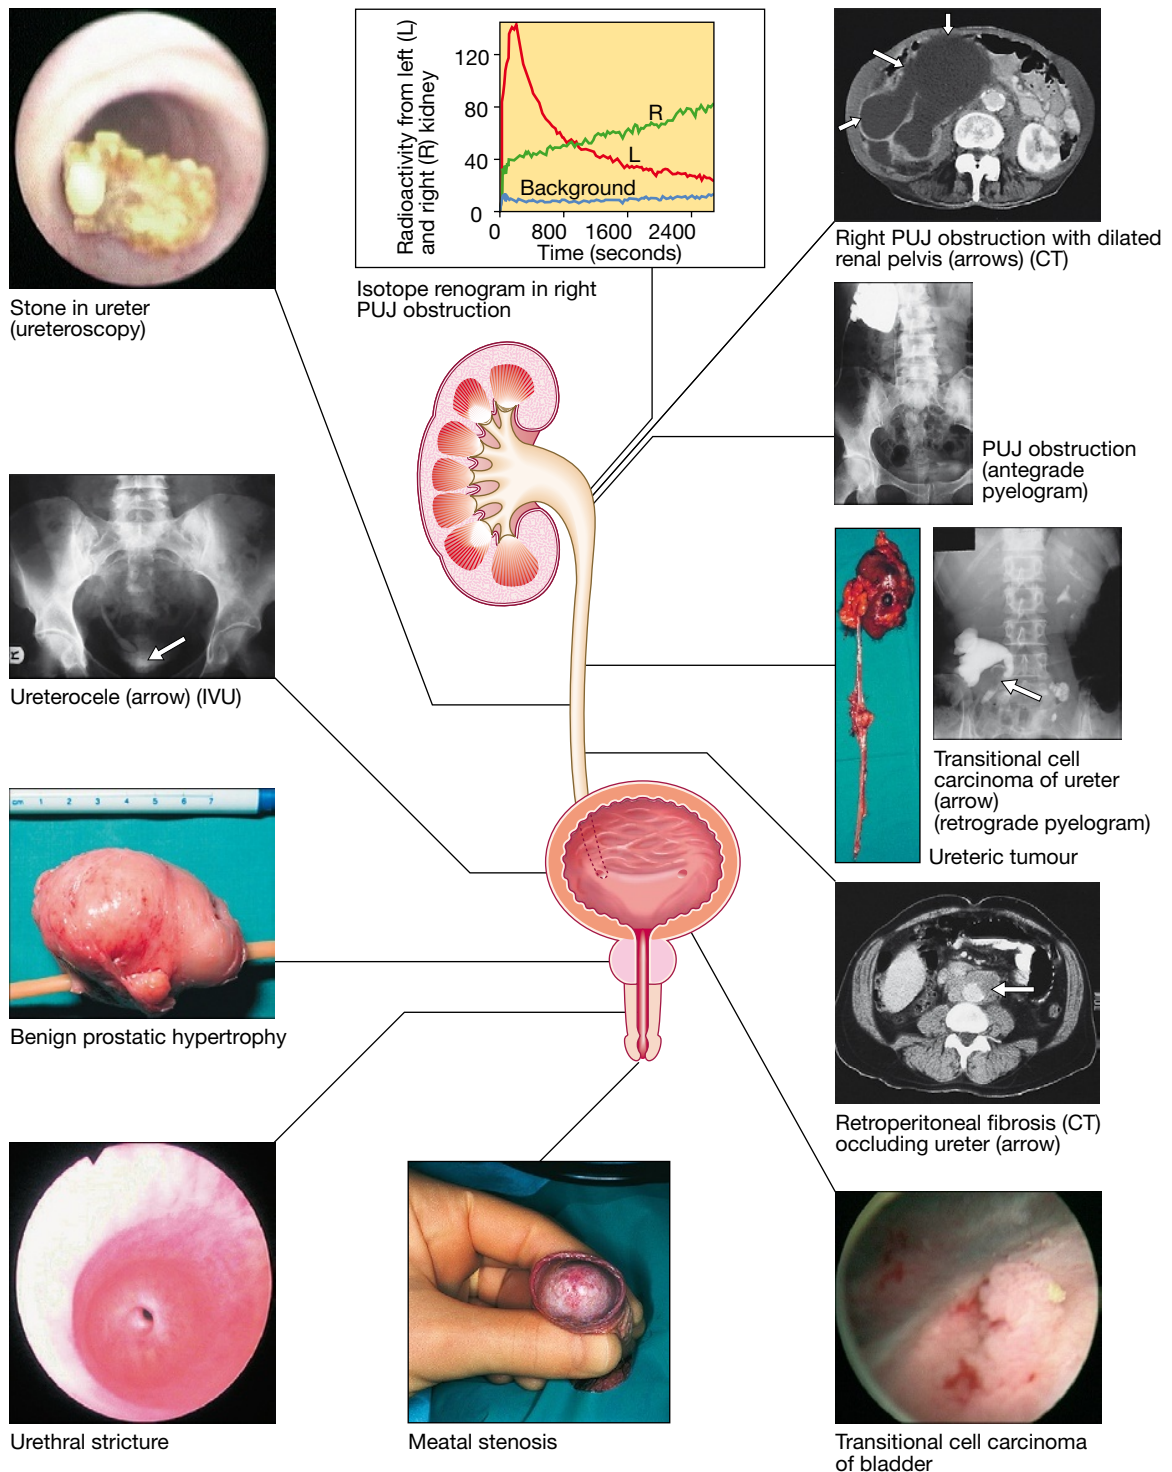

Fig. 17.9 Urinary tract obstruction. Some common causes and their locations. (PUJ = pelvi-ureteric junction)

p. 509), when typically loin pain is precipitated by a large fluid intake. Lower urinary tract obstruction usually presents with oliguria/anuria (p. 474).

Renal colic

Acute loin pain radiating anteriorly and often to the groin ('renal colic'), together with haematuria, is typical of ureteric obstruction most commonly due to calculi

(or 'stones', p. 510), although a sloughed renal papilla, tumour or blood clot may be responsible.

Clinical assessment

Renal colic occurs when a stone becomes impacted in the ureter. The patient is suddenly aware of pain in the loin, which radiates round the flank to the groin and often into the testis or labium, in the sensory distribution of the first

lumbar nerve. The pain steadily increases in intensity to reach a peak in a few minutes. The patient is restless and generally tries unsuccessfully to obtain relief by changing position or pacing the room. There is pallor, sweating and often vomiting, and the patient may groan in agony. Frequency, dysuria and haematuria may occur. The intense pain usually subsides within 2 hours, but may continue unabated for hours or days. It is usually constant during attacks, although slight fluctuations in severity may occur. Contrary to general belief, attacks rarely consist of intermittent severe pains coming and going every few minutes. Subsequent to an attack of renal colic there may be intermittent dull pain in the loin or back.

Investigations

The diagnosis of renal colic is usually made easily from the history and by finding red cells in the urine. Investigations are required to confirm the presence of a stone, and to identify the site of the stone and degree of obstruction. About 90% of stones contain calcium and are seen on a plain abdominal X-ray. When the stone is in the ureter an IVU shows delayed excretion of contrast from the kidney and a dilated ureter down to the stone (Fig. 17.10). IVU remains the most commonly used investigation world-wide, but spiral CT gives the most accurate assessment and will identify non-opaque stones (e.g. uric acid). Ultrasound may show dilatation of the ureter if the stone is obstructing urine flow. The stone may also cast an acoustic shadow.

Patients with a first renal stone should have a minimum set of investigations (Box 17.13); the yield of more detailed investigation is low, and hence usually reserved for those with recurrent or multiple stones, or those

Fig. 17.10 Unilateral obstruction. Intravenous urogram of a patient with a stone (not visible) at the lower end of the right ureter. This film, taken 2 hours post-contrast injection, demonstrates persistence of contrast medium in the right kidney, pelvicalyceal system and ureter, whereas only a small amount remains visible in the normal left pelvicalyceal system.

17.13 Investigations for renal stones

Sample	Test	First stone	Recurrent stone
Stone	Chemical composition—most valuable test when possible	✓	✓
Blood	Calcium	✓	✓
	Phosphate	✓	✓
	Uric acid	✓	✓
	Urea and electrolytes	✓	✓
	Parathyroid hormone—only if calcium or calcium excretion high		(✓)
Urine	Dipstick test for protein, blood, glucose	✓	✓
	Amino acids		✓
24-hour urine	Urea		✓
	Creatinine clearance		✓
	Sodium		✓
	Calcium		✓
	Oxalate		✓
	Uric acid		✓

with complicated or unexpected presentations (e.g. in the very young). Chemical analysis of stones is helpful. Since most stones pass spontaneously through the urinary tract, urine should be sieved for a few days after an episode of colic in order to collect the calculus for analysis.

Management

The immediate treatment of renal pain or renal colic is bed rest and application of warmth to the site of pain. Renal colic is often unbearably painful and demands powerful analgesia, e.g. morphine (10–20 mg), pethidine (100 mg) intramuscularly or diclofenac as a suppository (100 mg). Patients are advised to drink 2 L per day. Around 90% of stones < 4 mm in diameter will pass spontaneously, but only 10% of stones of > 6 mm will pass and these may require endoscopic surgical intervention. All stones are potentially infected and surgery should be covered with appropriate antibiotics. Immediate action is required if there is anuria or if severe infection occurs in the stagnant urine proximal to the stone (pyonephrosis).

Attempts to develop drugs that dissolve stones have so far been unsuccessful. However, most stones can now be fragmented by extracorporeal shock wave lithotripsy (ESWL; see Fig. 17.37, p. 511), in which shock waves generated outside the body are focused on the stone, breaking it into small pieces which can pass easily down the ureter. This requires free drainage of the distal urinary tract.

Further measures to prevent recurrent stone formation are discussed on page 511.

Abnormal micturition

Oliguria/anuria

On an average diet, between 300 and 500 mL/day of urine is required to excrete the solute load at maximum

concentration. Volumes below this are termed oliguria. Anuria is the (almost) total absence of urine (< 50 mL/day). A low measured urine volume is an important finding, as it suggests reduced production of urine or obstruction to urine flow.

Reduced urine production

The volume of urine produced is determined by the difference between glomerular filtration and tubular reabsorption. When GFR is very low, urine volumes may still be normal if tubular reabsorption is correspondingly low; hence urine volume is a poor indicator of CKD. Oliguria/anuria may be caused by a reduction in urine production, as typically seen in pre-renal acute renal failure, when GFR is reduced but intact tubular homeostatic mechanisms increase reabsorption to conserve salt and water. A high solute load or associated tubular dysfunction may, however, produce normal or high urine volumes in such cases until the pre-renal insult becomes severe and GFR is minimal, e.g. in diabetic ketoacidosis with marked glycosuria. Urine volumes are variable in acute renal failure due to intrinsic renal disease, but a rapid decline in urine volume occurs in renal infarction, if bilateral or in a single functioning kidney, and often in rapidly progressive glomerulonephritis.

Urinary tract obstruction

The most common causes of lower urinary tract obstruction causing reduced volume of micturition are urinary calculi (p. 510), prostatic enlargement (benign or malignant, p. 512), or pelvic and retroperitoneal tumours in an older age group. About 50% of cases of acute urinary retention are seen after general anaesthesia, particularly in those with pre-existing prostatic enlargement. In young men, bladder neck dyssynergia may also cause obstruction. Urethral strictures (more likely if there is a history of instrumentation), trauma or urethral infection, urethral valves, phimosis and meatal stenosis are other common causes (see Fig. 17.9, p. 473). Poor flow and post-micturition residual bladder volume are also seen in atonic bladders (e.g. in neurological disorders such as multiple sclerosis and spina bifida), when there is reduced/absent detrusor muscle activity and a failure of the distal sphincter to relax.

Obstruction may be acute or chronic, and partial or complete. Acute obstruction is often associated with pain due to distension of the urinary tract that may be exacerbated by a fluid load. The site of the pain can indicate the site of the obstruction. Obstruction at the bladder neck (acute urinary retention) is associated with lower midline abdominal discomfort due to bladder dilatation. Ureteric obstruction, e.g. from a renal calculus, typically presents as loin pain radiating to the groin. Higher obstructions, e.g. at the level of the renal pelvis, may present as flank pain. Chronic obstruction rarely produces pain but may produce a dull ache.

To produce oliguria/anuria, the obstruction must be complete and distal to the bladder neck, bilateral, or unilateral on the side of a single functioning kidney. If an obstruction is not relieved, the pressure transmitted back to the nephrons will result in cessation of glomerular filtration. All patients with acutely reduced urinary volumes should be palpated/percussed for a full bladder and catheterised. If oliguria persists without another clear explanation, radiological assessment, typically by

ultrasound, should be undertaken promptly. Rarely, in acute renal failure due to obstruction, urinary tracts may not be particularly dilated because of lack of urine production. Relief of an acute obstruction is usually accompanied by a rapid return of renal function, although tubular function may be impaired, resulting in polyuria and failure to conserve electrolytes.

Partial obstruction can be associated with normal or even high urine volumes due to chronic tubular injury, with a loss of tubular concentrating ability. This chronic tubular injury can also produce a type 1 renal tubular acidosis (p. 444). Over time, even partial obstruction will cause tubular atrophy and irreversible renal failure.

Polyuria

An inappropriately high urine volume (> 3 L/day) may result from increased urinary solute excretion (osmotic diuresis) or pure water diuresis (Box 17.14). In primary (or psychogenic) polydipsia, the increased urine output is an appropriate response to increased water intake; plasma sodium concentration is typically low-normal in such patients. In diabetes insipidus (p. 492), there is impaired urinary concentrating ability causing increased free water clearance (i.e. water free of solute); plasma sodium will usually be normal in such patients, since increased thirst will usually prevent high plasma sodium concentrations. However, restricted access to water may precipitate hypernatraemia. Free water clearance is calculated by measuring osmotic clearance:

$$\text{Osmotic clearance} = \text{urine flow rate} \times \frac{\text{urine osmolality}}{\text{plasma osmolality}}$$

$$\text{Free water clearance} = \text{urine flow rate} - \text{osmotic clearance}$$

Investigation of polyuria includes measurement of plasma electrolytes, glucose and calcium. A 24-hour urine collection may be helpful to confirm the severity of polyuria. Investigation of suspected diabetes insipidus is described on page 493.

17.14 Causes of polyuria

- Excess fluid intake
- Osmotic, e.g. hyperglycaemia, hypercalcaemia
- Cranial diabetes insipidus (reduced antidiuretic hormone (ADH) secretion)
 - Idiopathic (50%), mass lesion, trauma, infection
- Nephrogenic diabetes insipidus (tubular dysfunction)
 - Genetic tubular defects
 - Drugs/toxins, e.g. lithium, diuretics
 - Interstitial renal disease
 - Hypokalaemia, hypercalcaemia

Nocturia

Waking up at night to void urine may be a consequence of polyuria but may also result from fluid intake or diuretic use in the late evening. Nocturia also occurs in CKD, and in prostatic enlargement when it is associated with poor stream, hesitancy, incomplete bladder emptying, terminal dribbling and urinary frequency due to partial urethral obstruction (p. 512 and Fig. 17.11). Nocturia may also occur in sleep disturbance without functional abnormalities of the urinary tract.

Frequency

Frequency describes micturition more often than a patient's expectations. It may be a consequence of polyuria, most commonly due to diuretic therapy, when volumes passed are normal or high. It is also a symptom of UTIs (urethritis, cystitis, prostatitis) or urethral syndrome when urine volumes are typically low and associated with dysuria, urgency and a feeling of incomplete emptying.

Urinary incontinence

Urinary incontinence is defined as any involuntary leakage of urine. Urinary tract pathology causing incontinence is described below. It may also occur with a normal urinary

tract, e.g. in association with poor cognition or poor mobility, or transiently during an acute illness or hospitalisation, especially in older people (Box 17.15). Diuretics (medication, alcohol or caffeine) may worsen incontinence.

Clinical assessment and investigations

The pattern of micturition is important in classifying incontinence and patients should be encouraged to keep a voiding diary, including the estimated volume voided, frequency of voiding, precipitating factors and associated features, e.g. urgency.

Examination includes an assessment of cognitive function and mobility, and of perineal sensation and anal sphincter tone since the innervation is from the same

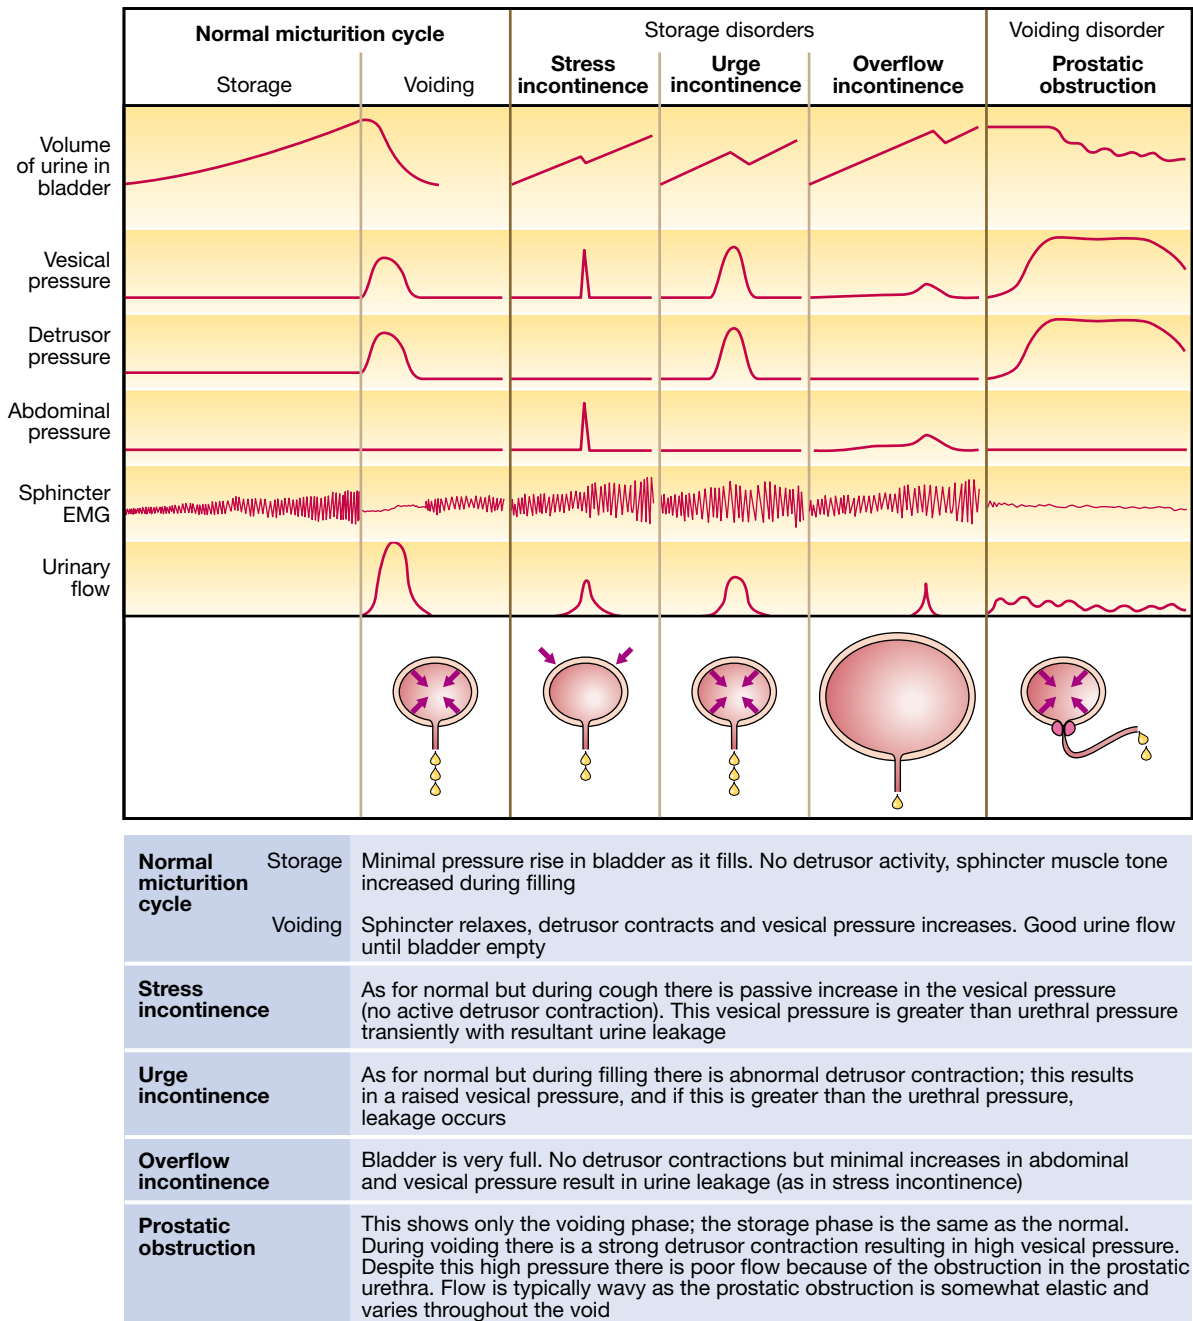

Fig. 17.11 Urodynamic abnormalities in patients with urinary incontinence. (EMG = electromyogram)

17.15 Incontinence in old age

- **Prevalence:** Urinary incontinence affects 15% of women and 10% of men aged over 65 years.
- **Cause:** incontinence may be transient due to an acute confusional state, urinary infection, medication (such as diuretics), faecal impaction or restricted mobility, and these should be treated before embarking on further specific investigation.
- **Detrusor over-activity:** established incontinence in old age is most commonly due to detrusor over-activity which may be caused by damage to central inhibitory centres or local detrusor muscle abnormalities.
- **Catheterisation:** poor manual dexterity or cognitive impairment may necessitate the help of a carer to assist with intermittent catheterisation.

sacral nerve roots that supply the bladder and urethral sphincter. A general neurological assessment is required to detect disorders such as multiple sclerosis that may affect the nervous supply of the bladder, and the lumbar spine should be inspected for features of spina bifida occulta. Rectal examination is needed to assess the prostate in men and to exclude faecal impaction as a cause of incontinence. Genital examination should identify phimosis and paraphimosis in men, and vaginal mucosal atrophy, cystoceles or rectoceles in women.

Urinalysis and culture should be performed in all patients. An assessment of post-micturition volume should be made, either by post-micturition ultrasound or catheterisation. Urine flow rates and full urodynamic assessment may also be helpful in selected cases (see Fig. 17.11).

Incontinence syndromes

Stress incontinence

In stress incontinence leakage occurs because passive bladder pressure exceeds the urethral pressure, due to either poor pelvic floor support or a weak urethral sphincter. Most often there is an element of both. This is very common in women and most often seen following childbirth. It is rare in men and then usually follows surgery to the prostate. Urine leaks when abdominal pressure rises, e.g. when coughing or sneezing. In women, perineal inspection may reveal leakage of urine when the patient coughs, and sometimes also a prolapse. Females in particular respond well to physiotherapy but if incontinence is persistent and troublesome, surgical treatment is indicated.

Urge incontinence

In urge incontinence leakage usually occurs because of detrusor over-activity producing an increased bladder pressure which overcomes the urethral sphincter (motor urgency). Urgency with or without incontinence may also be driven by a hypersensitive bladder (sensory urgency) resulting from UTI or bladder stone. The incidence of urge incontinence increases with age, occurring in 17% of the population aged over 65 years and around 50% of those requiring nursing home care. It is also seen in men with lower urinary tract obstruction and most often remits after the obstruction is relieved.

The diagnosis is often made simply on the basis of symptoms and the exclusion of urinary retention by bladder ultrasound; confirmation requires urodynamic testing (see Fig. 17.11). The mainstay of treatment is

bladder retraining, teaching patients to hold more urine voluntarily in their bladder, assisted by anticholinergic medication. Surgery is restricted to patients who have severe day-time incontinence despite such treatment.

Continual incontinence

This suggests the presence of a fistula, usually between the bladder and vagina (vesicovaginal) or the ureter and vagina (ureterovaginal). This is most common following gynaecological surgery but is also seen in patients with gynaecological malignancy or following radiotherapy. In parts of the world where obstetric services are scarce, prolonged obstructed labour can be a common cause of vesicovaginal fistulas. Continual incontinence may also be seen in infants with congenital ectopic ureters. Occasionally, stress incontinence is so severe that the patient leaks continuously. Diagnosis is confirmed by inspection of the perineum and by IVU. Treatment is surgical.

Overflow incontinence

This occurs when the bladder becomes chronically over-distended. It is most commonly seen in men with benign prostatic hyperplasia or bladder neck obstruction (p. 512), but may occur in either sex as a result of failure of the detrusor muscle (atonic bladder). The latter may be idiopathic but more commonly is the result of damage to the pelvic nerves, either from surgery (commonly, hysterectomy or rectal excision), trauma or infection, or from compression of the cauda equina from disc prolapse, trauma or tumour. Incomplete bladder emptying can be identified by ultrasound, which reveals a significant post-micturition volume (> 100 mL). Obstructed bladders should be treated surgically. Unobstructed bladders need to be drained, preferably by intermittent self-catheterisation. Urodynamic testing may help clarify the aetiology.

Post-micturition dribble

This is very common in men, even in the relatively young. It is due to a small amount of urine becoming trapped in the U-bend of the bulbar urethra, which leaks out when the patient moves. It is more pronounced if associated with a urethral diverticulum or urethral stricture. It may occur in females with a urethral diverticulum and may mimic stress incontinence.

Neurological causes

Neurological disease resulting in abnormal bladder function is almost always associated with obvious neurological signs; these are described on page 1167.

Erectile dysfunction

Causes of erectile failure are shown in Box 17.16. Vascular, neuropathic and psychological causes are most common. With the exception of diabetes mellitus, endocrine causes are relatively uncommon and are characterised by loss of libido as well as erectile dysfunction. Erectile dysfunction and reduced libido occur in over 50% of men with advanced CKD or on dialysis. Judging from experience gained in diabetes clinics, erectile dysfunction is a markedly under-diagnosed problem. It is important to be able to discuss matters frankly with the patient, and to establish whether there are associated features of hypogonadism (p. 757) and whether

17.16 Causes of erectile dysfunction

With reduced libido

- Hypogonadism
- Depression

With intact libido

- Psychological problems, including anxiety
- Vascular insufficiency (atheroma)
- Neuropathic causes (e.g. diabetes mellitus, alcohol excess, multiple sclerosis)
- Drugs (e.g. β -blockers, thiazide diuretics)

erections occur at any other time (e.g. if the patient has erections on waking in the morning, vascular and neuropathic causes are much less likely).

Investigations

Blood should be taken for glucose, prolactin, testosterone, luteinising hormone (LH) and follicle-stimulating hormone (FSH). A number of further tests are available but are rarely employed because they do not usually influence management. These include nocturnal tumescence monitoring (using a plethysmograph placed around the shaft of the penis overnight) to establish whether blood supply and nerve function are sufficient to allow erections to occur during sleep; intracavernosal injection of papaverine or prostaglandin E1 to test the adequacy of blood supply; internal pudendal artery angiography; and tests of autonomic and peripheral sensory nerve conduction.

Management

Psychotherapy which includes the sexual partner is most useful for psychological problems. Neuropathy and vascular disease are unlikely to improve but several treatments are available. First-line therapy is usually with oral phosphodiesterase inhibitors (e.g. sildenafil) which potentiate the vasodilator action of nitric oxide on cyclic guanosine monophosphate (cGMP). Co-administration of phosphodiesterase inhibitors with nitric oxide donors ('nitrate' drugs) is contraindicated because of the risk of severe hypotension. Caution should also be exercised in patients with chronic disease including ischaemic heart disease. Other treatments for impotence include self-administered intracavernosal injection or urethral gel administration of prostaglandin E1; vacuum devices which achieve an erection which is maintained by a tourniquet around the base of the penis; and prosthetic implants, either of a fixed rod or inflatable reservoir. Hypogonadism should be managed as described on page 757.

Haematuria

Haematuria may be visible and reported by the patient (macroscopic haematuria), or invisible and detected on dipstick testing of urine (microscopic haematuria). It indicates bleeding from anywhere in the renal tract (Fig. 17.12).

Microscopy shows that normal individuals have occasional red blood cells (rbc) in the urine (up to 12 500 rbc/mL). The detection limit for dipstick testing is 15–20 000 rbc/mL, which is sufficiently sensitive to detect all significant bleeding. However, dipstick tests

Fig. 17.12 Causes of haematuria.

are also positive in the presence of free haemoglobin or myoglobin. Urine microscopy (p. 461) can be valuable in confirming haematuria and in establishing the cause of bleeding (Box 17.17). Other causes of red or dark urine may sometimes be confused with haematuria but produce negative dipstick tests and microscopy (Box 17.18). True positive tests may occur during menstruation, infection or strenuous exercise, but persistent haematuria requires further investigation to exclude malignancy.

Glomerular bleeding is characteristic of inflammatory, destructive or degenerative processes that disrupt the glomerular basement membrane (GBM) to cause microscopic or macroscopic haematuria. In glomerulonephritis, one or more other features of the 'nephritic syndrome' (Box 17.19) may be present, but the full syndrome is rare (p. 500).

Macroscopic (visible) haematuria is more likely to be caused by tumours (p. 514 and Box 17.20). Severe infections or renal infarction can also cause macroscopic haematuria, usually accompanied by pain.

Investigations and management

Investigation of haematuria (Fig. 17.13), whether microscopic or macroscopic, should be directed first at the exclusion of an anatomical bleeding lesion, particularly in older patients or others at risk of carcinoma of the bladder or other malignancy (see Box 17.20). If haematuria

17.17 Interpretation of dipstick-positive haematuria

Dipstick test positive	Urine microscopy	Suggested cause
Haematuria	White blood cells Abnormal epithelial cells Red cell casts Dysmorphic erythrocytes (phase contrast microscopy)	Infection Tumour Glomerular bleeding*
Haemoglobinuria	No red cells	Intravascular haemolysis
Myoglobinuria (brown urine)	No red cells	Rhabdomyolysis

*Glomerular bleeding implies that the GBM is fractured. It can occur physiologically following very strenuous exertion but usually indicates intrinsic renal disease and is an important feature of the nephritic syndrome (see Box 17.19).

17.18 Dipstick-negative dark urine

Cause	Urine colour
Food dyes e.g. Acanthocyanins (beetroot)	Red
Drugs e.g. Phenolphthalein Senna/other anthraquinones Rifampicin Levodopa	Pink when alkaline Orange Orange Darkens on standing
Porphyria	Darkens on standing
Alkaptonuria	
Bilirubinuria e.g. Obstructive jaundice	Dark Dipstick-positive for bilirubin, negative for haemoglobin

17.19 Nephritic and nephrotic syndromes

Nephritic syndrome¹

- Haematuria (red or brown urine)
- Oedema and generalised fluid retention
- Hypertension
- Oliguria

Nephrotic syndrome²

- Overt proteinuria: usually > 3.5 g/24 hrs (urine may be frothy)
- Hypoalbuminaemia (< 30 g/L)
- Oedema and generalised fluid retention
- Intravascular volume depletion with hypotension, or expansion with hypertension, may occur

¹The complete form is classically seen in post-infectious glomerulonephritis, may occur in acute IgA nephropathy, and occasionally occurs in other types of glomerulonephritis. The presence of one or more features is common to many types of glomerular disease.

²Classically seen in non-inflammatory and subacute inflammatory/proliferative glomerular disorders (see Fig. 17.27, p. 500).

EBM 17.20 Haematuria and urothelial malignancy

'Macroscopic haematuria has a positive predictive value of 83% for bladder cancer and 22% for all urothelial tumours, rising to 41% in patients over the age of 40.'

• Buntinx F, et al. Fam Pract 1997; 14(1):63–68.

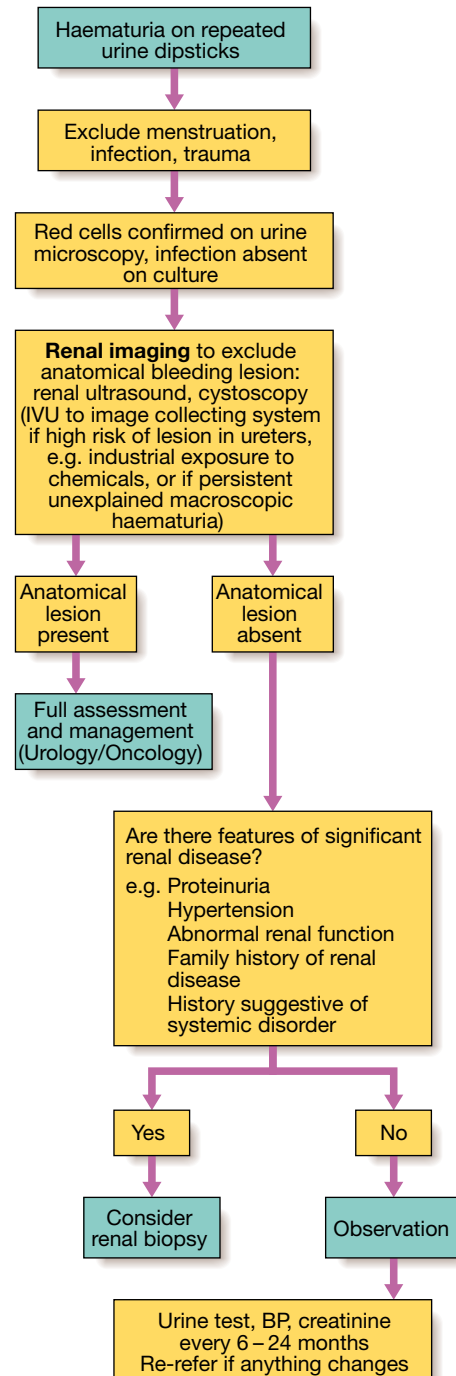

Fig. 17.13 Investigation of haematuria.

occurs with proteinuria or clinical features of kidney disease (see Box 17.19), inflammatory renal disease (p. 500) should be considered and a renal biopsy may be indicated. Where there are no features of significant kidney disease and malignancy has been excluded, patients with isolated microscopic haematuria may be managed by observation alone and biopsy is rarely warranted. Although this scenario occasionally precedes significant renal disease (e.g. Alport's syndrome, IgA nephropathy), it is commonly caused by the usually benign condition of thin basement membrane disease (p. 504), insignificant vascular malformations, renal cysts or renal stones. In 'loin pain-haematuria' syndrome, benign glomerular bleeding is associated with loin pain.

Management of haematuria depends upon the cause.

Proteinuria

Moderate amounts of low molecular weight protein pass through the healthy GBM. These proteins are normally reabsorbed by receptors on tubular cells. Less than 150 mg/day of protein normally appears in urine, and a proportion of that is Tamm-Horsfall protein secreted by the tubules.

Relatively minor leakage of albumin into the urine may occur transiently after vigorous exercise, during fever or UTI, and in heart failure. Tests should be repeated once the stimulus is no longer present. Occasionally, proteinuria occurs only during the day, and the first morning sample is negative. In the absence of other signs of renal disease, such 'orthostatic proteinuria' is usually regarded as benign.

As shown in Box 17.21, larger amounts of protein in the urine indicate renal damage; any renal disease or injury may cause proteinuria. Proteinuria is usually asymptomatic, although large amounts may make urine froth easily. The amount of protein in urine should be quantified to

17.21 Quantifying proteinuria in random urine samples			
ACR ¹	PCR ²	Typical dipstick results ³	Significance
< 3.5 (female) < 2.5 (male)		–	Normal
~3.5–15		–	Microalbuminuria
~15–50	~15–50	+ to ++	Dipsticks positive; equivalent to 24-hr protein excretion < 0.5 g
50–200	> 250	++ to +++	Glomerular disease more likely
> 200	> 300	+++ to ++++	Nephrotic range: always glomerular disease, equivalent to 24-hr protein excretion > 3 g

¹Urinary albumin (mg/L)/urine creatinine (mmol/L).
²Urine protein (mg/L)/urine creatinine (mmol/L).
³Dipstick results are affected by urine concentration and are occasionally weakly positive on normal samples.

guide further investigations (Fig. 17.14). Quantification in a 24-hour urine collection has been the traditional standard, but collections are arduous and often inaccurate. Use of the protein/creatinine ratio (PCR) in single samples makes allowance for the variable degree of urinary dilution and can allow extrapolation to 24 hour values (see Box 17.21). Changes in PCR give valuable information about the progression of renal disease. Albumin/creatinine ratio (ACR) requires a more expensive immunoassay. At significant levels of glomerular dysfunction, albumin accounts for 70% of serum protein, so ACR values are a little lower than comparable PCR values. Greater consistency in results can be achieved by using first morning urine samples but this is not essential for routine clinical use.

It is sometimes helpful to identify the type of protein in the urine. Low molecular weight proteins may appear in the urine in larger quantities than 150 mg/day, indicating failure of reabsorption by damaged tubular cells, i.e. 'tubular proteinuria'. This can be demonstrated by analysis of the size of excreted proteins or by specific assays for such proteins (e.g. β_2 -microglobulin, molecular weight 12 kDa). The amounts of such protein rarely exceed 1.5–2 g/24 hours (maximum PCR 150–200 mg/mmol), and proteinuria greater than this almost always indicates significant glomerular disease.

In many types of renal disease, the severity of proteinuria is a marker for an increased risk of progressive loss of renal function. Treatments that are effective

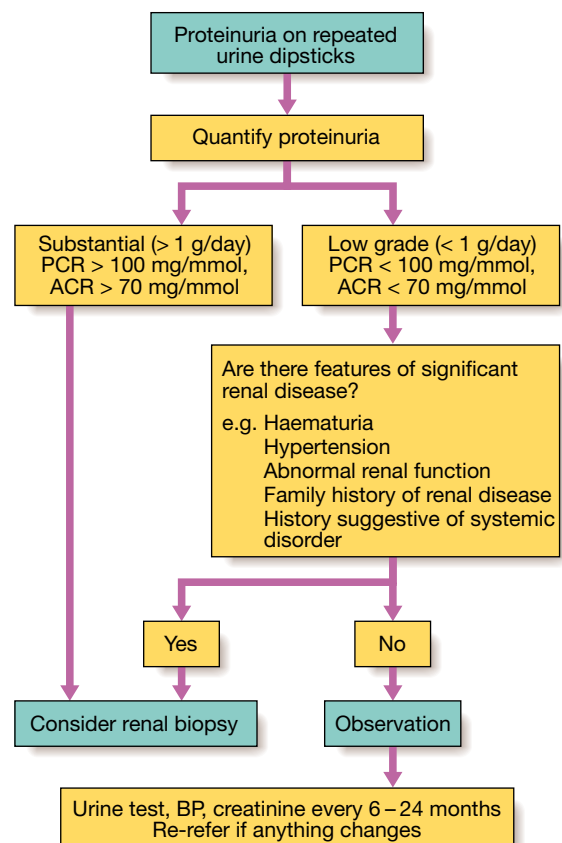

Fig. 17.14 Investigation of proteinuria. (ACR = albumin:creatinine ratio; PCR = protein:creatinine ratio.)

at lowering the risk of progression of kidney disease (e.g. angiotensin-converting enzyme (ACE) inhibitors in diabetic nephropathy) also reduce proteinuria.

Microalbuminuria

Microalbuminuria describes the urinary excretion of small amounts of albumin. The presence of albumin in the urine is a clear sign of glomerular abnormality and can identify the very early stages of progressive glomerular disease, e.g. in diabetic nephropathy (p. 829). Because significant renal damage will have occurred before dipstick tests become positive, patients with diabetes mellitus should be screened regularly for microalbuminuria. Persistent microalbuminuria has also been associated with an increased risk of atherosclerosis and cardiovascular mortality; neither the mechanism of proteinuria nor an explanation of these associations has yet been established.

Bence Jones proteinuria

Patients with a clone of B lymphocytes secreting free immunoglobulin light chains (molecular weight 25 kDa) filter these freely into the urine, and this can be identified as 'Bence Jones protein' in fresh urine samples. This may occur in amyloidosis (p. 84) and in B cell disorders, but is particularly important as a marker for myeloma (p. 1041). Bence Jones protein is poorly identified by dipstick tests and relatively low quantities of protein may be associated with significant pathology, so specific immunodetection methods are required when Bence Jones proteinuria is suspected. Highly sensitive serum assays for free light chains are becoming available for monitoring treatment.

Nephrotic syndrome

Nephrotic syndrome refers to the secondary phenomena that occur when substantial amounts of protein are lost in the urine (see Box 17.19, p. 479). The consequences are shown in Box 17.22.

Dependent oedema accumulates predominantly in the lower limbs in adults, extending to the genitalia and lower abdomen as it becomes more severe. In the morning, the upper limbs and face may be more affected. In children, ascites occurs early and oedema is often seen only in the face. Blood volume may be normal, reduced or increased. Avid renal sodium retention is an early and universal feature; the mechanisms are shown in Figure 16.5 (p. 432).

The diseases that cause nephrotic syndrome all affect the glomerulus (see Fig. 17.27, p. 500), affecting podocytes either directly, or indirectly by causing scarring or deposition of exogenous material (e.g. matrix proteins or amyloid deposits). In children, because minimal change glomerulonephritis is the most common diagnosis, initial management usually includes administration of high-dose corticosteroids. In older patients, and in children where this therapy is unsuccessful, a renal biopsy is required unless there is strong evidence for a specific aetiology (e.g. a long history of diabetes with other microvascular complications and a demonstrated progression from microalbuminuria, and with hypertension but no haematuria). Supportive management in patients with nephrotic syndrome is described in Box 17.22.

Oedema

Accumulation of interstitial fluid causes 'pitting' oedema, that leaves an indentation after pressure on the affected area. This results from disruption of the Starling forces dictating fluid transit across capillary basement membranes (Box 17.23). It is usually influenced by the effect of gravity on venous hydrostatic pressure and so accumulates in the ankles during the day and improves overnight ('dependent' oedema). Non-pitting oedema may reflect protein deposition—for example, in myxoedema associated with hypothyroidism (p. 741)—and also occurs in chronic

17.22 Consequences of the nephrotic syndrome and their management

Feature	Mechanism	Consequence	Management
Hypoalbuminaemia	Urinary protein losses exceed synthetic capacity of liver	Reduced oncotic pressure Oedema	Diuretics and a low-sodium diet*
Avid sodium retention	Secondary hyper-aldosteronism Additional poorly characterised intra-renal mechanisms	Oedema	
Hypercholesterolaemia	Non-specific increase in lipoprotein synthesis by liver in response to low oncotic pressure	High rate of atherosclerosis	Lipid-lowering drugs (e.g. HMG CoA reductase inhibitors, p. 455)
Hypercoagulability	Relative loss of inhibitors of coagulation (e.g. antithrombin III, protein C and S) and increase in liver synthesis of procoagulant factors	Venous thromboembolism	Consider prophylaxis in all patients with chronic or severe nephrotic syndrome
Infection	Hypogammaglobulinaemia (urinary losses)	Pneumococcal infection	Consider vaccination

*Severe nephrotic syndrome may need very large doses of combinations of diuretics acting on different parts of the nephron (e.g. loop diuretic plus thiazide plus amiloride). In occasional patients with hypovolaemia, intravenous salt-poor albumin infusions may help to establish a diuresis, although efficacy is controversial. Over-diuresis risks secondary impairment of renal function through hypovolaemia.

17.23 Causes of oedema

Increased total extracellular fluid

- Congestive heart failure
- Renal failure
- Other hypervolaemic states: iatrogenic, Conn's syndrome etc.

High local venous pressure

- Deep venous thrombosis or venous insufficiency
- Pregnancy
- Pelvic tumour

Low plasma oncotic pressure/serum albumin

- Increased loss: nephrotic syndrome
- Decreased synthesis: liver failure
- Malnutrition/malabsorption

Increased capillary permeability

- Leakage of proteins into the interstitium, reducing the osmotic pressure gradient which draws fluid into the lymphatics and blood
- Local: infection/inflammation
- Systemic: severe sepsis
- Drug-related, e.g. calcium channel blockers

Lymphatic obstruction

- Infection: filariasis, lymphogranuloma venereum (pp. 366 and 422)
- Malignancy
- Radiation injury
- Congenital abnormality

lymphoedema. In developed countries the most common causes of oedema are local venous problems and heart failure (p. 543), but it is important to identify other causes.

Lower limb oedema is common in morbid obesity. Although venous obstruction often contributes, the oedema may be multifactorial: for example, being exacerbated by right heart failure caused by sleep apnoea.

Clinical assessment

A substantial volume (litres) of extracellular fluid may accumulate without any clinical signs. In adults dependent regions or immobile limbs are usually the first site of oedema formation, where it is easy to mistake the early signs of generalised oedema for a local problem. Ankle swelling is characteristic, but oedema develops over the sacrum in bed-bound patients. It rises higher up the lower limbs with increasing severity, to affect the genitalia and abdomen. Ascites is common and often an earlier feature in children or young adults, and in liver disease. Pleural effusions are common and can be a feature of any cause of generalised oedema. Facial oedema on waking is common in adults with low oncotic pressure oedema and in young patients. Features of intravascular volume depletion (tachycardia, postural hypotension) may occur when oedema is due to decreased oncotic pressure or increased capillary permeability. If oedema is localised—for example, to one ankle but not the other—then features of venous thrombosis, inflammation and lymphatic disease should be sought.

Investigations

The cause of oedema is usually apparent from the history and examination of the cardiovascular system and

abdomen, combined with testing the urine for protein and measuring the serum albumin level. Where ascites or pleural effusions in isolation are causing diagnostic difficulty, aspiration of fluid with measurement of protein and glucose, and microscopy for cells, will usually clarify the diagnosis (p. 659).

Management

Specific causes (e.g. venous thrombosis) should be treated. Diuretics are commonly used for oedema but are also commonly abused. When there is sodium retention and generalised oedema, restriction of sodium (and sometimes fluid) intake, along with diuretic treatment, is rational. Mild fluid retention will respond to a thiazide or to a low dose of a loop diuretic such as furosemide or bumetanide. However, in oedema caused by venous or lymphatic obstruction or by increased capillary permeability, diuretics are likely to be hazardous, as they will cause hypovolaemia with secondary hyperaldosteronism and rebound exaggeration of oedema. Local treatments, such as the use of compression either continuously (e.g. compression stockings) or intermittently (with a mechanical device), can be useful in these circumstances.

In nephrotic syndrome, renal failure and severe cardiac failure, very large doses of diuretics, sometimes in combination, may be required to achieve a negative sodium and fluid balance.

Hypertension

Hypertension is a very common feature of renal disease, and a particularly early manifestation of renovascular and some glomerular diseases. Renal mechanisms seem to be important in essential hypertension (p. 605), and most genetic disorders of blood pressure have been attributed to altered salt and water handling by the kidney. In renal interstitial disorders, increased sodium loss (through reduced reabsorption from glomerular filtrate) may lead to hypotension. However, as GFR declines, hypertension becomes an increasingly common feature. When renal function is replaced by dialysis, control of hypertension often becomes easier as salt and volume balance are controlled. Control of hypertension is very important in patients with renal impairment because of its close relationship with further decline of renal function (p. 490) and because of the exaggerated cardiovascular risk associated with CKD.

Acute renal failure

Acute renal failure (ARF; also referred to as acute kidney injury, or AKI) describes a sudden and usually reversible loss of renal function, which develops over days or weeks and is usually accompanied by a reduction in urine volume. When faced with an abnormally high creatinine it is important to establish if this is acute, acute on chronic, or chronic kidney disease. Previous measurements of renal function should be sought for comparison. A renal ultrasound demonstrating two small kidneys indicates chronicity.

There are many possible causes of ARF (Fig. 17.15) and it is frequently multifactorial. The clinical picture is

Fig. 17.15 Causes of acute renal failure.

often dominated by the underlying condition (e.g. septic shock, trauma). If the cause cannot be rapidly corrected and renal function restored, temporary renal replacement therapy may be required (p. 492).

Reversible pre-renal acute renal failure

Haemodynamic disturbances can produce acute renal dysfunction that may be reversed rapidly by prompt recognition and treatment.

Pathogenesis

The kidney can regulate its own blood flow and GFR over a wide range of perfusion pressures. When the perfusion pressure falls—as in hypovolaemia, shock, heart failure or narrowing of the renal arteries—the resistance vessels in the kidney dilate to facilitate flow. Vasodilator prostaglandins are important, and this mechanism is markedly impaired by NSAIDs (p. 518). If autoregulation of blood flow fails, the GFR can still be maintained by selective constriction of the post-glomerular (efferent) arteriole. This is mediated through the release of renin and generation of angiotensin II, which preferentially constricts this vessel. ACE inhibitors interfere with this response (p. 518).

More severe or prolonged underperfusion of the kidneys may lead to failure of these compensatory mechanisms and hence an acute decline in GFR. This leads to the formation of a low volume of urine which is concentrated (osmolality > 600 mOsm/kg) but low in sodium (< 20 mmol/l). These urinary changes may be absent in patients with pre-existing renal impairment or those who have received diuretics.

Clinical assessment

There may be marked hypotension and signs of poor peripheral perfusion, such as delayed capillary return. However, pre-renal ARF may occur without systemic hypotension, particularly in patients taking NSAIDs or ACE inhibitors (see above). Postural hypotension (a fall in blood pressure > 20/10 mmHg from lying to standing) is a valuable sign of early hypovolaemia.

The cause of the reduced renal perfusion may be obvious, but concealed blood loss can occur into the gastrointestinal tract, following trauma (particularly where there are fractures of the pelvis or femur) and into the pregnant uterus. Large volumes of intravascular fluid are lost into tissues after crush injuries or burns, or in severe inflammatory skin diseases or sepsis. Metabolic acidosis and hyperkalaemia are often present.

In sepsis most patients, once volume-resuscitated, have a vasodilated systemic circulation; this leads to a relative underfilling of the arterial tree and the kidney responds as it would to absolute hypovolaemia. When it is severe or prolonged, sepsis is an important cause of established ARF with acute tubular necrosis. The combination of sepsis with nephrotoxins such as NSAIDs is a common cause of ARF.

Management

- Establish and correct the underlying cause of the ARF.
- If hypovolaemia is present, restore blood volume as rapidly as possible (with blood, plasma or isotonic saline (0.9%), depending on what has been lost).
- Optimise systemic haemodynamics. Monitoring of the central venous pressure or pulmonary wedge pressure may aid in determining the rate of administration of fluid. Critically ill patients may require inotropic drugs to restore an effective blood pressure. Trials do not support a specific role for low-dose dopamine (Box 17.24).
- Correct metabolic acidosis:
 - Restoration of blood volume will correct acidosis by restoring kidney function.
 - Sodium bicarbonate (e.g. 50 mL of 8.4%) may be used if acidosis is severe to lessen hyperkalaemia.

Prognosis

If treatment is given sufficiently early, renal function will usually improve rapidly; in such circumstances residual renal impairment is unlikely. In some cases, however, treatment is ineffective and renal failure becomes established.

EBM 17.24 Low-dose dopamine in acute renal failure

'Dopamine at low, 'renal' doses has been used in the belief that it may increase renal blood flow in critically ill patients (as it does in normal individuals) and prevent ARF. However, meta-analysis of clinical trials does not support its use in patients with, or at risk of, acute renal failure.'

• Friedrich JO, et al. *Ann Intern Med.* 2005; 142(7):510–524.

Established acute renal failure

Established ARF may develop following severe or prolonged underperfusion of the kidney (pre-renal ARF), when the histological pattern of acute tubular necrosis is usually seen. In patients without an obvious cause of pre-renal ARF, alternative 'renal' and 'post-renal' causes must be considered (Box 17.25 and Fig. 17.15).

17.25 Differential diagnosis of acute renal failure in a haemodynamically stable, non-septic patient**Urinary tract obstruction (see Fig. 17.9, p. 473)**

- Suggested by a history of loin pain, haematuria, renal colic or difficulty in micturition but often clinically silent
- Can usually be excluded by renal ultrasound: essential in any patient with unexplained ARF
- Prompt relief of the obstruction restores renal function

Drugs and toxins

- Poisoning, e.g. paraphenylenediamine hair dye, *Cortinarius* mushrooms, snake bite, paraquat, paracetamol
- Therapeutic agents: direct toxicity (aminoglycosides, amphotericin); or haemodynamic effects (NSAIDs, ACE inhibitors), often with other factors
- Auto-toxins: rhabdomyolysis releasing myoglobin; myeloma cast nephropathy

Vascular event

- Due to major vascular occlusion or small-vessel diseases (pp. 496–499), notably malignant hypertension and haemolytic uraemic syndrome/thrombotic thrombocytopenic purpura
- May be precipitated by ACE inhibitors in critical renal artery stenosis (p. 497)
- Urine usually shows minimal abnormalities but there may be haematuria in renal infarction

Rapidly progressive glomerulonephritis (RPGN) (p. 504)

- Typically, significant (dipsticks 3+) haematuria and minor proteinuria (often with red cell casts or 'glomerular' red cells)
- Sometimes associated with systemic features (e.g. systemic vasculitis, systemic lupus erythematosus (SLE), Goodpasture's (anti-GBM) disease)
- Useful blood tests include: antineutrophil cytoplasmic antibodies (ANCA), antinuclear antibodies (ANA), anti-GBM antibodies, complement, immunoglobulins
- Renal biopsy shows aggressive glomerular inflammation, usually with crescent formation

Acute interstitial nephritis (p. 504)

- Usually caused by an adverse drug reaction
- Characterised by small amounts of blood and protein in urine, often with leucocyturia
- Kidneys are normal size
- Requires cessation of drug and often prednisolone treatment

Acute tubular necrosis (ATN)

Acute necrosis of renal tubular cells (see Fig. 17.31B, p. 505) may result from ischaemia or nephrotoxicity, caused by chemical or bacterial toxins, or a combination of these factors. Drugs which are toxic to renal tubular cells include the aminoglycoside antibiotics, such as gentamicin, the cytotoxic agent cisplatin, and the antifungal drug amphotericin B.

Dead tubular cells may shed into the tubular lumen, leading to tubular obstruction. Focal breaks in the tubular basement membrane and interstitial oedema develop. Although tubular cell damage is the dominant phenomenon under the microscope, there may also be profound alterations in the renal microcirculation.

Recovery from ATN

Fortunately, tubular cells can regenerate and re-form the basement membrane. If the patient is supported during the regeneration phase, kidney function usually returns. During recovery, depending on the severity of the renal damage and the rate of recovery, there is often a diuretic phase in which urine output increases rapidly and remains excessive for several days before returning to normal. This is due in part to temporary loss of the medullary concentration gradient, which normally allows concentration of the urine in the collecting duct, and which depends on continued delivery of filtrate to the ascending limb of the loop of Henle and active tubular transport.

Features of established ARF

These reflect the causal condition, such as trauma, septicæmia or systemic disease, together with features of renal failure.

Urea and creatinine

The rate of rise in plasma urea and creatinine is determined by the rate of protein catabolism (tissue breakdown). In ARF associated with catabolic states, such as severe infections, major surgery or trauma, the daily rise in plasma urea often exceeds 5 mmol/L (30 mg/dL). At first the patient may feel well but, unless dialysis is instituted, the clinical features described below eventually appear.

Alterations in urine volume

Patients are usually oliguric (urine volume < 500 mL daily). Anuria (complete absence of urine) is rare and usually indicates acute urinary tract obstruction or vascular occlusion. In about 20% of cases, the urine volume is normal or increased, but with a low GFR and a reduction of tubular reabsorption (non-oliguric ARF). Excretion is inadequate despite good urine output, and the plasma urea and creatinine increase.

Disturbances of fluid, electrolyte and acid–base balance

Hyperkalaemia is common, particularly with massive tissue breakdown, haemolysis or metabolic acidosis (p. 443). Dilutional hyponatraemia occurs if the patient has continued to drink freely despite oliguria or has received inappropriate amounts of intravenous dextrose. Metabolic acidosis develops unless prevented by loss of hydrogen ions through vomiting or aspiration of gastric contents. Hypocalcaemia, due to reduced renal production of 1,25-dihydroxycholecalciferol, is common.

Fig. 17.16 Pulmonary oedema in acute renal failure. The appearances are indistinguishable from left ventricular failure but the heart size is usually normal. Blood pressure is often high.

Other features

- 'Uraemic' features include initial anorexia, nausea and vomiting followed by drowsiness, apathy, confusion, muscle-twitching, hiccups, fits and coma.
- Respiratory rate may be increased due to acidosis, pulmonary oedema or respiratory infection. Pulmonary oedema (Fig. 17.16) may result from the administration of excessive amounts of fluids relative to urine output and because of increased pulmonary capillary permeability.
- Anaemia is common, due to excessive blood loss, haemolysis or decreased erythropoiesis. Bleeding is more likely because of disordered platelet function and disturbances of the coagulation cascade. Spontaneous gastrointestinal haemorrhage may occur, often late in the illness, although this is less common with effective dialysis and the use of agents that reduce gastric acid production.
- Severe infections may complicate ARF because humoral and cellular immune mechanisms are depressed.

Management

In the absence of dialysis, the most common causes of death are hyperkalaemia and pulmonary oedema, followed by infection and uraemia itself. Initial management is targeted at these priorities.

Hyperkalaemia

Hyperkalaemia (a plasma K^+ concentration > 6 mmol/L) must be treated immediately, as described in Box 16.17 (p. 441), to prevent life-threatening cardiac arrhythmias.

Immediate fluid management

Circulating blood volume should be optimised to ensure adequate renal perfusion, with monitoring of central

venous pressure as required. Patients with pulmonary oedema or anuria usually require dialysis to remove sodium and water. Temporary respiratory support (continuous positive airways pressure (CPAP), intermittent positive pressure ventilation (IPPV)) may be life-saving. Severe acidosis can be ameliorated with sodium bicarbonate if volume status allows.

Addressing the underlying cause of the ARF

This may be obvious or revealed by simple initial investigations (e.g. ultrasound showing urinary tract obstruction). If not, a range of investigations, including renal biopsy, may be necessary (Boxes 17.27 and 17.28). In many cases, more than one factor contributes to the renal dysfunction.

There is no specific treatment for ATN, other than restoring renal perfusion. Intrinsic renal disease may require specific therapy; for example, immunosuppressive drugs are of value in some causes of rapidly progressive glomerulonephritis (p. 504), and plasma infusion and plasma exchange may be indicated in microangiopathic diseases (p. 498).

'Post-renal' obstruction should be relieved urgently. If pelvic or ureteric dilatation is found and not explained by bladder outlet obstruction, percutaneous nephrostomy is undertaken to decompress the urinary system (p. 467). Injection of dye through the nephrostomy tube (antegrade pyelography) reveals the site of the obstruction. Once obstruction has been relieved and blood chemistry is returning to normal, the underlying cause is treated whenever possible.

Fluid and electrolyte balance

After initial resuscitation, daily fluid intake should equal urine output plus an additional 500 mL to cover insensible losses; such losses are higher in febrile patients and in tropical climates. If abnormal losses occur, as in diarrhoea, additional fluid and electrolyte replacement is required. Measurement of fluid intake and urine output is subject to error so the patient should be weighed daily. Large changes in body weight, the development of oedema or signs of fluid depletion indicate that fluid intake should be reassessed.

17.26 Acute renal failure in old age

- **Physiological change:** nephrons decline in number with age and average GFR falls progressively.
- **Creatinine:** as muscle mass falls with age, less creatinine is produced each day. Serum creatinine can be misleading as a guide to renal function.
- **Renal tubular function:** declines with age, leading to loss of urinary concentrating ability.
- **Drugs:** increased drug prescription in older people (e.g. diuretics, ACE inhibitors and NSAIDs) may contribute to risk of ARF.
- **Causes:** infection, renal vascular disease, prostatic obstruction, hypovolaemia and severe cardiac dysfunction are common.
- **Mortality:** rises with age, primarily because of comorbid conditions.

17.27 Suggested investigations in all patients with established acute renal failure

Initial test	Interpretation and further tests	Initial test	Interpretation and further tests
Urea and creatinine	Compare to previous results. Chronically abnormal in CKD (see Box 17.30)	Urine microscopy	Casts or dysmorphic red cells suggest glomerulonephritis Leucocytes suggest infection/interstitial nephritis Crystals can be characteristic of drugs or uric acid
Electrolytes	If potassium > 6 mmol/L, treat urgently (p. 441)	Renal ultrasound	Hydronephrosis ± enlarged bladder in post-renal obstruction: request prostate-specific antigen (PSA) and imaging of prostate and urinary tract Small kidneys suggest CKD (see Box 17.30) Asymmetric kidneys in renovascular or developmental disease: consider renal artery imaging
Calcium and phosphate	Low calcium with high phosphate may indicate CKD (see Box 17.30) Abnormal in rhabdomyolysis: measure creatine kinase		
Albumin	Low albumin in nephrotic syndrome (see urinalysis below) Low albumin in sepsis: take blood cultures		
Full blood count	Anaemia may indicate CKD (see Box 17.30) or haemolysis in thrombotic microangiopathy: request blood film and lactate dehydrogenase (LDH) Low platelets and abnormal coagulation in disseminated intravascular coagulation, including in sepsis: take blood cultures	Cultures	Blood, urine, wounds etc. as appropriate Treat all infections
Clotting screen		Chest X-ray	Pulmonary oedema in fluid overload Globular heart in pericardial (uraemic) effusion: perform echocardiogram 'Bat wing' appearance with normal heart size (± low Hb) may suggest pulmonary haemorrhage: measure CO transfer factor Fibrotic change in systemic inflammatory disease with lung and kidney involvement: request pulmonary function and high-resolution CT
C-reactive protein (CRP)	Erythrocyte sedimentation rate (ESR) is misleading in renal failure High CRP may indicate sepsis or inflammatory disease	Serology	HIV and hepatitis serology is urgent if dialysis is needed
Urinalysis	Less reliable in an oliguric catheterised patient. Seek earlier results if possible Marked haematuria suggests severe glomerulonephritis or bladder/obstructive lesion Heavy proteinuria in glomerular disease: measure PCR or ACR	ECG	If patient is > 40 yrs or has electrolyte abnormalities or risk of cardiac disease

17.28 Suggested investigations in established acute renal failure in particular circumstances

Possibility	Consider
Vascular occlusion (Of aorta, or renal artery to single kidney); pointers include newly missing pulses, complete anuria	Kidney size may be normal if occlusion acute Urgent arteriography Doppler ultrasound
Malignant hypertension/scleroderma If very high blood pressure; often some rbc fragments on blood film and haemolysis	Clinical features; examine fundi, previous BP values Autoantibodies to extractable nuclear antigens
Systemic inflammatory disease Pointers include suggestive history, multi-organ involvement, rash and evidence of glomerular disease	Infection as a differential diagnosis, especially endocarditis or tuberculosis Opportunity for urgent treatment; discuss with nephrologist Complement (see Box 17.41), antineutrophil cytoplasmic antibodies (ANCA), antinuclear factor (ANF), anti-GBM, cryoglobulins and tissue biopsy
Glomerular disease Pointers include substantial haematuria or proteinuria	All tests for systemic inflammatory disease above <i>Plus</i> urgent renal biopsy, unless cause is already known
Interstitial nephritis Consider if urinary abnormalities minor but leucocytes present, exposure to possible causes, usually non-oliguric in early stages	Detailed history and timing of drug exposures Eosinophilia and urinary eosinophils Renal biopsy Uric acid if tumour lysis possible
Myeloma kidney Features of interstitial disease but cast formation often acute, so patients often oliguric	Other evidence of myeloma: blood count, serum calcium, skeletal lesions, bone marrow. However, renal disease can occur without overt myeloma Urinary light chains (serum paraproteins are very common and usually incidental unless at very high level) Renal biopsy
Other infections E.g. leptospirosis, hantavirus, syphilis, post-streptococcal glomerulonephritis	Serology, e.g. anti-streptolysin O titre

Since sodium and potassium are retained, intake of these should be restricted.

Protein and energy intake

In patients in whom dialysis is likely to be avoided, accumulation of urea is slowed by dietary protein restriction (to about 40 g/day) and by suppression of protein catabolism by giving as much energy as possible in the form of fat and carbohydrate. Patients treated by dialysis may have more dietary protein (e.g. 1 g/kg protein daily, 10–12 g nitrogen).

It is important to give adequate energy and nitrogen to hypercatabolic patients (e.g. sepsis, burns). Enteral or parenteral nutrition (pp. 123–124) may be required. However, tube or parenteral feeding may require large fluid volumes.

Infection control

Patients with ARF are at substantial risk of intercurrent infection. Regular clinical examination and microbiological investigation (Ch. 6), as clinically indicated, are required to diagnose and treat this complication promptly.

Drugs

Vasoactive drugs such as NSAIDs and ACE inhibitors may prolong ARF and they should usually be avoided. Many drugs are excreted by the kidneys and dose adjustment may be required.

Renal replacement therapy (p. 492)

This may be required as supportive management in ARF.

Recovery from ARF

This is usually heralded by a gradual return of urine output and subsequently a steady improvement in plasma biochemistry. Some patients, primarily those with ATN or after relief of chronic urinary obstruction, develop a 'diuretic phase'. Fluid should be given to replace the urine output as appropriate. Supplements of sodium chloride, sodium bicarbonate, potassium chloride, and sometimes phosphate, may be needed to compensate for increased urinary losses. After a few days urine volume falls to normal as the concentrating mechanism and tubular reabsorption are restored.

Prognosis

In uncomplicated ARF, such as that due to simple haemorrhage or drugs, mortality is low even when renal replacement therapy is required. In ARF associated with serious infection and multiple organ failure, mortality is 50–70%. Outcome is usually determined by the severity of the underlying disorder and other complications, rather than by renal failure itself.

Chronic kidney disease (chronic renal failure)

Chronic kidney disease (CKD) refers to an irreversible deterioration in renal function which classically develops over a period of years (see Box 17.3, p. 466). Initially, it is manifest only as a biochemical abnormality. Eventually, loss of the excretory, metabolic and endocrine functions of the kidney leads to the clinical symptoms and signs of renal failure, which are referred

to as uraemia. When death is likely without renal replacement therapy, it is called end-stage renal disease/failure (ESRD or ESRF). The social and economic consequences of CKD are considerable. In the UK, over 44 000 patients (725 per million) were kept alive by renal replacement therapy at the end of 2006 and over 110 new patients per million of the adult population are accepted for long-term dialysis treatment each year. Of these, 50% were aged over 65. The incidence of CKD is much higher in some countries due to differences in regional and racial incidences of disease, as well as differences in medical practice. For example, in the USA, incident rates are over 350 per million population, with nearly half of these patients having a primary diagnosis of diabetes mellitus.

Aetiology

Common causes of ESRD are shown in Box 17.29. The underlying diagnosis is not always established, especially amongst the large number of elderly patients with moderate GFR reductions (stage 3 CKD; see Box 17.3, p. 466). Many patients diagnosed at a late stage have bilateral small kidneys; renal biopsy is rarely undertaken in this group since it is more risky, less likely to provide a histological diagnosis because of the severity of damage, and unlikely to indicate treatment that would improve renal function.

17.29 Common causes of end-stage renal failure		
Disease	Proportion	Comments
Congenital and inherited	5%	E.g. polycystic kidney disease, Alport's syndrome
Renal artery stenosis	5%	
Hypertension	5–20%	
Glomerular diseases	10–20%	IgA nephropathy is most common
Interstitial diseases	20–30%	
Systemic inflammatory diseases	5–10%	e.g. SLE, vasculitis
Diabetes mellitus	20–40%	Large racial and geographical differences
Unknown	5–20%	

Clinical assessment

Chronic kidney disease may present as a raised blood urea and creatinine found during routine examination, often accompanied by hypertension, proteinuria or anaemia. The great majority of patients with slowly progressive disease are asymptomatic until GFR falls below 30 mL/min/1.73 m² (stage 4 or 5). Nocturia, due to the loss of concentrating ability and increased osmotic load per nephron, can be an early symptom. Thereafter, symptoms and signs may develop in almost every body system (Fig. 17.17), and typically include tiredness or breathlessness. In ESRD (stage 5) there may be pruritus, anorexia, nausea and vomiting. Later, hiccups, unusually deep respiration related to metabolic acidosis (Kussmaul's respiration), muscular twitching, fits, drowsiness and coma ensue.

Fig. 17.17 Physical signs in advanced chronic kidney disease. (*Features of renal replacement therapy)

Investigation and management of stages 1–3 CKD

The great majority of patients with CKD stages 1–3 will never develop ESRD—which is fortunate, as they may include 10% of the adult population in developed nations. The large numbers are mainly due to the steep increase in the prevalence of CKD in elderly patients, particularly over the age of 70. However, patients with proteinuria, microalbuminuria or $\text{GFR} < 50 \text{ mL/min/1.73 m}^2$ are at increased cardiovascular risk.

Recommended investigations in this group are shown in Box 17.30 and management should include:

- blood pressure control: maximum target 130/80 mmHg, reduced to 125/75 mmHg in diabetes mellitus, and anyone with an elevated PCR or ACR
- use of ACE inhibitors or angiotensin receptor blockers (ARBs) in those with proteinuria
- lipid management (pp. 454–456)
- lifestyle advice: smoking, exercise, diet and weight.

Referral to a nephrologist is most appropriate for patients with potentially treatable underlying disease or those who are likely to progress to ESRD:

- young age
- more severe renal damage: in the UK, referral to a nephrologist is recommended at CKD stage 4 (in the absence of other indications)
- deteriorating renal function (e.g. GFR fall $> 5 \text{ mL/min/1.73 m}^2$ in 1 year, or $> 10 \text{ mL/min/1.73 m}^2$ over 5 years): monitoring can be reduced to annual if disease is stable or very slowly progressive

- proteinuria: $\text{PCR} > 100 \text{ mg/mmol}$ or $\text{ACR} > 70 \text{ mg/mmol}$ has been suggested as a referral threshold, but this should be interpreted with reference to age, comorbidity and other factors
- haematuria: may be a marker for inflammatory nephritis.

Investigation and management of progressive and stage 4+ CKD

Box 17.30 suggests core investigations. The aims of investigation and management are to:

- Identify the underlying renal disease where possible. Additional investigations from Box 17.28 may be relevant, as the cause may be amenable to specific therapy, e.g. immunosuppression in some types of glomerulonephritis.
- Identify reversible factors which are making renal function worse, such as urinary tract obstruction, hypotension due to drug treatment, salt and water depletion, or nephrotoxic medications.
- Prevent further renal damage.
- Limit the adverse effects of the loss of renal function.
- Address any associated cardiovascular risk/disease.
- Institute renal replacement therapy (dialysis, transplantation, pp. 492 and 495) when appropriate.

Retarding the progression of CKD

The rate of deterioration in renal function varies between patients but is relatively constant for an individual patient. A plot of GFR , or of the reciprocal of

17.30 Suggested investigations in chronic kidney disease	
Initial tests	Interpretation
Urea and creatinine	To assess stability/progression: compare to previous results
Urinalysis and quantification of proteinuria	Haematuria and proteinuria may indicate cause. Proteinuria indicates risk of progressive CKD requiring preventive ACE inhibitor or ARB therapy
Electrolytes	To identify hyperkalaemia and acidosis
Calcium, phosphate, parathyroid hormone	To assess renal osteodystrophy
Albumin	Low albumin: consider malnutrition, inflammation
Full blood count (\pm Fe, ferritin, folate, B_{12})	If anaemic, exclude common non-renal explanations then manage as renal anaemia
Lipids, glucose \pm HbA1c	Cardiovascular risk high in CKD: treat risk factors aggressively
Renal ultrasound	Only if there are urinary symptoms (to exclude obstruction) or progressive CKD Small kidneys suggest chronicity Asymmetric renal size suggests renovascular or developmental disease
Hepatitis and HIV serology	If dialysis or transplant is planned Hepatitis B vaccination recommended if seronegative
ECG	If patient is > 40 yrs or hyperkalaemic, or there are risk factors for cardiac disease
Other tests	Consider relevant tests from Boxes 17.27 and 17.28, especially if the cause of CKD is unknown

the plasma creatinine concentration against time (Fig. 17.18), predicts when dialysis will be required and detects any unexpected worsening of kidney disease. It can also be used to monitor the success of interventions.

Control of blood pressure

Lowering of blood pressure slows the rate at which renal function declines in CKD, independently of the agent used (Box 17.31). No threshold for this effect has been found; reduction of any level of blood pressure is beneficial. Various target blood pressures have been suggested: for example, 130/80 mmHg for CKD alone, lowered to 125/75 mmHg for those with proteinuria > 1 g/day (PCR > 100 mg/mmol or ACR > 70 mg/mmol). Achieving these targets often requires multiple drugs and may be limited by toxicity or non-compliance. The high incidence of left ventricular hypertrophy, heart failure and occlusive vascular disease in patients with long-standing renal disease also justifies vigorous efforts to control blood pressure.

Proteinuria

There is a clear relationship between the degree of proteinuria and the rate of progression of renal disease, and strong evidence that reducing proteinuria reduces renal risk. ACE inhibitors and ARBs are more effective at reducing proteinuria and retarding the progression of kidney disease than other therapies which lower systemic blood pressure to a similar degree (Box 17.32), even though their effect on glomerular perfusion pressure often causes an immediate reduction in GFR when therapy is initiated (up to 20% reduction is often regarded as acceptable). ACE inhibitors also reduce cardiovascular events and all cause mortality in CKD patients. ACE inhibitors and/or ARBs should be used, if tolerated (check creatinine and potassium), in all patients with incipient or overt diabetic nephropathy or PCR > 50 mg/mmol (ACR > 30 mg/mmol), independently of the presence of hypertension.

Fig. 17.18 Plot of the reciprocal of serum creatinine concentration against time in a patient with type 1 diabetes mellitus. After approximately 6 years of monitoring (blue arrow) he entered an aggressive treatment programme aimed at optimising blood pressure and glycaemic control. The reduction in blood pressure was accompanied by a fall in proteinuria (protein:creatinine ratio, PCR; mg/mmol) and a stabilisation in renal function.

EBM 17.31 Blood pressure lowering and progression of chronic kidney disease

'In an analysis of 20 randomised controlled trials, including over 50 000 patients with CKD, the risk of ESRD reduced as BP was lowered. The group with the highest reduction in blood pressure (-6.9 mmHg (95% CI -9.1 to -4.8)) had a relative risk of ESRD of 0.74 (0.59 – 0.92).'

• Casas JP, et al. *Lancet* 2005; 366:2026–2033.

EBM 17.32 Renin–angiotensin system blockade in chronic kidney disease

'ACE inhibitors and ARBs reduce proteinuria and slow the decline in GFR in both diabetic and non-diabetic patients with hypertension, CKD and proteinuria to a greater degree than that seen with blood pressure reduction alone.'

• Scottish Intercollegiate Guidelines Network 103: Diagnosis and management of chronic kidney disease.

Dietary and lifestyle interventions

Although progressive renal disease can be retarded by restricting dietary protein in animals, results are less clear-cut in humans. Low-protein diets are difficult to adhere to and carry a risk of malnutrition. This remains a controversial area but, for most patients living in areas where renal replacement therapy is available, severe protein restriction is not recommended. Dietetic advice should be aimed at preventing excessive consumption of protein and, when approaching ESRD, target an adequate intake of calories to prevent malnutrition.

Smoking cessation also slows the decline in renal function. Exercise and weight loss may reduce proteinuria.

Limiting the adverse effects of CKD*Anaemia*

Anaemia is common; it usually correlates with the severity of kidney disease and contributes to many of the non-specific symptoms of CKD. Untreated, haemoglobin can be as low as 50 – 70 g/L in CKD stage 5. Several mechanisms are implicated, including:

- relative deficiency of erythropoietin
- diminished erythropoiesis due to toxic effects of uraemia on marrow precursor cells
- reduced red cell survival
- increased blood loss due to capillary fragility and poor platelet function
- reduced dietary intake and absorption and utilisation of iron.

In patients with polycystic kidneys, anaemia is often less severe or absent, while in some disorders it appears disproportionately severe for the degree of renal failure. This may be because of the effects of these disorders on the interstitial fibroblasts that secrete erythropoietin.

Recombinant human erythropoietin and other erythropoiesis-stimulating agents (ESAs) are effective in correcting the anaemia of CKD and improve the associated morbidity. However, effects on mortality have not been confirmed and correcting haemoglobin to normal levels may carry some extra risk, including hypertension and thrombosis (e.g. of arteriovenous fistulas used for haemodialysis). The target haemoglobin is usually

between 100 and 120 g/L. ESAs are less effective in the presence of iron deficiency, active inflammation or malignancy, or in patients with aluminium overload, which may occur in dialysis.

Fluid and electrolyte balance

Fluid retention is common in advanced CKD. Disproportionate fluid retention in milder CKD, sometimes leading to episodic pulmonary oedema, is particularly associated with renal artery stenosis. Good practice is to limit sodium intake (e.g. 100 mmol/day), for its effects on both fluid balance and blood pressure. Loop diuretics are often also required.

However, some patients with so-called 'salt-wasting' disease may require a high sodium and water intake, including supplements of sodium salts, to prevent fluid depletion and worsening of renal function. This most often occurs in patients with renal cystic disease, obstructive uropathy, reflux nephropathy or other tubulo-interstitial diseases, and is not seen in patients with primary glomerular disease.

If hyperkalaemia occurs, drug therapy should be reviewed, e.g. to avoid potassium-sparing diuretics, ACE inhibitors and ARBs. Correction of acidosis and calcium resonium therapy may be helpful, but limiting potassium intake (e.g. to 70 mmol/day) may be necessary in late CKD.

Acidosis

Declining renal function is associated with metabolic acidosis (p. 443), which is often asymptomatic. Acidosis is associated with increased tissue catabolism and decreased protein synthesis, and may exacerbate bone disease and rate of decline of renal function.

The plasma bicarbonate should be maintained > 22 mmol/L by giving sodium bicarbonate supplements (starting dose of 1 g 8-hourly, increasing as required). The increased sodium intake may induce hypertension or oedema; calcium carbonate (up to 3 g daily) is an alternative that is also used to bind dietary phosphate.

Cardiovascular disease and lipids

CKD is an independent risk factor for occlusive cardiovascular disease. Atherosclerosis is common and may be accelerated by hypertension. Medial vascular calcification, accelerated by high phosphate levels, may develop and is associated with vascular rigidity and occlusion. Left ventricular hypertrophy is frequent in ESRD and may account for many presumed arrhythmic deaths in this group. Pericarditis is common in untreated or inadequately treated ESRD. It may lead to pericardial tamponade and, later, constrictive pericarditis.

Hypercholesterolaemia is almost universal in patients with significant proteinuria, and increased triglyceride levels are also common in patients with CKD. HMG CoA reductase inhibitors (p. 455) achieve substantial reductions in lipids in CKD. In addition to their cardioprotective effect, there is some evidence that control of dyslipidaemia with statins slows the rate of progression of renal disease. Trials to establish the benefits in this patient group are under way.

Renal osteodystrophy

This metabolic bone disease which accompanies CKD consists of a mixture of osteomalacia, hyperparathyroid bone disease (osteitis fibrosa), osteoporosis and osteosclerosis (Fig. 17.19). Osteomalacia (p. 1121) results

Fig. 17.19 Pathogenesis of renal osteodystrophy. The net result of decreased 1,25(OH)₂ cholecalciferol levels and increased parathyroid hormone (PTH) levels in the presence of high [PO₄] is bone which exhibits increased osteoclastic activity and increased osteoid as a consequence of decreased mineralisation.

from loss of the renal 1 α -hydroxylase enzyme, with failure to convert cholecalciferol (vitamin D) to its active metabolite, 1,25-dihydroxycholecalciferol, and hence diminished intestinal absorption of calcium, hypocalcaemia and reduction in the calcification of osteoid in bone. The parathyroid glands are stimulated by the low plasma calcium, and also by hyperphosphataemia consequent upon reduced urinary phosphate excretion in CKD and poor clearance by conventional haemodialysis. Secondary hyperparathyroidism in the presence of hyperphosphataemia causes osteitis fibrosa. In some patients tertiary (or autonomous) hyperparathyroidism develops, resulting in hypercalcaemia.

Secondary hyperparathyroidism is prevented by giving 1 α -hydroxylated vitamin D in patients with hypocalcaemia or high parathyroid hormone (PTH) levels (e.g. more than twice normal). The dose is adjusted to avoid hypercalcaemia. Calcimimetic agents can also reduce PTH via a direct action on the parathyroid glands. In tertiary hyperparathyroidism, parathyroidectomy is sometimes required.

Hyperphosphataemia is controlled by dietary restriction of foods with high phosphate content (milk, cheese, eggs) and the use of phosphate-binding drugs administered with food to prevent absorption (e.g. calcium carbonate, aluminium hydroxide and lanthanum carbonate). Polymer-based phosphate binders are also available.

Other adverse effects

Cellular and humoral immunity are impaired in CKD, with increased susceptibility to infection. Infections

are the second most common cause of death in dialysis patients, after cardiovascular disease. Many are staphylococcal infections associated with access devices but some are common infections such as pneumonias.

There is an increased bleeding tendency in CKD which manifests in patients with advanced disease as cutaneous ecchymoses and mucosal bleeds. Platelet function is impaired and bleeding time prolonged. Adequate dialysis treatment partially corrects the bleeding tendency in those with severe uraemia, but dialysis patients have been shown to be at significantly increased risk of complications from anticoagulant therapy.

Generalised myopathy in CKD is due to a combination of poor nutrition, hyperparathyroidism, vitamin D deficiency and disorders of electrolyte metabolism. Muscle cramps are common. The 'restless leg syndrome', in which the patient's legs are jumpy during the night, may be troublesome.

Neuropathy may appear late in the course of CKD but may improve or even resolve once dialysis is established. Sensory neuropathy may cause paraesthesiae. Motor neuropathy may present as foot drop.

A number of hormonal abnormalities may be present. In both sexes there is loss of libido and sexual function, related at least in part to hyperprolactinaemia (p. 788). The half-life of insulin is prolonged in CKD due to reduced tubular metabolism of insulin; insulin requirements may therefore decline in diabetic patients in advanced CKD. However, there is also relative insulin resistance and reduced appetite, so the scale of this effect is unpredictable.

Gastrointestinal manifestations are common at low GFRs. These include anorexia, nausea and vomiting, and a higher incidence of peptic ulcer disease. H_2 -receptor antagonists or proton pump inhibitors are used for established peptic ulcer disease in CKD, and as routine prophylaxis in ARF.

Depression is common in patients on or approaching renal replacement therapy, and support should be provided for both them and their relatives.

RENAL REPLACEMENT THERAPY

The facility to replace some functions of the kidney artificially by dialysis first became generally available in the mid-1960s and is now routine in patients with acute or chronic kidney failure. It does not replace the endocrine and metabolic functions of the kidney, but aims to maintain the plasma biochemistry (uraemic toxins, electrolytes and acid-base status) at acceptable levels. Dialysis can also remove fluid from the circulation (ultrafiltration) to maintain euvolaemia.

The original renal replacement therapy (RRT) was haemodialysis, and this is still the most common form of treatment. A variety of other types have been developed, particularly for unstable patients with ARF (Fig. 17.20).

Renal replacement in acute renal failure

The decision to institute RRT is made on an individual basis, taking account of other aspects of the patient's care. Guideline indications are as follows:

- **Hyperkalaemia.** A plasma potassium > 6 mmol/L is hazardous. Elevated plasma potassium can usually be reduced by medical measures in the short term (see Box 16.17, p. 441), and by early restoration of renal function if possible, but dialysis is otherwise often required.
- **Fluid overload and pulmonary oedema.** In patients with continued urine output, this may be controlled by careful fluid balance and use of diuretics, but in oliguric/anuric patients may be an indication for RRT.
- **Metabolic acidosis.** This will often occur together with hyperkalaemia and raise the plasma potassium further.
- **Increased plasma urea and creatinine.** Plasma urea > 30 mmol/L (180 mg/dL) and creatinine > 600 μ mol/L (6.8 mg/dL) are undesirable in ARF. At lower levels, if there is progressive biochemical deterioration, and particularly if there is little or no urine output, it may be appropriate to commence dialysis. There is a trend towards earlier institution of dialysis in ARF, although trials of very early dialysis in post-operative or septic patients with oliguria have not shown consistent benefit compared with the more conventional strategy above.
- **Uraemic pericarditis/uraemic encephalopathy.** These are features of severe untreated renal failure; they are uncommon in ARF but are strong indications for RRT.

The principal options for RRT in ARF are haemodialysis, high-volume haemofiltration, or continuous arteriovenous or venovenous haemofiltration. Peritoneal dialysis is less favoured, as it is less efficient and seldom achieves adequate biochemical control in catabolic patients.

Intermittent haemodialysis

This modality offers the best rate of small solute clearance. In previously undialysed patients with ARF and elevated plasma urea, haemodialysis should be started gradually because of the risk of confusion and convulsions due to cerebral oedema (dialysis disequilibrium). Typically, 1 hour of treatment is prescribed initially. Subsequently, patients with ARF who are haemodynamically stable can be treated by 4–5 hours of haemodialysis on alternate days, or 2–3 hours every day if they are severely catabolic. For patients at risk of bleeding, epoprostenol may be used instead of heparin for anticoagulation but can cause hypotension. For short dialyses or patients with abnormal clotting, it may be possible to avoid anticoagulation.

Haemofiltration

This may be either intermittent or continuous, with 1–2 L/hour of filtrate replaced (equivalent to a GFR of 15–30 mL/min); higher rates of filtration may be of benefit in patients with sepsis and multi-organ failure. In continuous, arteriovenous haemofiltration (CAVH) the extracorporeal blood circuit is driven by the arteriovenous pressure difference. Poor filtration rates and clotting of the filter are common and this treatment has fallen out of favour. Continuous venovenous haemofiltration (CVVH, Fig. 17.21) is pump-driven, providing a reliable extracorporeal circulation. Issues concerning anticoagulation are similar to those for haemodialysis, but may be more problematic because longer or continuous anticoagulation is necessary.

Renal replacement in end-stage renal disease (ESRD) (CKD stage 5)

When patients are known to have progressive CKD (see Box 17.3, p. 466) and are under regular clinic review, preparation for RRT should begin at least 12 months before the predicted start date. This involves psychological and social support, assessment of home circumstances and discussion about choice of treatment. The principal decisions required are whether to commence RRT or opt for conservative treatment (see below), the choice between haemodialysis and peritoneal dialysis (Box 17.33), and referral for renal transplantation. In view of the historical high incidence of viral transmission in dialysis units, all patients opting for RRT must be screened in advance for hepatitis B, hepatitis C and HIV, and have hepatitis B vaccine if they are not immune.

The timing of initiation of dialysis is not clear-cut. Typically, it is started when the patient has symptomatic advanced kidney disease but before the development of serious complications, often with a plasma creatinine of 600–800 μ mol/L (6.8–9.0 mg/dL) or an eGFR 8–10 mL/min/1.73 m². There is no evidence that early initiation improves survival and the decision to start is usually driven by a combination of patient symptoms and biochemistry.

Of patients starting dialysis in the UK, 77% are treated by haemodialysis and 23% by peritoneal dialysis. Mortality figures in the UK indicate 81% survival at 1 year (87% counted from day 90 of treatment) and 42% at 5 years. Mortality is strongly influenced by age; patients over 75 have an 18% survival at 5 years, whereas patients aged under 35 have an 87% survival at 5 years. Comorbid conditions such

Haemodialysis

There is bidirectional diffusion of solutes between plasma and dialysate across a semipermeable membrane following concentration gradients. The dialysate composition is chosen to achieve a suitable gradient. Fluid is removed by applying negative pressure to the dialysate side (ultrafiltration)

- Typical small solute clearance 160 mL/min
- Used in both acute and chronic renal failure

- **Access to the circulation** for haemodialysis or filtration is required. Arteriovenous fistulae, temporary or semi-permanent tunnelled central venous lines or arterio-venous shunts (e.g. Scribner shunt) may be used. The extracorporeal circuit requires anticoagulation, typically with heparin

Haemofiltration

There is filtration of water from plasma to ultrafiltrate across a more porous semipermeable membrane down a pressure gradient with removal of solutes by convection. 'Replacement' fluid of chosen electrolytic composition is added to the blood circuit after the filter. If fluid removal is required, less is replaced than filtered

- Typical small solute clearance (2 L/hr exchanges) 33 mL/min
- ? Less circulatory instability than haemodialysis
- Used mostly in acute renal failure

Peritoneal dialysis

This uses peritoneum as a semipermeable dialysis membrane. Solutes move down a concentration gradient, and water down an osmotic gradient achieved by using an osmolar compound (typically glucose) in the dialysis fluid

- **Access to the peritoneal cavity** via 'Tenckhoff' catheter
- **Continuous ambulatory peritoneal dialysis (CAPD)**: typically 4 exchanges of 2 L of fluid a day 4–6 hrs apart
- **Automated peritoneal dialysis (APD)**: uses a machine to perform exchanges overnight (8–10 hrs)
- Used mostly in chronic renal failure (CRF)

Transplantation

A functioning transplant replaces all of the functions of the failed kidneys

- Successful transplantation extends the life expectancy of patients with end-stage CKD
- Requires long-term use of immunosuppressives with attendant risks

Conservative management

Some patients may elect not to dialyse and can be actively supported to control the symptoms of ESRD

Fig. 17.20 Options for renal replacement therapy.

as diabetes mellitus (30% 5-year survival) and generalised vascular disease (34% 5-year survival) also have a strong influence. However, many patients lead normal and active lives, and patient survival for more than 20 years is commonplace in young patients without extrarenal disease.

Intermittent haemodialysis

This is the standard blood purification therapy in ESRD (Fig. 17.22). Vascular access is required; an arteriovenous fistula should be formed, usually in the forearm, up to a year before dialysis is contemplated, so that the fistula has time to develop. After 4–6 weeks, increased pressure

Fig. 17.21 Continuous venovenous haemofiltration (CVVH) on an intensive care unit. In this hypothermic patient the haemofilter and blood lines have been wrapped to reduce heat loss.

17.33 Comparison of haemodialysis and peritoneal dialysis

Haemodialysis	Peritoneal dialysis
Efficient 4 hrs three times per wk is usually adequate	Less efficient Four exchanges per day usually required, each taking 30–60 mins (continuous ambulatory peritoneal dialysis) or 8–10 hrs each night (automated peritoneal dialysis)
2–3 days between treatments	A few hours between treatments
Requires visits to hospital (although home treatment possible for some patients)	Performed at home
Requires adequate venous circulation for vascular access	Requires an intact peritoneal cavity without major scarring from previous surgery
Careful compliance with diet and fluid restrictions required between treatments	Diet and fluid less restricted
Fluid removal compressed into treatment periods; may cause symptoms and haemodynamic instability	Slow continuous fluid removal, usually asymptomatic
Infections related to vascular access may occur	Peritonitis and catheter-related infections may occur
Patients are usually dependent on others	Patients can take full responsibility for their treatment

Fig. 17.22 Haemodialysis. A patient receiving haemodialysis through a forearm subcutaneous (Brescia–Cimino) fistula. She subsequently received a live related transplant.

in the vein leading from the fistula causes distension and thickening of the vessel wall (arterialisation). Large-bore needles can then be inserted into the vein to provide access for each haemodialysis treatment. Preservation of arm veins is thus very important in patients with progressive renal disease who may require haemodialysis in the future. If this access is not possible, plastic cannulae in central veins can be used for short-term access.

Haemodialysis is usually carried out for 3–5 hours three times weekly, either at home or in an outpatient dialysis unit. The dialysis ‘dose’ required is adjusted to achieve a reduction in urea during dialysis (urea reduction ratio) of over 65%. Most patients notice an improvement in symptoms during the first 6 weeks of treatment. Plasma urea and creatinine are lowered by each treatment but do not return to normal. Studies of more frequent (e.g. daily) or longer (e.g. nocturnal) dialysis are under way. These may achieve better fluid balance and electrolyte control. Box 17.34 summarises some of the problems related to haemodialysis.

Haemodiafiltration

This technique uses a large pore membrane and combines the improved middle molecule clearance of haemofiltration with the higher small solute clearance of haemodialysis, but it is more expensive and long-term benefits are not yet established.

Peritoneal dialysis (PD)

Continuous ambulatory peritoneal dialysis (CAPD) involves insertion of a permanent Silastic catheter into the peritoneal cavity. Two litres of sterile, isotonic dialysis fluid are introduced and left in place for approximately 6 hours. Metabolic waste products diffuse from peritoneal capillaries into the dialysis fluid down a concentration gradient. The fluid is then drained and fresh dialysis fluid introduced, in a continuous four-times-daily cycle. The inflow fluid is rendered hyperosmolar by the addition of glucose; this results in net removal of fluid from the patient during each cycle (ultrafiltration).

17.34 Problems with haemodialysis			
Problem	Clinical features	Cause	Treatment
Hypotension during dialysis	Sudden ↓BP; often leg cramps; sometimes chest pain	Fluid removal and hypovolaemia	Saline infusion; exclude cardiac ischaemia; quinine may help cramp
Cardiac arrhythmias	↓BP; sometimes chest pain	Potassium and acid–base shifts	Check K ⁺ and arterial blood gases; review dialysis prescription; ?stop dialysis
Haemorrhage	Blood loss (overt or occult); ↓BP	Anticoagulation Venous needle disconnection	Stop dialysis; seek source; consider heparin-free treatment
Air embolism	Circulatory collapse; cardiac arrest	Disconnected or faulty lines and equipment malfunction	Stop dialysis
Dialyser hypersensitivity	Acute circulatory collapse	Allergic reaction to dialysis membrane or sterilisant	Stop dialysis; change to different artificial kidney
Emergencies between treatments			
Pulmonary oedema	Breathlessness	Fluid overload	Ultrafiltration ± dialysis
Systemic sepsis	Rigors; fever; ↓BP	Usually involves vascular access devices (catheter or fistula)	Blood cultures; antibiotics

The patient is mobile and able to undertake normal daily activities.

CAPD is particularly useful in young children, and in elderly patients with cardiovascular instability. Its long-term use may be limited by episodes of bacterial peritonitis and damage to the peritoneal membrane, but patients have been treated successfully for more than 10 years. Box 17.35 summarises some of the problems related to CAPD treatment.

The use of automated peritoneal dialysis (APD) is now widespread. This system is similar to CAPD but uses a mechanical device to perform the fluid exchanges during the night, leaving the patient free, or with only a single exchange to perform, during the day.

Conservative treatment of stage 5 CKD

In older patients with multiple comorbidity, 'conservative' treatment, aimed at limiting the adverse symptomatic effects of ESRD without commencing dialysis,

is increasingly viewed as a positive choice (Box 17.36). Current evidence suggests that these patients' survival without dialysis can be similar to equivalent cohorts opting for RRT, but they avoid the hospitalisation and interventions associated with dialysis. Patients are offered full medical, psychological and social support to optimise and sustain their existing renal function and ameliorate the consequences (e.g. erythropoietin treatment for anaemia) for as long as possible, and appropriate palliative care in the terminal phase of their disease. Many of these patients enjoy a good quality of life for several years. It is also appropriate to discontinue dialysis treatment, with the consent of the patient, and to offer conservative therapy and palliative care when quality of life on dialysis is clearly inadequate.

Renal transplantation

Renal transplantation offers the best chance of long-term survival and complete rehabilitation, and is the

17.35 Problems with continuous ambulatory peritoneal dialysis (CAPD)			
Problem	Clinical features	Cause	Treatment
CAPD peritonitis	Cloudy drainage fluid; abdominal pain and systemic sepsis are variable	Usually entry of skin contaminants via catheter; bowel organisms less common	Culture of peritoneal dialysis fluid Intraperitoneal antibiotics, e.g. tobramycin, vancomycin Catheter removal sometimes required
Catheter exit site infection	Erythema and pus around exit site	Usually skin organisms	Antibiotics; sometimes surgical drainage
Ultrafiltration failure	Fluid overload	Damage to peritoneal membrane, leading to rapid transport of glucose and loss of osmotic gradient	Replace glucose with synthetic poorly absorbed polymers for some exchanges (e.g. icodextrin)
Peritoneal membrane failure	Inadequate clearance of urea etc.	Scarring/damage to peritoneal membrane	Increase exchange volumes; consider automated peritoneal dialysis or switch to haemodialysis
Sclerosing peritonitis	Intermittent bowel obstruction Malnutrition	Unknown; typically occurs after many years	Switch to haemodialysis (may still progress) Surgery and tamoxifen may be used

17.36 Renal replacement therapy in old age

- **Quality of life:** age itself is not a barrier to good quality of life on RRT.
- **Coexisting cardiovascular disease:** older people are more sensitive to fluid balance changes, predisposing to hypotension during dialysis with rebound hypertension between dialyses. A failing heart cannot cope with fluid overload and pulmonary oedema develops easily.
- **Provision of treatment:** often only hospital-provided haemodialysis is suitable and older patients require more medical and nursing time.
- **Survival on dialysis:** difficult to predict for an individual patient, but old age plus substantial comorbidity are associated with poor median survival.
- **Withdrawal from dialysis:** a common cause of death in older patients with comorbid disease.
- **Transplantation:** relative risks of surgery and immunosuppression, and limited organ availability exclude most older people from transplantation.
- **Conservative therapy:** i.e. without dialysis but with adequate support; may be a popular option for patients at high risk of complications from dialysis, who have a limited prognosis and little hope of functional recovery.

most cost-effective treatment in patients with ESRD. It can restore normal kidney function and correct all the metabolic abnormalities of CKD. All patients should be considered for transplantation unless there are active contraindications (Box 17.37).

Kidney grafts may be taken from a cadaver or from a living donor. As described on pages 93–94, matching of a donor to a specific recipient is strongly influenced by immunological factors, since graft rejection is the major cause of transplant failure. ABO (blood group) compatibility between donor and recipient is required, and the degree of matching for major histocompatibility (MHC) antigens, particularly HLA-DR, influences the incidence of rejection. Further tests pre-transplantation include T- and B-cell cross-matching and tests for antibodies against HLA antigens. Positive tests predict early rejection.

In the transplant operation, the donor vessels are anastomosed to the recipient iliac artery and vein, and the donor ureter to the bladder (see Fig. 17.20; p. 493). Peri-operative problems include:

- **Fluid balance.** Careful matching of input to output is required.
- **Primary graft non-function.** Causes include hypovolaemia, preservation injury/acute tubular necrosis during storage and transfer, other pre-existing renal damage, hyperacute rejection, vascular occlusion and urinary tract obstruction.
- **Sepsis** (risks from operation compounded by uraemia and immunosuppression).

Once the graft begins to function, normal or near-normal biochemistry is usually achieved within days to weeks.

Management after transplantation

All transplant patients require regular life-long follow-up to monitor renal function and immunosuppression. Life-long immunosuppressive therapy (see Box 4.25, p. 94) is required to prevent rejection but it is more intensive in the early post-transplant period when the risk is

17.37 Contraindications to renal transplantation

Absolute

- Active malignancy: a period of at least 2 yrs of complete remission recommended for most tumours
- Active vasculitis or recent anti-GBM disease
- Severe heart disease
- Severe occlusive aorto-iliac vascular disease

Relative

- Age: while practice varies, transplants are not routinely offered to very young children (< 1 yr) or older people (> 75 yrs)
- High risk of disease recurrence in the transplant kidney
- Disease of the lower urinary tract: in patients with impaired bladder function, an ileal conduit may be considered
- Significant comorbidity

highest. A common regimen is triple therapy with prednisolone, ciclosporin or tacrolimus, and azathioprine or mycophenolate mofetil. Rapamycin is an alternative that can be introduced later. Antibodies to deplete or modulate specific lymphocyte populations are increasingly used; targeting the lymphocyte IL-2 receptor is particularly effective for preventing rejection. Acute rejection is usually treated by short courses of very high-dose corticosteroids in the first instance, although other more potent therapies, such as antilymphocyte antibodies or plasma exchange, can be used in resistant episodes.

Complications of immunosuppression include infections and malignancy (p. 94). Approximately 50% of white patients develop skin malignancy by 15 years after transplantation.

The prognosis after kidney transplantation has improved significantly. Recent UK statistics for transplants from cadaver donors indicate 96% patient survival and 92% graft survival at 1 year, and 87% patient survival and 82% graft survival at 5 years. Even better figures are obtained with living donor transplantation (88% graft survival at 5 years). Advances in immunosuppression have greatly improved results using genetically unrelated donors such as spouses.

RENAL VASCULAR DISEASES

Diseases which affect renal blood vessels may cause renal ischaemia, leading to acute or chronic kidney disease or secondary hypertension. The rising prevalence of atherosclerosis and diabetes mellitus in ageing populations has made renovascular disease an important cause of ESRD.

Large-vessel disease: renal artery stenosis

Presentations

Hypertension

Renal artery stenosis classically presents as hypertension if it affects a single kidney or as renal failure if it is bilateral. The hypertension is driven by activation of the renin-angiotensin system in response to renal ischaemia. In atherosclerotic renal artery disease, there is usually evidence of vascular disease elsewhere, particularly

17.38 Renal artery stenosis

Renal artery stenosis is more likely if:

- Hypertension is severe, or of recent onset, or difficult to control
- Kidneys are asymmetrical in size
- Flash pulmonary oedema occurs repeatedly
- There is peripheral vascular disease of lower limbs
- Renal function has deteriorated on ACE inhibitors

in the legs. The selection of hypertensive patients who warrant investigation for secondary hypertension is discussed on page 608. Factors which predict renovascular disease are shown in Box 17.38.

Deterioration of renal function on ACE inhibitors

When renal perfusion pressure drops, the renin-angiotensin-aldosterone system is activated and angiotensin II-mediated glomerular efferent arteriolar vasoconstriction maintains glomerular filtration pressure. ACE inhibitors or ARBs block this physiological response. A drop in GFR of > 20%, or a > 25% rise in creatinine, on ACE inhibitors raises the possibility of renal artery stenosis. This is not a sensitive diagnostic test, however.

Flash pulmonary oedema

Repeated episodes of acute pulmonary oedema associated with severe hypertension, occurring without other obvious cause (e.g. myocardial infarction, dysrhythmia, anaemia, thyrotoxicosis) in patients with normal or only mildly impaired renal and cardiac function, can occur in renal artery stenosis. This presentation is characteristic of bilateral renovascular disease because in unilateral disease salt and water retention are partly corrected by increased 'pressure natriuresis' in the normal kidney.

Acute renal infarction

Sudden occlusion of the renal arteries causes acute loin pain, usually with dipstick haematuria. It may be caused by local atherosclerosis (atheroembolic) or by thromboemboli from a distant source, e.g. mural cardiac thrombus. Bilateral occlusion (as in aortic occlusion—look for absent femoral pulses and reduced lower limb perfusion), or acute occlusion of the artery to a single kidney, will cause acute renal failure. Severe hypertension is common but not universal; presumably, some residual renal perfusion is required to generate renin release.

Aetiology

Reduction of renal blood flow is associated with > 70% narrowing of the artery, and commonly with a dilated region more distally (post-stenotic dilatation).

Atherosclerosis is the most common cause, especially in older patients. The characteristic lesion is an ostial stenosis that is associated with atherosclerosis within the aorta and affecting other major branches, particularly the iliac vessels. Renal impairment is not simply related to the degree of stenosis. The picture is often complicated by small-vessel disease in affected kidneys that may be related to subclinical atheroemboli, hypertension or other disease. As the stenosis becomes more severe, global renal ischaemia leads to shrinkage of the

affected kidney and may cause renal failure (ischaemic nephropathy). However, the progression of stenosis is not easily predictable, and many patients die from coronary, cerebral or other vascular disease rather than renal failure.

In younger patients (< 50 years), fibromuscular dysplasia is a more likely cause of renal artery stenosis. This is an uncommon congenital disorder of unknown cause affecting the media ('medial fibroplasia'), which narrows the artery but rarely leads to total occlusion. It may be associated with disease in other arteries; for example, those who have carotid artery dissections are more likely to have this appearance in their renal arteries. It most commonly presents with hypertension in patients aged 15–30 years, and in women more frequently than men. Irregular narrowing ('beading') affects the distal renal artery, sometimes extending into intrarenal branches.

Rarely, large-vessel vasculitis, particularly Takayasu's arteritis (p. 1113), may involve renal arteries. Medium-sized arteries are more typically affected in polyarteritis nodosa (p. 1113).

Investigations

A number of investigations may be abnormal in patients with renovascular disease. Renal function may be impaired and plasma renin activity may be elevated, sometimes with hypokalaemia due to hyperaldosteronism. Ultrasound may reveal a discrepancy in size between the two kidneys. Unfortunately, these simple non-invasive tests are insufficiently sensitive for screening in hypertensive patients and vascular imaging is required to diagnose renovascular disease. Such imaging is usually undertaken only in patients in whom intervention to improve renal perfusion would be contemplated; this is usually limited to young patients and those in whom blood pressure cannot be controlled with antihypertensive agents ('resistant hypertension'), those who have a history of 'flash' pulmonary oedema or accelerated phase ('malignant') hypertension, or those in whom renal function is deteriorating.

CT and MRI angiographic techniques have largely replaced Doppler ultrasound or renal isotope scanning (including 'captopril renography') in diagnosing renal artery stenosis. Conventional renal artery cannulation and arteriography is now usually undertaken for therapeutic rather than diagnostic purposes. CT angiography entails large intravenously administered doses of contrast medium which may be nephrotoxic. MR angiography (Fig. 17.23) is expensive and also carries some risks in patients with severe renal impairment (see Box 17.4, p. 467). Although these techniques at present give good views of the main renal arteries only, these are the vessels affected in atherosclerosis and the most amenable to intervention.

Management

Untreated, atheromatous renal artery stenosis is thought to progress to complete arterial occlusion and loss of kidney function in about 15% of cases. This figure is increased with more severe degrees of stenosis. If the progression is gradual, collateral vessels may develop and some function may be preserved, preventing infarction and loss of kidney structure. Conversely, at least 85% of patients with renal artery stenosis will not develop progressive renal impairment, and indeed in many patients

Fig. 17.23 Renal artery stenosis. A magnetic resonance angiogram following injection of contrast. The abdominal aorta is severely irregular and atheromatous. The left renal artery is stenosed (arrow).

the stenosis may be haemodynamically insignificant and not responsible for coexisting essential hypertension. Unfortunately, methods to predict which patients are at risk of progression or will respond to treatment are still imperfect.

Surgical intervention is rarely undertaken now for atherosclerotic disease, as it is associated with high morbidity and mortality. Treatment options are:

- medical management with blood pressure-lowering, low-dose aspirin and lipid-lowering drugs; this should usually have been attempted before angiography is performed.
- angioplasty, with placement of stents in atherosclerotic disease areas to improve primary patency rates and prevent rapid recurrence.

Angioplasty is widely used but there may be substantial risks in patients with atherosclerosis: contrast nephropathy (see Box 17.4, p. 467), renal artery occlusion and renal infarction, and atheroemboli (p. 499) from manipulations in a severely diseased aorta. Small-vessel disease distal to the stenosis may preclude substantial functional recovery. Randomised trials have so far failed to show improved outcome with angioplasty in patients with stable renal function.

In non-atheromatous fibromuscular dysplasia, the renal artery stenosis is much more likely to be the cause of the presentation, and angioplasty has a high chance of success in improving blood pressure and protecting renal function.

Diseases of small intrarenal vessels

A number of conditions are associated with acute damage and occlusion of small blood vessels (arterioles and capillaries) in the kidney (Box 17.39). They may be associated with similar changes elsewhere in the body. A common feature of these syndromes is microangiopathic haemolytic anaemia, in which haemolysis occurs as a consequence of damage incurred to red blood cells during

17.39 Microvascular disorders associated with acute renal damage

- Thrombotic microangiopathy (haemolytic uraemic syndrome and thrombotic thrombocytopenic purpura)
Associated with verotoxin-producing *E. coli*
Other (familial, drugs, cancer etc.)
- Disseminated intravascular coagulation
- Malignant hypertension
- Small-vessel vasculitis
- Systemic sclerosis (scleroderma)
- Atheroemboli ('cholesterol' emboli)

passage through the abnormal vessels; fragmented red cells can be seen on a blood film.

Thrombotic microangiopathy: haemolytic uraemic syndrome and thrombotic thrombocytopenic purpura

Haemolytic uraemic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) are types of thrombotic microangiopathy. Common features include damage to endothelial cells of the microcirculation, which is followed by cell swelling, platelet adherence and thrombosis. A severe microangiopathy causes a marked reduction in the platelet count and anaemia. Other features of intravascular haemolysis (p. 1023) – raised bilirubin and LDH, decreased haptoglobins – are also present. A reticulocytosis is often seen. The aetiology of the syndromes may be different, although there is substantial overlap. The kidney microcirculation tends to be most affected in HUS, with involvement of other organs (including the brain) in more severe cases. In TTP the brain is commonly affected and involvement of the kidney is usually less severe.

E. coli O157-associated HUS

Thrombotic microangiopathy associated with *E. coli* infection (especially O157 serotypes) is caused by verotoxin-producing organisms (p. 337). Although the bacteria live as commensals in the gut of cattle and other domestic livestock, they can cause haemorrhagic diarrhoea in humans when the infection is contracted from contaminated food products, water or other infected individuals. In a proportion of cases, verotoxin produced by the organisms enters the circulation and binds to specific glycolipid receptors that are expressed on the surface of microvascular endothelial cells. In children, this causes diarrhoea-associated (D+)HUS, although in more severe cases the brain and other organs are also affected. D+HUS is now the most common cause of ARF in children in developed countries. Recovery is good in most patients, often after 5–15 days of dialysis. No specific treatments have been shown to help.

TTP and other HUS

Other causes of thrombotic microangiopathy have a less certain outlook and are more likely to recur (sometimes after renal transplantation). Inherited causes may reflect an abnormality of endothelial cell defence against damage or thrombosis, including deficiency of complement activation inhibitors (associated with familial HUS) or of von Willebrand protease (associated with TTP, p. 1048). The disease may also occur post-partum, in response to

certain drugs (especially chemotherapy), after bone marrow transplantation, in malignancy and apparently spontaneously. Plasma exchange using fresh frozen plasma is effective in many of these cases, probably by replacing a deficient substance (e.g. the von Willebrand protease) and sometimes removing an autoantibody.

Disseminated intravascular coagulation

In this condition, consumption of clotting factors and platelets occurs due to uncontrolled thrombosis in the microvasculature (p. 1050). Precipitating conditions include: septic shock, in which bacterial endotoxin directly activates the coagulation cascade; obstetric complications; disseminated cancer; massive transfusion; and other causes of coagulation activation or depletion.

Accelerated phase ('malignant') hypertension

Hypertension is described as being in accelerated phase (p. 608) when it causes acute damage to renal and other arterioles. It is often symptomatic, with headache, impaired vision and, finally, manifestations of renal failure (Fig. 17.24). Severe hypertensive retinopathy with papilloedema is almost always present, usually with some of the features of microangiopathy described above. In the absence of a previous history, it may be difficult to distinguish these patients from those with HUS and hypertension. Patients usually respond to effective control of blood pressure, although renal function is permanently lost in 20% of cases.

Fig. 17.24 Glomerular capillary thrombosis in malignant hypertension. Similar changes occur in thrombotic microangiopathy. The adjacent arteriole (arrow) shows gross intimal thickening.

Systemic sclerosis (scleroderma)

This connective tissue disease is described on page 1109. Renal involvement is a serious feature, characterised by intimal cell proliferation and luminal narrowing of intrarenal arteries and arterioles. Clinically, it usually presents as 'scleroderma renal crisis', with severe hypertension, microangiopathic features and progressive oliguric renal failure. There is intense intrarenal vasospasm and plasma renin activity is markedly elevated. Use of ACE inhibitors to control the hypertension has improved the 1-year survival from 20% to 75%; however, about 50% of patients continue to require RRT. Onset or acceleration of the syndrome after stopping ACE inhibitors is now well described.

Atheroembolic renal disease ('cholesterol' emboli)

This is caused by showers of cholesterol-containing microemboli, arising in atheromatous plaques in major arteries. It occurs in patients with widespread atheromatous disease, usually after interventions such as surgery or arteriography but sometimes after anticoagulation. There is loss of renal function, haematuria and proteinuria, and sometimes eosinophilia and inflammatory features which may mimic a small-vessel vasculitis. Accompanying signs of microvascular occlusion in the lower limbs (e.g. ischaemic toes, livedo reticularis) are common but not invariable (Fig. 17.25). There is no specific treatment but anticoagulation may be detrimental.

Fig. 17.25 The foot of a patient who suffered extensive atheroembolism following coronary artery stenting.

Small-vessel vasculitis

Renal disease caused by small-vessel vasculitis usually affects the glomeruli, as described in the next section and on page 516.

GLOMERULAR DISEASES

Glomerular diseases account for a significant proportion of acute and chronic kidney disease. Glomerular damage may follow a number of insults: immunological injury, inherited abnormality (e.g. Alport's syndrome, p. 504), metabolic stress (e.g. diabetes mellitus, p. 829), deposition of extraneous materials (e.g. amyloid), or other direct injury to glomerular cells. The cell types of the glomerulus that may be the target of injury are shown in Figure 17.26. The response of the glomerulus to injury and hence the predominant clinical features vary according to the nature of the insult (Fig. 17.27). Glomerular diseases cause some or all of:

- leakage of cells and macromolecules across the glomerular filtration barrier
 - proteinuria*: characteristic of podocyte diseases or of alteration of architecture by scarring or deposition of foreign material
 - haematuria*: characteristic of inflammatory and destructive processes
- loss of filtration capacity (GFR)
- hypertension.

Most patients with glomerular disease do not present acutely and are essentially asymptomatic, with abnormalities of blood or urine detected on routine screening, often accompanied by high blood pressure, with or without reduced GFR.

Circulating immune complexes

Cryoglobulinaemia
Serum sickness
?Endocarditis

Fig. 17.26 Cells of the glomerulus and targets of immunity and autoimmunity. Antibodies and antigen–antibody (immune) complexes are described according to their site of deposition: subepithelial, between podocyte and GBM; intramembranous, within the GBM; subendothelial, between endothelial cell and GBM; and mesangial, within the mesangial matrix.

Glomerulonephritis

Glomerulonephritis means ‘inflammation of glomeruli’ and, although inflammation is not apparent in all varieties (‘glomerulopathy’ is sometimes used to denote this), the name sticks.

Most types of glomerulonephritis seem to be immunologically mediated and several respond to immunosuppressive drugs. Deposition of antibody occurs in many types of glomerulonephritis (Box 17.40) but frequently the presumed mechanisms involve cellular immunity, which is more difficult to investigate. Although deposition of circulating immune complexes was previously thought to be a common mechanism, it now seems that most granular deposits of immunoglobulin are formed ‘in situ’ by antibodies which complex about glomerular antigens, or about other antigens (‘planted’ antigens, e.g. viral or bacterial ones) that have localised in glomeruli (see Fig. 17.26).

Classifications of glomerulonephritis are largely histopathological and may appear daunting, but the details are largely a specialist concern. Clinically important types are described in the text. Box 17.40 and Figure 17.29 on pages 502–503 show additional detail and illustrate the major types.

Minimal change nephropathy

Minimal change disease occurs at all ages but accounts for nephrotic syndrome (Box 17.19, p. 479) in most children and about one-quarter of adults. Proteinuria usually remits on high-dose corticosteroid therapy (1 mg/kg prednisolone for 6 weeks), although some patients who respond incompletely or relapse frequently need maintenance corticosteroids, cytotoxic therapy or other agents. Minimal change disease does not progress to CKD; the main problems are those of the nephrotic syndrome and complications of treatment.

Primary focal segmental glomerulosclerosis (FSGS)

FSGS is a histological description (Fig. 17.29B) with many causes. As FSGS is a focal process, abnormal glomeruli

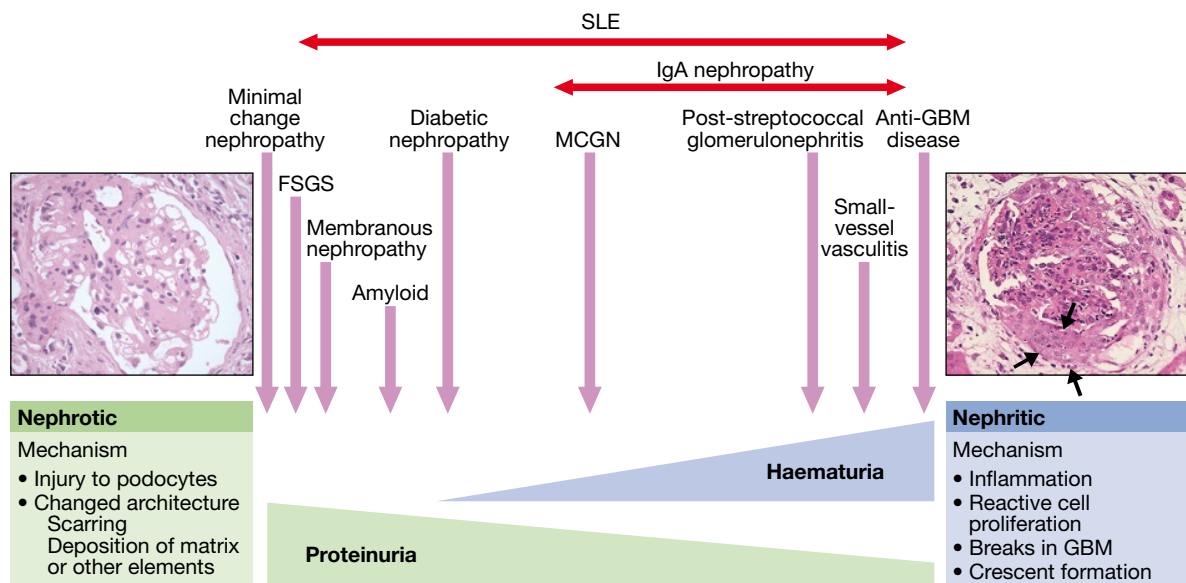

Fig. 17.27 Spectrum of glomerular diseases. At one extreme, specific injury to podocytes, or structural alteration of the glomerulus affecting podocyte function (for example, by scarring or deposition of excess matrix or other material), causes proteinuria and nephrotic syndrome (see Box 17.19, p. 479). The histology to the left shows diabetic nephropathy. At the other end of the spectrum, inflammation leads to cell damage and proliferation, breaks form in the GBM and blood leaks into urine. In its extreme form, with acute sodium retention and hypertension, such disease is labelled nephritic syndrome (FSGS = focal and segmental glomerulosclerosis; MCGN = mesangiocapillary glomerulonephritis). The histology to the right shows a glomerulus with many extra nuclei from proliferating intrinsic cells and influx of inflammatory cells shows crescent formation (arrows) in response to severe post-infectious glomerulonephritis.

may not be seen on renal biopsy if only a few are sampled, leading to an initial diagnosis of minimal change nephropathy. Juxtamedullary glomeruli are more likely to be affected in early disease.

The primary FSGS group that present with idiopathic nephrotic syndrome and no other cause of renal disease typically show little response to corticosteroid treatment and often progress to renal failure. This disease frequently recurs after renal transplantation, and sometimes proteinuria recurs almost immediately. However, a proportion of patients with FSGS do respond to corticosteroids (a good prognostic sign).

In other patients with the histological appearances of FSGS but lesser proteinuria, focal scarring reflects healing of previous focal glomerular injury, such as HUS, cholesterol embolism or vasculitis. In others, it seems to represent particular types of nephropathy: for example, those associated with HIV infection, some podocyte toxins and massive obesity. Associations with numerous other forms of injury and renal disorders are reported. There is no specific treatment for most of these.

Membranous nephropathy

This is the most common cause of nephrotic syndrome in adults. A proportion of cases are associated with known causes (Box 17.40 and Figs 17.29D and F) but most are idiopathic. Of this group, approximately one-third remit spontaneously, one-third remain in a nephrotic state, and one-third show progressive loss of renal function. Short-term treatment with high doses of corticosteroids and alkylating agents (e.g. cyclophosphamide) may improve both the nephrotic syndrome and the long-term prognosis. However, because of the toxicity of these regimens, most nephrologists reserve such treatment for those with severe nephrotic syndrome or deteriorating renal function.

IgA nephropathy and Henoch–Schönlein purpura

IgA nephropathy is the most commonly recognised type of glomerulonephritis and can present in many ways (Figs 17.28 and 17.29G). Haematuria is the earliest sign and is almost universal, proteinuria a later feature, and hypertension very common. There may be severe proteinuria or in some cases progressive loss of renal function. The disease is a common cause of ESRD. A particular hallmark in young adults is acute self-limiting exacerbations, often with gross haematuria, in association with minor respiratory infections. This may be so acute as to resemble acute post-infectious glomerulonephritis, with fluid retention, hypertension and oliguria with dark or red urine. Characteristically, the latency from clinical infection to nephritis is short: a few days or less. Occasionally, IgA nephropathy progresses rapidly and crescent formation may be seen. The response to immunosuppressive therapy is usually poor. The management of less acute disease is largely directed towards the control of blood pressure in an attempt to prevent or retard progressive renal disease.

In children, and occasionally in adults, a systemic vasculitis occurring in response to similar infections is called Henoch–Schönlein purpura. A characteristic petechial rash (cutaneous vasculitis, typically affecting buttocks and lower legs) and abdominal pain (gastrointestinal

Fig. 17.28 Clinical presentations of IgA nephropathy in relation to age at diagnosis. Henoch–Schönlein purpura is most common in childhood but may occur at any age. Macroscopic haematuria is very uncommon over the age of 40 years. The detection of IgA nephropathy amongst patients with asymptomatic urine abnormality will depend on attitudes to routine urine testing and renal biopsy. It is uncertain whether patients presenting with chronic renal impairment have a disease distinct from that of patients presenting at a younger age with macroscopic haematuria.

vasculitis) usually dominate the clinical picture, with mild glomerulonephritis being indicated by haematuria. When the disease occurs in older children or adults, the glomerulonephritis is usually more prominent. Renal biopsy shows mesangial IgA deposition and appearances indistinguishable from acute IgA nephropathy.

Glomerulonephritis associated with infection

Bacterial infections, usually subacute (typically subacute bacterial endocarditis), may cause a variety of histological patterns of glomerulonephritis, most typically with membranous and mesangiocapillary lesions, and usually with plentiful immunoglobulin deposition and often evidence of complement consumption (low serum C3, Box 17.41). In the developed world, hospital-acquired infections are now a common cause of these syndromes. World-wide, glomerulonephritis occurs more commonly following hepatitis B, hepatitis C, schistosomiasis, leishmaniasis and possibly malaria and other chronic infections. FSGS associated with HIV infection is prevalent in black races. Proving a causative relationship between renal disease and infection in individual cases is difficult. Acute and chronic infections may also cause interstitial renal disease (p. 504).

Acute post-infectious glomerulonephritis

This is most common following infection with certain strains of streptococcus and therefore is often called post-streptococcal nephritis, but it can occur following other infections. It is much more common in children than adults but is now rare in the developed world. The latency is usually about 10 days after a throat infection or longer after skin infection, suggesting an immune mechanism rather than direct infection.

An acute nephritis of varying severity occurs. Sodium retention, hypertension and oedema are particularly

17.40 Glomerulonephritis: types, associations and causes

Histology	Immune deposits	Pathogenesis	Associations	Comments
Minimal change				
Normal, except on electron microscopy, where fusion of podocyte foot processes is seen (a non-specific finding)	None	Unknown	Atopy HLA-DR7 Drugs	Acute and often severe nephrotic syndrome Good response to corticosteroids Dominant cause of idiopathic nephrotic syndrome in childhood
Focal segmental glomerulosclerosis (FSGS)				
Segmental scars in some glomeruli No acute inflammation Podocyte foot process fusion seen in primary FSGS with nephrotic syndrome	Non-specific trapping in focal scars	Unknown; in some, circulating factors increase glomerular permeability Injury to podocytes may be a common feature	Healing of previous local glomerular injury HIV infection Heroin misuse Morbid obesity	<i>Primary FSGS</i> presents as idiopathic nephrotic syndrome but is less responsive to treatment than minimal change; may progress to renal impairment, can recur after transplantation <i>Secondary FSGS</i> presents with variable proteinuria and outcome
Focal segmental (necrotising) glomerulonephritis				
Segmental inflammation and/or necrosis in some glomeruli ± crescent formation	Variable according to cause, but typically negative (or 'pauci-immune')	Small-vessel vasculitis	Primary or secondary small-vessel vasculitis	Usually implies presence of systemic disease, and responds to treatment with corticosteroids and cytotoxic agents Check ANCA, ANA
Membranous nephropathy				
Thickening of GBM Progressing to increased matrix deposition and glomerulosclerosis	Granular subepithelial IgG	Antibodies to a podocyte surface antigen, with complement-dependent podocyte injury	HLA-DR3 (for idiopathic) HLA association varies in different populations Drugs Mercury, heavy metals Hepatitis B virus Malignancy	Usually idiopathic; common cause of adult idiopathic nephrotic syndrome One-third progress; may respond to chemotherapy/prednisolone
IgA nephropathy				
Increased mesangial matrix and cells Focal segmental nephritis in acute disease	Mesangial IgA	Unknown	Usually idiopathic Liver disease	Very common disease with range of presentations, but usually including haematuria and hypertension
Mesangiocapillary glomerulonephritis (MCGN) (= membranoproliferative glomerulonephritis, MPGN)				
<i>Type I</i>				
Mesangial cells interpose between endothelium and GBM	Subendothelial	Deposition of circulating immune complexes or 'planted' antigens	Bacterial infection Hepatitis B virus Cryoglobulinaemia ± hepatitis C virus	Usually proteinuria ± haematuria Most common pattern found in association with subacute bacterial infection No proven treatments
<i>Type II</i>				
Mesangial cells interpose between endothelium and GBM	Intramembranous dense deposits	Associated with complement consumption caused by autoantibodies	C3 nephritic factor and partial lipodystrophy	Also known as dense deposit disease
Post-infection				
Diffuse proliferation of endothelial and mesangial cells Infiltration by neutrophils and macrophages ± crescent formation	Subendothelial	Immune response to streptococcal infection with presumed cross-reactive epitopes	Streptococcal and other infections	Now rare in developed countries Presents with severe sodium and fluid retention, hypertension, haematuria, oliguria Usually resolves spontaneously
Goodpasture's disease (anti-GBM disease)				
Usually crescentic nephritis	Linear IgG along GBM	Autoantibodies to $\alpha 3$ chain of type IV collagen	HLA-DR15 (previously known as DR2)	Associated with lung haemorrhage but either may occur alone Treat with corticosteroids, cyclophosphamide and plasma exchange
Lupus nephritis				
Almost any histological type	Always positive and often profuse Pattern varies according to type	Some anti-DNA antibodies also bind to glomerular targets	Complement deficiencies Complement consumption	Very variable presentation, sometimes as renal disease alone without systemic features Responds to cytotoxic therapy in addition to prednisolone

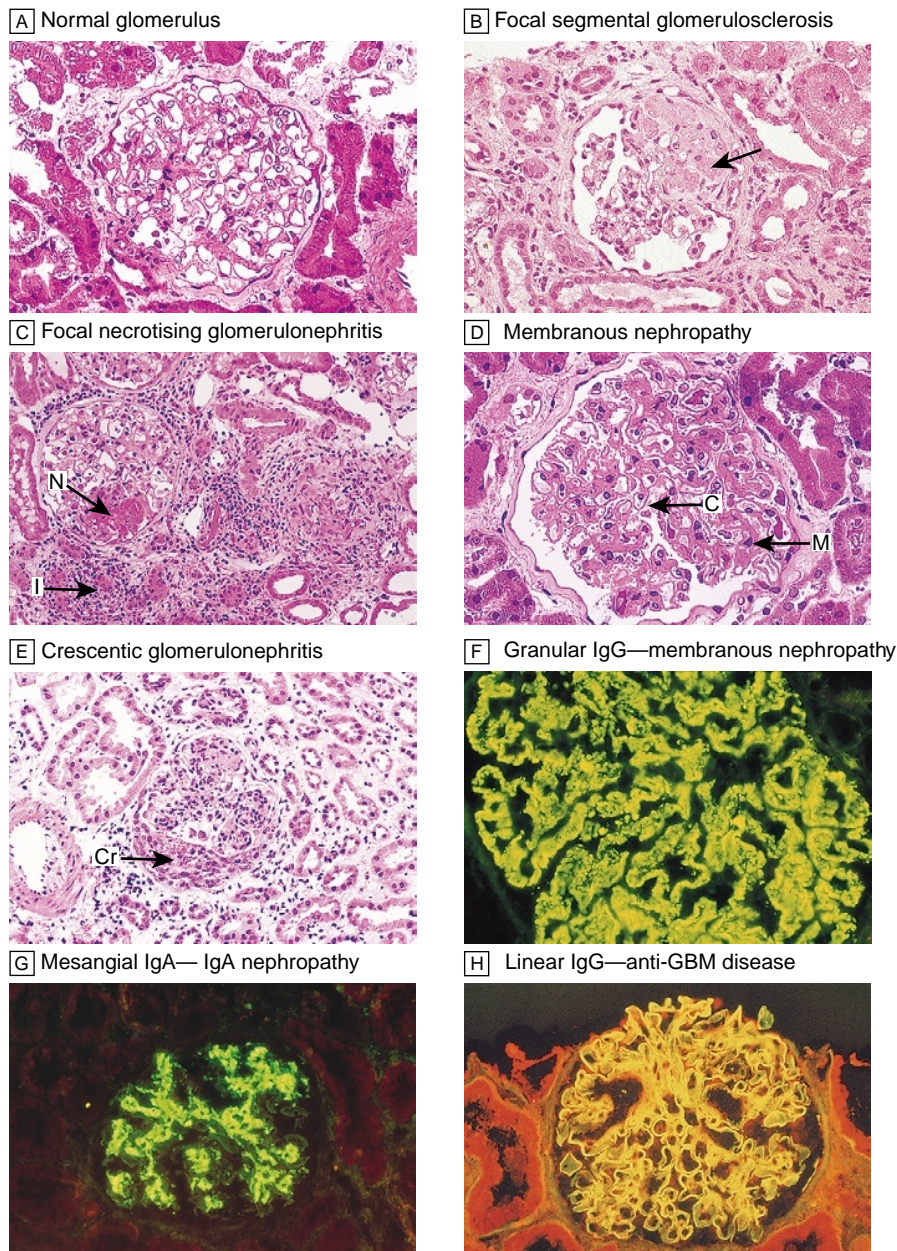

Fig. 17.29 Histopathology of glomerular disease. (**A–E** light microscopy) **A** A normal glomerulus. Note the open capillary loops and thinness of their walls—‘should look as if you could cut yourself on them’. **B** Focal segmental glomerulosclerosis. The portion of the glomerulus arrowed shows loss of capillary loops and cells, which are replaced by matrix. **C** Focal necrotising glomerulonephritis. A portion of the glomerulus (N = focal necrotising lesion) is replaced by bright pink material with some ‘nuclear dust’. Neutrophils may be seen elsewhere in the glomerulus. There is surrounding interstitial inflammation (I). This is most commonly associated with small-vessel vasculitis and may progress to crescentic nephritis (see **E**). **D** Membranous nephropathy. The capillary loops (C) are thickened (compare with the normal glomerulus) and there is expansion of the mesangial regions by matrix deposition (M). However, there is no gross cellular proliferation or excess of inflammatory cells. **E** Crescentic glomerulonephritis. The lower part of Bowman’s space is occupied by a semicircular formation (‘crescent’, Cr) of large pale cells, compressing the glomerular tuft. This is usually seen in aggressive inflammatory types of glomerulonephritis. **Antibody deposition in the glomerulus.** (**F–H** direct immunofluorescence) **F** Granular deposits of IgG along the basement membrane in a subepithelial pattern, typical of membranous nephropathy. **G** IgA deposits in the mesangium, as seen in IgA nephropathy. **H** Ribbon-like linear deposits of anti-GBM antibodies along the GBM in Goodpasture’s disease. Glomerular structure is well preserved in all of these examples.

pronounced. There is also reduction of GFR, proteinuria, haematuria and reduced urine volume. Characteristically, this gives the urine a red or smoky appearance. There are low serum concentrations of C3 and C4 (see Box 17.41) and evidence of streptococcal infection (perform antistreptolysin O (ASO) titre, culture of throat swab, and other microbiological sampling if skin infection is suspected).

Renal function begins to improve spontaneously within 10–14 days, and management by fluid and sodium restriction and use of diuretic and hypotensive agents is usually adequate. Remarkably, the renal lesion in almost all children and many adults seems to resolve completely despite the severity of the glomerular inflammation and proliferation seen histologically.

17.41 Causes of glomerulonephritis associated with low serum complement

- Post-infection glomerulonephritis
- Subacute bacterial infection: especially endocarditis
- SLE
- Cryoglobulinaemia
- Mesangiocapillary glomerulonephritis, usually type II

Rapidly progressive (crescentic) glomerulonephritis

This describes an extreme inflammatory nephritis which causes rapid loss of renal function over days to weeks. Renal biopsy shows crescentic lesions often associated with necrotising lesions within the glomerulus (focal segmental (necrotising) glomerulonephritis). It is typically seen in Goodpasture's disease, where there are specific anti-GBM antibodies, and in small-vessel vasculitides (pp. 516 and 1112), but can also be seen in SLE (pp. 517 and 1107) and occasionally IgA and other nephropathies.

Inherited glomerular diseases

Alport's syndrome

A number of uncommon diseases may affect the glomerulus in childhood, but the most important one affecting adults is Alport's syndrome. Most cases arise from a mutation or deletion of the *COL4A5* gene on the X chromosome which encodes type IV collagen, resulting in inheritance as an X-linked recessive disorder (p. 50). Mutations in *COL4A3* or *COL4A4* genes are less common and cause autosomal recessive disease. The accumulation of abnormal collagen results in a progressive degeneration of the GBM (Fig. 17.30). Affected patients progress from haematuria to ESRD in their late teens or twenties. Female carriers of *COL4A5* mutations usually have haematuria but rarely develop significant renal disease. Some other basement membranes containing the same collagen isoforms are similarly affected, notably in the cochlea, so that Alport's syndrome is associated with sensorineural deafness and ocular abnormalities.

No specific treatment is available, but patients with Alport's syndrome are good candidates for RRT, as they are young and usually otherwise healthy. Some of these patients develop an immune response to the

normal collagen antigens present in the GBM of the donor kidney, and in a small minority anti-GBM disease develops and destroys the allograft.

Thin GBM disease

In 'thin GBM' disease there is glomerular bleeding, usually only at the microscopic or dipstick level, without associated hypertension, proteinuria or reduction of GFR. The glomeruli appear normal by light microscopy but on electron microscopy the GBM is abnormally thin. This autosomal dominant condition accounts for a large proportion of 'benign familial haematuria' and has an excellent prognosis. Some families may be carriers of autosomal recessive Alport's syndrome but this does not account for all cases.

TUBULO-INTERSTITIAL DISEASES

Acute tubular necrosis is the most common cause of the clinical syndrome of acute renal failure and is described on page 484. Illustrations of this and other tubulo-interstitial pathologies are shown in Figure 17.31.

Interstitial nephritis

A group of inflammatory, inherited and other diseases affect renal tubules and the surrounding interstitium. The clinical presentation is often simply with renal impairment. Proteinuria is generally low level (PCR < 100 mg/mmol) and tubular in type (p. 480). Urine may contain red and white blood cells.

Acute interstitial nephritis (AIN)

Acute inflammation within the tubulo-interstitium is most commonly allergic, particularly to drugs, but other causes include toxins and a variety of systemic diseases and infections (Box 17.42). Deterioration of renal function in drug-induced AIN may be dramatic and resemble rapidly progressive glomerulonephritis.

Diagnosis

A minority of patients with drug-induced AIN have a generalised drug hypersensitivity reaction (e.g. fever, rash, eosinophilia). Dipstick testing of the urine is usually unremarkable, but leucocyturia is common and eosinophils are found in the urine in up to 70% of patients. Many patients are not oliguric despite moderately severe

Fig. 17.30 Alport's syndrome. **A** Diagrammatic structure of the normal GBM. **B** The normal GBM (electron micrograph) contains mostly the tissue-specific $\alpha 3$, $\alpha 4$ and $\alpha 5$ chains of type IV collagen. **C** In Alport's syndrome this network is disrupted and replaced by $\alpha 1$ and $\alpha 2$ chains. Although the GBM appears structurally normal in early life, in time thinning appears, progressing to thickening, splitting and degeneration.

A Normal tubular histology**B** Acute tubular necrosis**C** Acute pyelonephritis**D** Acute interstitial nephritis

Fig. 17.31 Tubular histopathology. **A** Normal tubular histology. The tubules are back to back. Brush borders can be seen on the luminal borders of cells in the proximal tubule. **B** Acute tubular necrosis. There are scattered breaks (B) in tubular basement membranes, swelling and vacuolation of tubular cells, and in places apoptosis and necrosis of tubular cells with shedding of cells into the lumen. During the regenerative phase there is increased tubular mitotic activity. The interstitium (I) is oedematous and infiltrated by inflammatory cells. The glomeruli (not shown) are relatively normal, although there may be endothelial cell swelling and fibrin deposition. **C** Acute bacterial pyelonephritis. A widespread inflammatory infiltrate that includes many neutrophils is seen. Granulocyte casts (G) are forming within some dilated tubules (T). Other tubules are scarcely visible because of the extent of the inflammation and damage. **D** Acute (allergic) interstitial nephritis. In this patient who received an NSAID, an extensive mononuclear cell infiltrate (no neutrophils) involving tubules (T) is seen. This inflammation does not involve the glomeruli (not shown). Sometimes eosinophils are prominent. Transplant rejection looks similar to this.

ARF, and AIN should always be considered in patients with non-oliguric ARF.

Renal biopsy is usually required to confirm the diagnosis (see Fig. 17.31), showing intense inflammation,

with polymorphonuclear leucocytes and lymphocytes surrounding tubules and blood vessels and invading tubules (tubulitis), and occasional eosinophils (especially in drug-induced disease). The degree of chronic inflammation in a biopsy is a useful predictor of the eventual outcome for renal function.

Management

Some patients with drug-induced AIN recover following withdrawal of the drug alone, but corticosteroids (e.g. prednisolone 1 mg/kg/day) accelerate recovery and may prevent long-term scarring. Dialysis is sometimes necessary but is usually only short-term. Other specific causes (see Box 17.42) should be treated if possible.

Chronic interstitial nephritis

Aetiology

Chronic interstitial nephritis (CIN) is caused by a heterogeneous group of diseases, summarised in Box 17.43. However, it is quite common for the condition to be diagnosed late and for no aetiology to be apparent.

17.42 Causes of acute interstitial nephritis

Allergic

Many drugs, but particularly

- Penicillins
- NSAIDs
- Proton pump inhibitors
- Mesalazine (delayed)

Immune

- Autoimmune nephritis ± uveitis
- Transplant rejection

Infections

- Acute bacterial pyelonephritis
- Leptospirosis
- Tuberculosis
- Hantavirus

Toxic

- Myeloma light chains
- Mushrooms (*Cortinarius*)

Toxic causes of CIN

The combination of interstitial nephritis and tumours of the collecting system is seen in 'Chinese herb nephropathy' (a rapidly progressive syndrome caused by mistaken identity of ingredients in herbal preparations), in analgesic nephropathy, and in Balkan nephropathy (an endemic chronic nephropathy). A plant toxin found in *Aristolochia clematis* is probably responsible for the herb nephropathy and possibly also for Balkan nephropathy. Confusing *Cortinarius* species for wild edible or 'magic' mushrooms causes a devastating irreversible renal tubular toxicity encountered occasionally in Scandinavia and Scotland.

Papillary necrosis and analgesic nephropathy

The renal papillae are at the end of the capillary distribution in the kidney, and may necrose in diabetes mellitus, rarely in infections, in sickle-cell disease and occasionally in other conditions. Necrosed papillae may cause ureteric obstruction and renal colic. Papillary necrosis is difficult to identify other than on pyelography.

Long-term ingestion (years to decades) of certain NSAIDs may cause CIN and renal papillary necrosis. In animals, lesions can be induced with almost any NSAID; however a dramatic fall in the incidence of analgesic nephropathy has been observed which appears to coincide with the withdrawal of phenacetin from compound analgesics.

Clinical and biochemical features

Most patients with CIN present in adult life with CKD, hypertension and small kidneys. CKD is often moderate (stage 3) but, because of tubular dysfunction, electrolyte abnormalities are typically more severe (e.g. hyperkalaemia, acidosis). Urinalysis abnormalities are non-specific. A minority of patients present with salt-losing nephropathy, causing hypotension, polyuria and features of sodium and water depletion (e.g. low blood pressure and jugular venous pressure). Impairment of urine-concentrating ability and sodium conservation places patients with CIN at risk of superimposed ARF with even moderate salt and water depletion during an acute illness.

Hyperkalaemia may be disproportionate in CIN or in diabetic nephropathy because of hyporeninaemic hypoaldosteronism (p. 829). Renal tubular acidosis (p. 444) is seen most often in myeloma, sarcoidosis, cystinosis, amyloidosis and Sjögren's syndrome.

Sickle-cell nephropathy

The longer survival of patients with sickle-cell disease (p. 1028) means that a larger proportion live to develop chronic complications of microvascular occlusion. In the kidney these changes are most pronounced in the medulla, where the vasa recta are the site of sickling because of hypoxia and hypertonicity. Loss of urinary concentrating ability and polyuria are the earliest changes; distal renal tubular acidosis and impaired potassium excretion are typical. Papillary necrosis (as seen in analgesic nephropathy) is very common. A minority of patients develop ESRD. This is managed according to the usual principles, but response to recombinant erythropoietin is poor in the presence of haemoglobinopathy. Patients with sickle trait have an increased incidence of unexplained microscopic haematuria, and occasionally overt papillary necrosis.

Cystic kidney diseases**Polycystic kidney disease**

Adult polycystic kidney disease (PKD) is a common condition (prevalence approximately 1:1000) that is inherited as an autosomal dominant trait. Small cysts lined by tubular epithelium develop from infancy or childhood and enlarge slowly and irregularly. Surrounding normal kidney tissue is progressively attenuated. Renal failure is associated with grossly enlarged kidneys (Fig. 17.32).

Mutations in the *PKD1* gene account for 85% of cases and *PKD2* for about 15%. ESRD occurs in approximately 50% of patients with *PKD1* mutations with a mean age of onset of 52 years, but in a minority of patients with *PKD2* mutations with a mean age of onset of 69 years.

Clinical features

Common clinical features are shown in Box 17.44. Affected subjects are usually asymptomatic until later life. After the age of 20 there is often insidious onset of hypertension. One or both kidneys may be palpable and the surface may feel nodular. There is then a gradual reduction in renal function.

About 30% of patients with PKD have hepatic cysts (see Fig. 23.40, p. 967) but disturbance of liver function

Fig. 17.32 MRI images of kidneys. **A** Normal kidneys. **B** Polycystic kidneys; although the kidney enlargement is extreme, this patient had only slightly reduced GFR.

17.44 Adult polycystic kidney disease: common clinical features

- Vague discomfort in loin or abdomen due to increasing mass of renal tissue
- Acute loin pain or renal colic due to haemorrhage into a cyst
- Hypertension
- Haematuria (with little or no proteinuria)
- Urinary tract or cyst infections
- Renal failure

is rare. Sometimes (almost always in women) this causes massive and symptomatic hepatomegaly, usually concurrent with renal enlargement but occasionally with only minor renal involvement.

Berry aneurysms of cerebral vessels are an associated feature and about 10% of patients have a subarachnoid haemorrhage. This feature appears to be largely restricted to certain families (and presumably specific mutations). Mitral and aortic regurgitation are frequent but rarely severe, and colonic diverticulae and abdominal wall hernias may occur.

PKD is not a pre-malignant condition. The rate of renal malignancy is no different from that of other patients with renal failure.

Investigations and screening

The diagnosis is usually based on family history, clinical findings and ultrasound. Ultrasound demonstrates cysts in approximately 95% of affected patients over the age of 20 but may not detect small developing cysts in younger patients. It is important to identify multiple cysts, not just two or three (see Fig. 17.32). Now that the gene defects responsible for PKD have been identified, it is sometimes possible to make a specific genetic diagnosis, but detecting mutations in the *PKD1* gene is particularly problematic because of its size, the existence of a closely related pseudogene, and the wide variety of mutations that have been described. Linkage analysis (p. 57) may be used to exclude the diagnosis in a young adult with normal renal imaging.

Screening for intracranial aneurysms is not generally indicated. Where non-invasive MR angiography is available, some centres screen patients in families with a history of subarachnoid haemorrhage. However, even then, the yield of screening has been low, and the risk-benefit ratio of intervention in asymptomatic aneurysms in this disease is not known.

Management

Nothing has yet been found to alter the rate of progression of renal failure in human PKD but the first clinical trials of drugs that seem to slow cyst growth are under way. Good control of blood pressure is important because cardiovascular morbidity and mortality are so common in renal disease, but there is no evidence that control of moderate hypertension retards the development of renal failure in PKD, in contrast to the evidence for glomerular diseases.

Patients with PKD are usually good candidates for dialysis and transplantation. Sometimes kidneys are so large that one or both have to be removed to make space for a renal transplant. Otherwise, unless they are a source of pain or infection, they are usually left in situ.

Other cystic diseases

Medullary cystic diseases

Medullary sponge kidney is characterised by cysts confined to papillary collecting ducts. The disease is not inherited and its cause is unknown. Patients usually present as adults with renal stones. These are often recurrent, and preventive measures (p. 511) need to be implemented if so, but the prognosis is generally good. The diagnosis is made by ultrasound or IVU (Fig. 17.33). Contrast medium is seen to fill dilated or cystic tubules, which are sometimes calcified.

Medullary cystic kidney diseases are a heterogeneous group of inherited disorders, known as nephronophthisis in children. Small cortical cysts are associated with progressive destruction of the nephron. The childhood variants are characterised by thirst and polyuria due to nephrogenic diabetes insipidus, often with a family

Fig. 17.33 Medullary sponge kidney. Intravenous urogram showing contrast medium filling both the collecting system and cavities arising from collecting ducts, especially within papillae of the upper pole. The cavities have been likened to bunches of grapes. A plain abdominal X-ray may show calcification in the same regions.

history of similar disease. Sometimes, affected patients are 'salt-losing', which aggravates the degree of renal failure. Even when they are treated appropriately, serious renal failure is usual. The genetic basis of these disorders is emerging; several genes involving multiple mechanisms are involved.

Other cystic diseases

A number of other rarer inherited cystic diseases, having some similarities to PKD but distinct genetic causes, are recognised.

Multicystic dysplastic kidneys are often unilateral and are a developmental abnormality found in children. Most of these seem to involute during growth, leaving a solitary kidney in adults.

Acquired cystic kidney disease develops in patients with a very long history of renal failure, usually including many years of dialysis. It is associated with increased erythropoietin production and sometimes with the development of renal cell carcinoma.

Isolated defects of tubular function

An increasing number of disorders are now known to be due to specific defects of transporter molecules or other functions in renal tubular cells. Only the most common are mentioned here.

Renal glycosuria is a benign autosomal recessive defect of tubular reabsorption of glucose, caused by

mutations of the sodium/glucose cotransporter *SGLT2*. Glucose appears in the urine in the presence of a normal blood glucose concentration. Targeting of this transporter has been proposed as a treatment for diabetes mellitus.

Cystinuria is a rare condition in which reabsorption of filtered cystine, ornithine, arginine and lysine is defective. It is caused by mutations in the *SLC3A1* amino acid transporter gene. The high concentration of cystine in urine leads to cystine stone formation (pp. 510–511).

Other uncommon tubular disorders include vitamin D-resistant rickets (pp. 112 and 1123), in which reabsorption of filtered phosphate is reduced; nephrogenic diabetes insipidus (p. 792), in which the tubules are resistant to the effects of vasopressin; and Bartter's and Gitelman's syndromes, in which there is sodium-wasting and hypokalaemia (p. 439).

The term 'Fanconi syndrome' is used to describe generalised proximal tubular dysfunction. It is not related to Fanconi anaemia. Notable abnormalities include low blood phosphate and uric acid, the finding of glucose and amino acids in urine, and proximal renal tubular acidosis (p. 444). In addition to the causes of interstitial nephritis described above, some congenital metabolic disorders are associated with Fanconi syndrome, notably Wilson's disease, cystinosis and hereditary fructose intolerance.

Renal tubular acidosis describes the common endpoint of a variety of diseases affecting distal (classical or type 1) or proximal (type 2) renal tubular function. These syndromes are described on page 444.

DISEASES OF THE COLLECTING SYSTEM AND URETERS

Congenital abnormalities

Congenital anomalies of the urinary tract (Fig. 17.34) affect more than 10% of infants and, if not immediately lethal, may lead to complications in later life, including obstructive nephropathy and CKD. About 1 in 500 infants are born with only one kidney. Although usually compatible with normal life, this is often associated with other abnormalities.

A ureterocele (see Fig. 17.9, p. 473) occurs behind a pin-hole ureteric orifice when the intramural part of the ureter dilates and bulges into the bladder. It can become very large and cause lower urinary tract obstruction. Incision of the pin-hole opening relieves the obstruction.

Ectopic ureters occur with congenital duplication of one or both kidneys (duplex kidneys). Developmentally, the ureter has two main branches and, if this arrangement persists, the two ureters of the duplex kidneys may drain separately into the bladder. One ureter enters normally on the trigone, while the ectopic ureter (from the upper renal moiety) enters the bladder or, more rarely, the vagina or seminal vesicle. A ureter that is ectopic and drains into the bladder is liable to have an ineffective valve mechanism so that urine passes up the ureter on voiding (vesico-ureteric reflux, see below). Reflux can occur in normally sited ureters if the intramural ureter fails to act as a valve. The management of vesico-ureteric reflux and associated reflux nephropathy is outlined below.

Fig. 17.34 Congenital abnormalities of the urinary tract.

In primary obstructive megaureter there is dilatation of the ureter in all but its terminal segment without obvious cause and without vesico-ureteric reflux. Radiographic and pressure/flow studies may be needed to determine whether there is obstruction to urine flow. Narrowing of the ureter and reimplantation may be necessary.

Pelviureteric junction obstruction

This causes idiopathic hydronephrosis and results from a functional obstruction at the junction of the ureter and renal pelvis. The aetiology is obscure. The abnormality is likely to be congenital and is often bilateral. It can be seen in very young children but gross hydronephrosis may present at any age.

The common presentation is ill-defined renal pain or ache exacerbated by drinking large volumes of liquid. Rarely, it is asymptomatic. Diagnosis is suspected after ultrasound or IVU, and confirmed with a diuretic renogram. Treatment is surgical excision of the PUJ and reanastomosis (pyeloplasty). This can now be performed laparoscopically. Less invasive alternatives are also possible, including balloon dilatation and endoscopic pyelotomy, but are less effective.

Retroperitoneal fibrosis

Fibrosis of the retroperitoneal connective tissues may encircle and compress the ureter(s), causing obstruction. This fibrosis is most commonly idiopathic, but can represent a reaction to infection, radiation or aortic aneurysm, or be caused by cancer or a drug reaction: to methysergide, for example. Patients usually present with ill-defined symptoms of ureteric obstruction. Typically, there is an acute phase response (high CRP and ESR). IVU or CT shows ureteric obstruction with medial deviation of the ureters. Idiopathic retroperitoneal fibrosis

responds well to corticosteroids and may respond more slowly to tamoxifen, but ureteric stenting is often used to relieve obstruction initially. Failure to respond indicates the need for surgery to relieve obstruction and exclude malignancy.

Reflux nephropathy (chronic pyelonephritis)

This is a chronic interstitial nephritis (p. 505) associated with vesico-ureteric reflux (VUR) in early life, and with the appearance of 'scars' in the kidney, as demonstrated by various imaging techniques. The incidence of reflux nephropathy is not known. About 12% of patients in Europe requiring treatment for ESRD are said to have renal scarring but diagnostic criteria are imprecise.

Pathogenesis

VUR, in which urine refluxes back from the bladder into the ureter, is closely associated with recurrent UTI in childhood, and until recently it was widely assumed that ascending infection is critical in the association of VUR with progressive renal damage. However, antenatal ultrasound has shown that renal scars occur in utero in the absence of infection. Furthermore, epidemiological surveys and controlled trials have found that efforts to reduce progression to ESRD by surgical or other means have not been effective. Reflux diminishes as the child grows and usually disappears. It is often not demonstrable in an adult with a scarred kidney.

Susceptibility to VUR has a genetic component and may be associated with renal dysplasia and other congenital abnormalities of the urinary tract. It can be associated with outflow obstruction, usually caused by urethral valves, but usually occurs in an apparently normal bladder.

Pathology

Abnormalities may be unilateral or bilateral and of any grade of severity. Renal scars are juxtaposed to dilated calyces. Gross scarring of the kidneys, commonly at the poles, is seen, with reduced size and narrowing of the cortex and medulla. In patients who develop heavy proteinuria and hypertension, renal biopsies show glomerulomegaly and focal glomerulosclerosis, probably as a secondary response to reduced nephron number and functional mass.

Clinical features

Usually the renal scarring and dilatation is asymptomatic and the patient presents at any age with hypertension (sometimes severe), proteinuria or features of CKD. There may be no history of overt UTI. However, symptoms arising from the urinary tract may be present and include frequency of micturition, dysuria and aching lumbar pain. Urinary white cells and moderate proteinuria (usually < 1 g/24 hrs) are common but not invariable. There is an increased prevalence of renal calculi.

A number of women first present with hypertension and/or proteinuria in pregnancy. In some families there is a clear inheritance pattern.

Investigations

For detecting renal scars, ultrasound is an insensitive technique, although it will detect major dysplasia and

Fig. 17.35 Vesico-ureteric reflux (grade IV) shown by micturating cystogram. The bladder has been filled with contrast medium through a urinary catheter. After micturition there was gross VUR into widely distended ureters and pelvicalyceal systems.

renal dysgenesis, and exclude significant obstruction. Radionuclide DMSA scans are more sensitive (see Fig. 17.7, p. 468). Longitudinal imaging by MRI or CT may be useful.

To investigate VUR, radionuclide techniques can also be used as an alternative to micturating cystourethrography (MCUG, when the bladder is filled with contrast media through a urinary catheter and images are taken during and after micturition, Fig. 17.35). However, as surgical intervention for VUR has declined in popularity (see below), these techniques are used less often.

Management

Infection, if present, should be treated (Box 17.45); if recurrent, it should be prevented with prophylactic therapy, as described for UTI (p. 471). If pyelonephrosis develops or unilateral renal infection or pain persists, nephrectomy or other measures may be indicated. Occasionally, hypertension is cured by the removal of a diseased kidney when the disease is predominantly or entirely unilateral.

As most childhood reflux tends to disappear spontaneously and trials have shown small or no benefits from anti-reflux surgery, such intervention is now less common.

EBM 17.45 Prophylactic antibiotics and vesico-ureteric reflux

'Prophylactic antibiotics reduce recurrences of UTI but there is no evidence that they protect against further renal scarring or dysfunction.'

• Smellie JM, et al. *Lancet* 2001; 357:1329–1333.

For further information:  www.clinicalevidence.org

Prognosis

Children and adults with small or unilateral renal scars have a good prognosis, provided renal growth is normal. With significant unilateral scars there is usually compensatory hypertrophy of the contralateral kidney.

In patients with more severe bilateral disease, prognosis is predicted by the severity of renal dysfunction, hypertension and proteinuria. If the serum creatinine is normal and hypertension and proteinuria are absent, then the long-term prognosis is usually good.

Urinary tract calculi and nephrocalcinosis

Urinary calculi (stones) consist of aggregates of crystals containing small amounts of proteins and glycoprotein. It is surprising that stones and nephrocalcinosis are not more common, since some of the constituents are present in urine in concentrations which exceed their maximum solubility in water. However, urine contains proteins, glycosaminoglycans, pyrophosphate and citrate, which help to keep otherwise insoluble salts in solution.

Different types of stone vary in frequency around the world, probably as a consequence of dietary and environmental factors, but genetic factors may also contribute. In Europe, 80% of renal stones contain crystals of calcium (most commonly as oxalate but also as phosphate). About 15% contain magnesium ammonium phosphate (struvite; these are often associated with infection), and small numbers of pure cystine or uric acid stones are found. Rarely, drugs may form stones (e.g. indinavir, ephedrine). In a North American survey, 12% of men and 5% of women had experienced a renal stone by the age of 70 years. A number of risk factors are known for renal stone formation (Box 17.46). However, in developed countries, most calculi occur in healthy young men in whom investigations reveal no clear predisposing cause.

Urinary concretions vary greatly in size. There may be particles like sand anywhere in the urinary tract, or large round stones in the bladder. In developing countries, bladder stones are common, particularly in children. In

i 17.46 Predisposing factors for kidney stones

Environmental and dietary

- Low urine volumes: high ambient temperatures, low fluid intake
- Diet: high protein, high sodium, low calcium
- High sodium excretion
- High oxalate excretion
- High urate excretion
- Low citrate excretion

Acquired causes

- Hypercalcaemia of any cause (p. 764)
- Ileal disease or resection (increases oxalate absorption and urinary excretion)
- Renal tubular acidosis type I (distal, p. 444)

Congenital and inherited causes

- Familial hypercalciuria
- Medullary sponge kidney
- Cystinuria
- Renal tubular acidosis type I (distal)
- Primary hyperoxaluria

developed countries, the incidence of childhood bladder stones is low; renal stones in adults are more common. Staghorn calculi fill the whole renal pelvis and branch into the calyces (Fig. 17.36); they are usually associated with infection and composed largely of struvite.

Deposits of calcium may be present throughout the renal parenchyma, giving rise to fine calcification within the renal parenchyma (nephrocalcinosis), especially in patients with renal tubular acidosis, hyperparathyroidism, vitamin D intoxication and healed renal tuberculosis. Cortical nephrocalcinosis occurs in areas of cortical necrosis, typically after ARF in pregnancy or other severe ARF.

Fig. 17.36 Radio-opaque bilateral staghorn calculi visible during IVU. The intravenous pyelogram demonstrates that, while some dye is being excreted by the right kidney, there is little function on the left.

17.47 Measures to prevent calcium stone formation

Diet

Fluid

- At least 2 L output per day (intake 3–4 L): check with 24-hr urine collections
- Intake distributed throughout the day (especially before bed)

Sodium

- Restrict intake

Protein

- Moderate, not high

Calcium

- Plenty in diet (because calcium forms an insoluble salt with dietary oxalate, lowering oxalate absorption and excretion)
- Avoid supplements away from meals (increase calcium excretion without reducing oxalate excretion)

Oxalate

- Avoid foods that are rich in oxalate (spinach, rhubarb)

N.B. Citrate supplementation is of unproven value

Drugs

Thiazide diuretics

- Reduce calcium excretion
- Valuable in recurrent stone-formers and patients with hypercalciuria

Allopurinol

- If urate excretion high (unproven except for urate stones)

Avoid

- Vitamin D supplements as they increase calcium absorption and excretion
- Vitamin C hypersupplementation as this increases oxalate excretion

Indications for intervention

- Obstructive anuria or severe infection (pyonephrosis)
→ Emergency percutaneous nephrostomy only
- Severe pain or solitary kidney
→ Urgent ESWL or surgery
- Pain and failure of the stone to move
→ Elective ESWL or surgery

Extracorporeal shock wave lithotripsy (ESWL)

Fig. 17.37 Surgical options for urinary stones.

Investigations and management

The most common presentation is with renal colic, for which investigations and acute management are described on page 474. Large stones, or stones which do not pass spontaneously through the urinary tract, may require surgical removal and/or fragmentation by extracorporeal shock wave lithotripsy (Fig. 17.37).

Measures to prevent further stone formation are guided by the results of the investigations in Box 17.13 (p. 474). Some general principles apply to almost every patient with calcium-containing stones (Box 17.47). More specific measures apply to some stone types. Urate stones can be prevented by allopurinol, but the role of allopurinol in patients with calcium stones and high urate excretion is uncertain. Stones formed in cystinuria can be reduced by penicillamine therapy. It may also be helpful to attempt to alter urine pH with ammonium chloride (low pH discourages phosphate stone formation) or sodium bicarbonate (high pH discourages urate and cystine stone formation).

DISEASES OF THE LOWER GENITOURINARY TRACT

Several pathologies of the lower urinary tract are discussed elsewhere in this chapter, including infection (pp. 469–472), bladder and urethral dysfunction causing incontinence (p. 476), and urinary tract cancer (p. 515). Testicular tumours are discussed on page 763. Chapter 15 describes infections affecting the genitalia.

DISEASES OF THE PROSTATE GLAND

Benign prostatic hyperplasia

From 40 years of age the prostate increases in volume by 2.4 cm³ per year on average. The process begins in the periurethral (transitional) zone and involves both glandular and stromal tissue to a variable degree. Associated symptoms are common from 60 years of age, and some 50% of men over 80 years will have lower urinary tract symptoms associated with benign prostatic hyperplasia (BPH).

Clinical features

The primary symptoms of BPH are due to the prostate obstructing the urethra; they consist of hesitancy, poor prolonged flow and a sensation of incomplete emptying. Secondary (irritative) symptoms comprising urinary frequency, urgency of micturition and urge incontinence are not specific to BPH.

Patients may present more dramatically with acute urinary retention when they are suddenly unable to micturate and develop a painful distended bladder. This is often precipitated by excessive alcohol intake, constipation or prostatic infection. It is an emergency and requires the bladder to be drained by a catheter to relieve the retention.

In chronic urinary retention the bladder slowly distends due to inadequate emptying over a long period of time. This condition is characterised by pain-free

bladder distension which may result in hydronephrosis, hydronephrosis and renal failure. Patients with chronic retention can also develop acute retention: so-called acute on chronic retention. They require careful management because of their renal failure.

Investigations

Symptoms are scored on the international prostate symptom score (IPSS, Box 17.48), which serves as a valuable starting point for the assessment of urinary problems. Once a baseline value is established, any improvement/deterioration may be assessed on subsequent visits. Flow rates are accurately measured with a flow meter, and prostate volume can be estimated by rectal examination or more accurately by transrectal ultrasound scan (TRUS). Objective assessment of obstruction is only possible by urodynamics (see Fig. 17.11, p. 476). Renal function should be assessed and, if appropriate, obstructive nephropathy identified by ultrasound.

Management

Mild to moderate symptoms can be treated by medication (Boxes 17.49 and 17.50). Alpha-adrenoceptor blockers (e.g. alfuzosin, tamsulosin) reduce the tone of smooth muscle cells in the prostate and bladder neck, thereby reducing the obstruction. 5 α -Reductase inhibitors (finasteride and dutasteride) stop the conversion of testosterone to more potent dihydrotestosterone in the prostate and so cause the prostate to shrink. Severe symptoms require surgical removal of some of the obstructing prostate tissue. Transurethral resection of the prostate (TURP) remains the gold standard treatment but enucleation of the prostate by holmium laser appears as effective and has potentially fewer complications. Open surgery is

 17.48 How to determine the international prostate symptom score (IPSS) and quality of life scores		
Symptom	Score	
1. Straining	} Each scored	
2. Weak stream		
3. Intermittency		0 Not at all
4. Incomplete emptying		1 Less than 1 time in 5
5. Frequency		2 Less than half the time
6. Urgency		3 About half the time
7. Nocturia (times per night)		4 More than half the time
	5 Almost always	
Total IPSS score 0–7 = mild symptoms 8–19 = moderate symptoms 20–35 = severe symptoms In addition, consider the quality of life score below

17.49 Treatment for benign prostatic hypertrophy

Medical

- Prostate < 40 cm³: α -adrenoceptor blockers
- Prostate > 40 cm³: 5 α -reductase inhibitors

Non-surgical intervention

- Thermotherapy

Surgical

- Transurethral resection of prostate (TURP)
- Holmium laser enucleation
- Open prostatectomy

EBM 17.50 Medical management of benign prostatic hyperplasia

'Oral α -adrenoceptor blockers produce rapid improvement in urinary flow in 60–70% of patients. The 5 α -reductase inhibitor, finasteride, causes slow shrinkage of large prostate glands with improvement in symptoms.'

- Clifford GM, et al. Eur Urol 2000; 38:2–19.
- Boyle P, et al. Urology 2001; 58:717–722.

For further information: www.cochrane.org

rarely required, except in very large glands (> 100 cm³). Thermotherapy, where the prostate is heated by micro-waves of radiofrequency through a urethral catheter, is little better than medication but may have a place in the patient unfit for surgery.

Prostate cancer

Prostatic cancer is common in northern Europe and the USA (particularly in the black population) but rare in China and Japan. In the UK it is the second most common malignancy in males, with a prevalence of 50 per 100 000 population, and is increasing in frequency. It rarely occurs before the age of 50 and has a mean age at presentation of 70 years.

Prostate cancers arise within the peripheral zone of the prostate and almost all are carcinomas. Metastatic spread to pelvic lymph nodes occurs early and metastases to bone, mainly the lumbar spine and pelvis, are common. Prostatic specific antigen (PSA) is a good tumour marker and 40% of patients with a serum PSA > 4.0 ng/mL will have prostate cancer on biopsy. This has led to the introduction of screening programmes, principally in the USA, despite a lack of consensus about their utility.

Clinical features

Most patients present with lower urinary tract symptoms indistinguishable from BPH. Symptoms and signs due to metastases are much less common and include back pain, weight loss, anaemia and obstruction of the ureters. On rectal examination the prostate often feels nodular and stony hard, and the median sulcus may be lost. However, 10–15% of tumours are not palpable.

Whenever possible, the diagnosis is confirmed by needle biopsy, usually aided by TRUS, or by histological examination of tissue removed by endoscopic resection if this is needed to relieve outflow obstruction.

Investigations

Since most patients present with outflow tract obstruction, an ultrasound scan and serum creatinine determination are used to assess the urinary tract. A plain X-ray of the pelvis and lumbar spine (to investigate backache) may show osteosclerotic metastases as the first evidence of prostatic malignancy.

The patient is assessed for distant metastases by a radioisotope bone scan but high levels of serum PSA (> 100 ng/mL) almost always indicate distant bone metastases. PSA is useful for monitoring response to treatment and disease progression.

Management

Tumour confined to the prostate is potentially curable by either radical prostatectomy or radical radiotherapy, and these options should be considered in all patients with more than 10 years' life expectancy. A small focus of tumour found incidentally at TURP does not significantly alter life expectancy and only requires follow-up.

Approximately half of men with prostate cancer will have metastatic disease at the time of diagnosis. Prostatic cancer, like breast cancer, is sensitive to steroid hormones; locally advanced or metastatic prostate cancer is treated by androgen depletion, involving either surgery (orchidectomy) or, more commonly now, androgen-suppressing drugs (Box 17.51). Androgen receptor antagonists such as cyproterone acetate may prevent tumour cell growth. Gonadotrophin-releasing hormone (GnRH) analogues such as goserelin continuously occupy pituitary receptors, preventing them from responding to the GnRH pulses which normally stimulate luteinising hormone (LH) and follicle-stimulating hormone (FSH) release. This initially causes an increase in testosterone before producing a prolonged reduction, and for this reason the initial dose must be covered with an anti-androgen to prevent a tumour flare.

A small proportion of patients fail to respond to endocrine treatment. A larger number respond for a year or two, but then the disease progresses. Chemotherapy with 5-fluorouracil, cyclophosphamide or nitrogen mustard can then be effective. Radiotherapy is useful for localised bone pain. For severe generalised bone pain, hemi-body radiotherapy or ⁸⁹strontium may give effective palliation but the basis of treatment remains pain control by analgesia (p. 281).

Prognosis

The life expectancy of a patient with an incidental finding of focal carcinoma of the prostate is normal. With more substantial tumours localised to the prostate, the 10-year survival rate is 60–75%, but if metastases are present this falls to 10%.

EBM 17.51 Hormone manipulation in prostate cancer

'Reducing circulating testosterone levels (either by castration or by medication) results in a 70% initial response rate. Additional androgen blockade produces a small increase in survival but with poorer quality of life.'

Prostatitis

Inflammation of the prostate gland may be acute or chronic. It can be caused by infection with the same bacteria that are associated with UTI (p. 469) or, more commonly, may be 'non-bacterial' (no organisms cultured from urine). Clinical features include frequency, dysuria, perineal or groin pain, difficulty passing urine and, in acute disease, considerable systemic disturbance. The prostate is enlarged and tender. Bacterial prostatitis is confirmed by a positive culture from urine or from urethral discharge obtained after prostatic massage, and the treatment of choice is trimethoprim or a quinolone antibiotic. A 4–6-week course is required (see Box 17.11, p. 471). Non-bacterial prostatitis can be treated with drugs to relax the prostate and bladder neck, such as terodiline or terazosin.

TUMOURS OF THE KIDNEY AND URINARY TRACT

Tumours of the kidney

Tumours of the kidney account for 3% of all malignancies, and a variety of benign, malignant and secondary tumours can occur.

Renal adenocarcinoma

This is by far the most common malignant tumour of the kidney in adults, with a prevalence of 16 cases per 100 000 population. It is twice as common in males as in females. The peak incidence is between 65 and 75 years of age and it is uncommon before 40. The tumour arises from renal tubules. Haemorrhage and necrosis give the cut surface a characteristic mixed golden-yellow and red appearance (Fig. 17.38B). Microscopically, 'clear cell' carcinomas are more common than 'granular cell' tumours. There is early spread of the tumour into the renal pelvis, causing haematuria, and along the renal vein, often extending into the inferior vena cava. Direct invasion

of perinephric tissues is common. Lymphatic spread occurs to para-aortic nodes, while blood-borne metastases (which may be solitary) may develop almost anywhere in the body.

Clinical features

In an increasing number of cases, asymptomatic renal tumours are identified incidentally during imaging investigations carried out for other reasons. Amongst symptomatic patients, about 60% of cases present with haematuria, 40% with loin pain and only 25% with a mass; about 15% have the triad of pain, haematuria and a mass. A remarkable range of systemic effects may be present, including fever, raised ESR, polycythaemia, disorders of coagulation, and abnormalities of plasma proteins and liver function tests. The patient may present with pyrexia of unknown origin or, rarely, with neuropathy. Systemic effects may be due to tumour secretion of products such as renin, erythropoietin, PTH-related peptide and gonadotrophins. The effects disappear when the tumour is removed but may reappear when metastases develop, and so can be used as markers of tumour activity.

Investigations

Ultrasound is often the initial investigation and allows differentiation between solid tumour and simple renal cysts. Contrast-enhanced CT of the abdomen and chest should be performed for staging (see Fig. 17.38A). For tumours < 3 cm in diameter with no evidence of metastatic spread and when the nature of the lesion is uncertain, ultrasound or CT-guided biopsy may be used to avoid nephrectomy for benign disease.

Management and prognosis

Radical nephrectomy that includes the perirenal fascial envelope and ipsilateral para-aortic lymph nodes is performed whenever possible. It should be considered even when metastases are present, as not only do systemic effects often disappear, but also metastases may regress. Solitary metastases tend to remain single for long periods and excision may be worthwhile. Patients at high

Fig. 17.38 Renal adenocarcinoma. [A] In this CT, the right kidney is expanded by a low-density tumour which fails to take up contrast material. Tumour is shown extending into the renal vein and inferior vena cava (arrow). [B] Pathology specimen showing typical necrosis.

operative or other risk (e.g. single functioning kidney) who have small tumours may be treated percutaneously by radiofrequency ablation or by tissue-sparing surgery or cryoablation.

Renal adenocarcinoma is resistant to most chemotherapeutic agents, although interferon and interleukin-2 therapy are sometimes beneficial. Two new classes of drug have recently shown promising results: tyrosine kinase inhibitors such as sorafenib and sunitinib; and mTOR (mammalian target of rapamycin) inhibitors such as temsirolimus and everolimus.

Survival studies that antedate the introduction of new chemotherapeutic agents show that if the tumour is confined to the kidney, 5-year survival is 75%, but this falls to 5% when there are distant metastases.

Tumour syndromes

Some uncommon autosomal dominant inherited conditions are associated with multiple renal tumours in adult life. In tuberous sclerosis (p. 1283), replacement of renal tissue by multiple angiomyolipomas (tubers) may occasionally cause renal failure in adults. Other organs affected include the skin (adenoma sebaceum on the face) and brain (causing seizures and mental retardation). The von Hippel-Lindau syndrome (p. 1219) is associated with multiple renal cysts, renal adenomas and renal adenocarcinoma. Other organs affected include the central nervous system (haemangioblastomas) and the adrenals (phaeochromocytoma).

Tumours of the renal pelvis, ureters and bladder

The vast majority of these tumours arise from the urothelium or transitional cell lining. The urothelium is exposed to chemical carcinogens excreted in the urine, such as naphthylamines and benzidine which were extensively used in the chemical and dye industries until their carcinogenic properties were recognised. Almost all tumours are transitional cell carcinomas. Squamous carcinoma may occur in urothelium that has undergone metaplasia, usually following chronic inflammation or irritation due to a stone or schistosomiasis.

The incidence of transitional cell carcinoma in the bladder in the UK is 45 cases per 100 000 population, and is three times more common in men than women. The appearance of a transitional cell tumour ranges from a delicate papillary structure with relatively good prognosis to a solid ulcerating mass in more aggressive disease (Fig. 17.39).

Clinical features and investigations

More than 80% of patients have haematuria, which is usually macroscopic and painless. It should be assumed that such bleeding is from a tumour until proved otherwise (p. 478). A tumour at the lower end of a ureter or a bladder tumour (see Fig. 17.9, p. 473) involving the ureteric orifice may cause obstructive symptoms. Examination is usually unhelpful. Rectal examination detects only very advanced tumours.

Investigation of haematuria is described on page 478. If a suspicious defect is seen on IVU in the ureter or renal pelvis, a retrograde ureteropyelogram is required. Solid invasive tumours are staged by CT of the abdomen, pelvis and chest.

Fig. 17.39 Transitional cell carcinoma of the bladder. Stages are shown from carcinoma in situ (Cis) to invasive tumour progressing beyond the bladder and prostate (T4b). See also Figure 17.9 (p. 473).

Management

Small, large and even multiple superficial bladder tumours can be treated endoscopically by transurethral resection of the tumour(s) (TURBT). Intravesical chemotherapy (e.g. epirubicin, mitomycin C) is useful for treating multiple low-grade bladder tumours and for reducing their recurrence rate. Regular 'check' cystoscopies are required and recurrences can usually be controlled by diathermy; only rarely will cystectomy be required for superficial disease.

Untreated patients with carcinoma in situ (Cis) have a high risk of progression to invasive cancer. The tumour responds well to intravesical bacille Calmette-Guérin (BCG) treatment but more aggressive treatment may be needed.

The management of invasive bladder tumours is debated and is largely a matter for specialist urological surgeons, many of whom recommend radical cystectomy with urinary diversion into an incontinent ileal conduit or a continent catheterisable bowel pouch for patients under 70 years of age.

Transitional cell carcinoma of the renal pelvis and ureter is usually treated by nephroureterectomy, but if the tumour is solitary and low-grade it may be treated endoscopically.

Prognosis

The prognosis of bladder tumours depends on tumour stage and grade. The 5-year survival rate varies from 50–60% in those with superficial tumours to 20–30% for those with deep muscle invasion. Overall, about one-third of patients survive for 5 years.

RENAL INVOLVEMENT IN SYSTEMIC CONDITIONS

The kidneys may be directly involved in a number of multisystem diseases or secondarily affected by diseases of other organs. Involvement may be at a pre-renal, renal (glomerular or interstitial) or post-renal level. Many of the diseases are described in other sections of this chapter or in other chapters of the book.

Diabetes mellitus

In patients with diabetes, the steady advance from microalbuminuria to dipstick-positive proteinuria, and the progression to frank nephrotic syndrome and renal failure are described on pages 829–831. Few patients require renal biopsy to establish the diagnosis, but atypical features or progression should lead to suspicion that an alternative condition could be present.

Management with ACE inhibitors and other hypotensive agents to slow progression is described on page 830, and has been dramatically effective. In some patients, proteinuria may be eradicated and progression completely halted, even if renal function is abnormal.

Hepatic-renal disease

Severe hepatic dysfunction may cause a haemodynamically mediated type of renal failure, hepatorenal syndrome, described on page 944. It also predisposes the kidney to develop acute renal failure (acute tubular necrosis) in response to relatively minor insults including bleeding and infection. Such patients are often difficult to treat by dialysis and have a poor prognosis. Where treatment is justified—for example, if there is a good chance of recovery or of a liver transplant—very slow or continuous treatments are less likely to precipitate or exacerbate hepatic encephalopathy.

IgA nephropathy (p. 501) is more common in patients with liver disease.

Pulmonary-renal disease

The pulmonary-renal syndrome is a dramatic presentation with renal and respiratory failure that is not explained by excess intravascular fluid or by severe pneumonia; it occurs in Goodpasture's (anti-GBM) disease and small-vessel vasculitis (see below). There are some other uncommon causes of a similar syndrome, including poisoning with the herbicide paraquat.

Malignant diseases

Cancer may affect the kidney in many ways (Box 17.52).

17.52 Renal effects of malignancies

Direct involvement

- Kidney: primary adenocarcinoma (hypernephroma), lymphoma
- Urinary tract: e.g. urothelial tumours, cervical carcinoma

Immune reaction

- Glomerulonephritis: especially membranous nephropathy

Metabolic consequences

- Hypercalcaemia (p. 764)
- Uric acid crystal formation in tubules: usually in tumour lysis syndromes

Remote effects of tumour products

- Light chains in myeloma (p. 1041), amyloidosis (p. 84)
- Antibodies in cryoglobulinaemia (p. 1114)

Tuberculosis of the kidney and urinary tract

Tuberculosis of the kidney is secondary to tuberculosis elsewhere (p. 688) and is the result of blood-borne

infection. Initially, lesions develop in the renal cortex; these may ulcerate into the renal pelvis and involve the ureters, bladder, epididymis, seminal vesicles and prostate. Calcification in the kidney and stricture formation in the ureter are typical.

Clinical features may include symptoms of bladder involvement (frequency, dysuria); haematuria (sometimes macroscopic); malaise, fever, night sweats, lassitude, weight loss; loin pain; associated genital disease; and chronic renal failure as a result of urinary tract obstruction or destruction of kidney tissue.

Neutrophils are present in the urine but routine urine culture may be negative ('sterile pyuria'). Special techniques of microscopy and culture may be required to identify tubercle bacilli and are most usefully performed on early morning urine specimens. Bladder involvement should be assessed by cystoscopy. Radiology of the urinary tract and a chest X-ray to look for pulmonary tuberculosis are mandatory. Anti-tuberculous chemotherapy follows standard regimes (p. 693). Surgery to relieve urinary tract obstruction or to remove a very severely infected kidney may be required.

Systemic vasculitis

Medium- to large-vessel vasculitis (e.g. classical polyarteritis nodosa, p. 1113) only causes renal disease when arterial involvement leads to hypertension or renal infarction. In contrast, small-vessel vasculitis (p. 1112) commonly affects the kidneys with rapid and profound impairment of glomerular function.

Small-vessel vasculitis

This causes a focal inflammatory glomerulonephritis, usually with focal necrosis (see Box 17.40, p. 502, and Fig. 17.29, p. 503) and often with crescentic changes. It is usually associated with a systemic illness with acute phase response, weight loss and arthralgia, and characteristically in some patients causes pulmonary haemorrhage, which can be life-threatening. However, in other patients it presents as a kidney-limited disorder, with rapidly deteriorating renal function and crescentic nephritis.

The most important causes of this syndrome, microscopic polyangiitis and Wegener's granulomatosis, are usually associated with antibodies to neutrophil granule enzymes (ANCA, p. 1114); these antibodies are non-specific, however, and cannot be relied upon to make the diagnosis and so biopsy of the affected tissue is usually required. Henoch-Schönlein purpura (pp. 501 and 1114) is associated with IgA nephropathy and ANCA are usually absent. Vasculitis in other organs may give clues to the underlying systemic disorder and its subtype: for example, ear, nose and throat involvement and lung disease in Wegener's granulomatosis, or rash on the buttocks in Henoch-Schönlein purpura.

Treatment of the primary types of small-vessel vasculitis with cyclophosphamide, mycophenolate mofetil or corticosteroids is life-saving (p. 1114). Death from extrarenal manifestations of the disease is prevented and renal function can be salvaged in acute disease, even if the glomerulonephritis is so severe as to cause oliguria. In these circumstances, plasma exchange offers additional benefit.

Vasculitis may also be seen in rheumatoid arthritis, SLE and cryoglobulinaemia, although SLE usually involves the kidney in different ways (see below).

Systemic lupus erythematosus (SLE)

The diverse manifestations of SLE are described on page 1107. Subclinical renal involvement, with low-level haematuria and proteinuria but minimally impaired or normal renal function, is common in SLE. Usually this is due to glomerular disease, although serologically and sometimes clinically overlapping syndromes (e.g. mixed connective tissue disorder, Sjögren's syndrome) may cause interstitial nephritis. As indicated in Box 17.40 (p. 502) and Figure 17.27 (p. 500), SLE can produce almost any histological pattern of glomerular disease and clinical features ranging from florid, rapidly progressive glomerulonephritis to nephrotic syndrome.

Diffuse proliferative lupus nephritis

Typically, patients present with subacute disease and inflammatory features (haematuria, hypertension, variable renal impairment), accompanied by heavy proteinuria that often reaches nephrotic levels. In severely affected patients the most common histological pattern is an inflammatory, diffusely proliferative glomerulonephritis with substantial deposits of immunoglobulins on immunofluorescence. Controlled trials have shown that the risk of ESRD in this type of disease is significantly reduced by cyclophosphamide, often given as regular intravenous pulses, though mycophenolate mofetil appears as effective in short-term studies.

Dialysis and transplantation in SLE

Many patients go into relative remission from SLE once ESRD has developed. This may be because ESRD itself is an immunosuppressed state, as indicated by the higher incidence of bacterial infections in ESRD from all causes. Patients with ESRD caused by SLE are usually good candidates for dialysis and transplantation. Although it may recur in renal allografts, the immunosuppression required to prevent allograft rejection usually controls SLE too.

Pregnancy

Pregnancy has important physiological effects on the renal system. Some diseases are more common in pregnancy, the manifestations of others are modified by the physiological changes of pregnancy, and a few diseases (e.g. pre-eclampsia) are unique to pregnancy.

Physiological adaptations begin in the first few weeks. Peripheral vascular resistance declines, blood volume, cardiac output and GFR increase, and there is usually a reduction in blood pressure and plasma creatinine and urea values in the first trimester. Recordings of baseline blood pressure and urine testing from the first antenatal clinic visit are valuable if problems arise later.

Pregnancy and renal disease

Pyelonephritis is more common during pregnancy, perhaps because of dilatation of the urinary collecting system and ureters, so asymptomatic bacteriuria should be treated (Box 17.53 and p. 472).

Proteinuria caused by glomerular disease is usually exacerbated, and nephrotic syndrome may develop without any alteration in the underlying disease activity in individuals who had only slight proteinuria before pregnancy. This further increases the risk of venous

EBM	17.53 Treatment of asymptomatic bacteriuria in pregnancy
	'Antibiotic therapy for asymptomatic bacteriuria reduces the incidence of pyelonephritis by 75% and pre-term delivery by 40%.'
	• Small F. (Cochrane Review). Cochrane Library, issue 2, 2007. Oxford: Update Software.
	For further information:  www.cochrane.org

thromboembolism, which is the leading cause of maternal deaths in developed countries.

Systemic autoimmune diseases are typically relatively quiescent during pregnancy but tend to relapse in the first few weeks and months following delivery. Pre-existing renal disease increases the fetal and maternal risk involved in pregnancy, to a degree dependent on the level of renal function, proteinuria and hypertension. Patients with such diseases who may become pregnant should be aware of the extra associated risks. During pregnancy, therapy should not usually be stopped, but blood pressure targets may be modified (after discussion with the patient) and agents altered to those of proven safety.

Pre-eclampsia and related disorders

Pre-eclampsia is a systemic disorder that occurs in or near the third trimester of pregnancy (Box 17.54). Its aetiology is unknown, although a number of risk factors are described (Box 17.55).

Diagnosis

Pre-eclampsia is traditionally defined by the triad of oedema, proteinuria and hypertension. However, oedema is common in late pregnancy, proteinuria is a late sign and, while hypertension is usually present, it

	17.54 Pre-eclampsia and related diseases in pregnancy
	Clinical syndromes
	<ul style="list-style-type: none"> • Eclampsia: severe hypertension, encephalopathy and fits • Disseminated intravascular coagulation • Thrombotic microangiopathy: may also occur post-partum (post-partum haemolytic uraemic syndrome) • Acute fatty liver of pregnancy • 'HELLP' syndrome: haemolysis, elevated liver enzymes, low platelets (thrombotic microangiopathy with abnormal liver function)
	Clinical signs
	<ul style="list-style-type: none"> • Hypertension • Proteinuria • Oedema • Other evidence of the clinical syndromes listed above
	Investigations
	<ul style="list-style-type: none"> • Uric acid levels increased (before renal impairment apparent) • Platelets decreased • Reduced GFR (late) • Fetus small for dates and growing slowly • Fetal distress (late)

17.55 Risk factors for pre-eclampsia

- First pregnancy
- First pregnancy with a new partner or long inter-pregnancy interval
- Pre-eclampsia in previous pregnancies
- Age < 20 yrs or > 35 yrs
- Multiple pregnancy (singleton < twin < triplets etc.)
- Pre-existing hypertension
- Pre-existing renal disease

may be relative, mild or even absent. Furthermore, all these features occur in pre-existing renal disease exacerbated by pregnancy. Distinguishing pre-eclampsia from pre-existing renal disease is important. Pre-eclampsia presents progressively, increasing risks to mother and fetus which can be reversed almost immediately by early delivery. In contrast, in pre-existing renal disease, con-

tinuing the pregnancy for as long as possible may permit delivery of a healthier, more mature baby. Proteinuria and hypertension in the first trimester of pregnancy suggest pre-existing renal disease.

Management

The only effective management for pre-eclampsia is delivery. The role of antiplatelet therapy (low-dose aspirin) remains controversial. Hypertension is a consequence and not the cause of the disorder, and treatment is only justified to lower it from severe and immediately dangerous levels (e.g. > 150–160/100–110 mmHg). Treating lower levels has been shown to confer no benefit and exposes the fetus to additional drugs. If life-threatening complications are not present and the baby is immature, corticosteroids may be given to induce maturation of fetal lungs, and delivery postponed while mother and baby are closely observed. Magnesium sulphate reduces the incidence of eclamptic convulsions.

17.56 Mechanisms and examples of drug-induced renal disease/dysfunction

Mechanism	Drug or toxin	Comments
Haemodynamic	NSAIDs ACE inhibitors	Especially as a co-factor. Via inhibition of prostaglandin synthesis Reduce efferent glomerular arteriolar tone. Toxic in the presence of renal artery stenosis and other conditions of renal hypoperfusion Multifactorial aetiology may include intense vasoconstriction
	Radiographic contrast media	
Acute tubular necrosis	Aminoglycosides, amphotericin	In most examples there is evidence of direct tubular toxicity but haemodynamic and other factors probably contribute
	Paracetamol overdose	May occur with or without serious hepatotoxicity
	Radiographic contrast media	May be secondary to precipitation in tubules. Furosemide is a co-factor
Loss of tubular/collecting duct function	Lithium Cisplatin	Dose-related, partially reversible loss of concentrating ability
	Aminoglycosides, amphotericin	At lower exposures than cause acute tubular necrosis
Immune (glomerular)	Penicillamine, gold Penicillamine	Membranous nephropathy Crescentic or focal necrotising glomerulonephritis in association with ANCA and systemic small-vessel vasculitis
	NSAIDs	Minimal change nephropathy
Immune (interstitial)	NSAIDs, penicillins, proton pump inhibitors, many others	Acute interstitial nephritis
Chronic interstitial nephritis (alone)	Lithium Ciclosporin, tacrolimus	As a consequence of acute toxicity. Otherwise controversial The major problem with these drugs
Chronic interstitial nephritis (with papillary necrosis)	Various analgesics (p. 506)	
Obstruction (crystal formation)	Aciclovir	Crystals of the drug form in tubules. Aciclovir is now more common than the original example of sulphonamides
	Chemotherapy	Uric acid crystals forming as a consequence of tumour lysis (typically a first-dose effect in haematological malignancy)
Nephrocalcinosis	Oral sodium phosphate containing bowel cleansing agents	Precipitation of calcium phosphate occurring in 1–4% and exacerbated by volume depletion. Usually mild but damage can be irreversible
Retroperitoneal fibrosis	Ergolinic dopamine agonists (e.g. cabergoline), methysergide*, practolol*	Idiopathic is more common (p. 509)

*These drugs are no longer in use in the UK.

Acute renal failure in pregnancy

Maternal acute renal failure may occur in almost any of the pre-eclamptic syndromes. Worldwide, an important cause of acute renal failure is septic abortion, when the uterus becomes infected because of retained products of conception or poor sterility in an often illegally induced abortion. Renal function is usually recoverable, but acute renal failure in pregnancy is particularly prone to progress to cortical necrosis with incomplete or total failure to recover renal function.

DRUGS AND THE KIDNEY

Prescribing in renal disease

Many drugs and drug metabolites are excreted by the kidney so the presence of renal impairment alters the required dose and frequency. This is discussed on page 27.

Drug-induced renal disease

The kidney is susceptible to damage by drugs because it is the route of excretion of many water-soluble compounds, including drugs and their metabolites. Some may reach high concentrations in the renal cortex as a result of proximal tubular transport mechanisms. Others are concentrated in the medulla by the operation of the counter-current system. The same applies to certain toxins.

Toxic renal damage may occur by a variety of mechanisms (Box 17.56). Very commonly, drugs contribute as one of multiple insults to the development of acute tubular necrosis. Numerically, reactions to NSAIDs and ACE inhibitors are the most important. Haemodynamic renal impairment, acute tubular necrosis and allergic reactions are usually reversible if recognised early enough. However, other types, especially those associated with extensive fibrosis, are less likely to be reversible.

NSAIDs

As described on page 483, NSAIDs impair renal function in individuals in whom prostaglandin-dependent

compensatory mechanisms are maintaining renal function (e.g. heart failure, cirrhosis, sepsis and renal impairment of almost any type), and may precipitate ARF in susceptible patients. In addition, idiosyncratic immune reactions may occur; causing minimal change nephrotic syndrome (p. 500) and acute interstitial nephritis (p. 504). Analgesic nephropathy (p. 506) is now a rare complication of long-term use.

ACE inhibitors

These abolish the compensatory angiotensin II-mediated vasoconstriction of the glomerular efferent arteriole that occurs to maintain glomerular perfusion pressure distal to a renal artery stenosis and in renal hypoperfusion (see Fig. 17.1, p. 463). Monitoring of renal function before and after initiation of therapy is essential.

4 Examination of the arterial pulse

- The character of the pulse is determined by stroke volume and arterial compliance, and is best assessed by palpating a major artery, such as the carotid or brachial.
- Aortic regurgitation, anaemia, sepsis and other causes of a large stroke volume typically produce a bounding pulse with a high amplitude and wide pulse pressure (panel A).
- Aortic stenosis impedes ventricular emptying and may cause a slow rising, weak and delayed pulse (panel A).
- Normal sinus rhythm produces a pulse that is regular in time and force. Arrhythmias may cause irregularity. Atrial fibrillation produces a pulse that is irregular in time and volume (panel B).

A

B

5 Examination of the jugular venous pulse

The internal jugular vein, superior vena cava and right atrium are in continuity, so the height of the jugular venous pulsation reflects right atrial pressure. When the patient is placed at 45°, with the head supported and turned a few degrees to the left, the jugular venous pulse (JVP) is visible along the line of the sternocleidomastoid muscle (see opposite).

- The height of the JVP is determined by right atrial pressure and is therefore elevated in right heart failure and reduced in hypovolaemia.
- If the JVP is not easily seen, it may be highlighted by gentle pressure on the abdomen (so-called 'hepato-jugular' reflux).
- In normal sinus rhythm the two venous peaks, the *a* and *v* waves, approximate to atrial and ventricular systole respectively.
- The *x* descent reflects atrial relaxation and apical displacement of the tricuspid valve ring. The *y* descent reflects atrial emptying early in diastole. These signs are subtle.
- Tricuspid regurgitation produces giant *v* waves that coincide with ventricular systole.

Waveform of the jugular venous pulse.

Features that distinguish venous from arterial pulsation in the neck

- Venous pulse has two peaks in each cardiac cycle (arterial has one).
- The height of the venous pulse varies with respiration (falls on inspiration) and position.
- Abdominal compression causes the venous pulse to rise.
- Venous pulse is not palpable and can be occluded by light pressure.

7 Palpation of the precordium

Technique

- Place fingertips over apex (1) to assess for position and character. Place heel of hand over left sternal edge (2) for a parasternal heave or 'lift'. Assess for the presence of thrills in all areas, including the aortic and pulmonary areas (3).

Common abnormalities of the apex beat

- Volume overload, such as mitral or aortic regurgitation: displaced, forceful
- Pressure overload, such as aortic stenosis, hypertension: discrete, thrusting
- Dyskinetic, such as left ventricular aneurysm: displaced, incoordinate

Other abnormalities

- Palpable S1 (tapping apex beat: mitral stenosis)
- Palpable P2 (severe pulmonary hypertension)
- Left parasternal heave or 'lift' felt by heel of hand (right ventricular hypertrophy)
- Palpable thrill (aortic stenosis)

Palpation of the precordium.

8 Auscultation of the heart

- Use the diaphragm to examine at the apex, lower left sternal edge (tricuspid area) and upper left (pulmonary area) and right (aortic area) sternal edges.
- Use the bell to examine low-pitched noises, particularly at the apex for mid-diastolic murmurs.
- Time the sounds and murmurs by feeling the carotid pulse; systolic murmurs are synchronous with the pulse.
- Listen for radiation of systolic murmurs, over the base of the neck (aortic stenosis) and in the axilla (mitral incompetence).
- Listen over the left sternal border with the patient sitting forward (aortic incompetence), then at the apex with the patient rolled on to the left side (mitral stenosis).

The haemodynamic effects of respiration are discussed on page 528.

See pages 557–559 for analysis and interpretation of heart sounds and murmurs.

Cardiovascular disease is the most frequent cause of adult death in the Western world; in the UK one-third of men and one-quarter of women will die as a result of ischaemic heart disease. In many developed countries, the incidence of ischaemic heart disease has been falling for the last two or three decades, but it is rising in Eastern Europe and Asia. Cardiovascular disease may thus soon become the leading cause of death on all continents. Strategies for the treatment and prevention of heart disease can be highly effective and have been subjected to rigorous evaluation. The evidence base for the treatment of cardiovascular disease is stronger than for almost any other disease group.

Valvular heart disease is common, but the aetiology varies in different parts of the world. On the Indian subcontinent and in Africa, it is predominantly due to rheumatic fever, whereas calcific aortic valve disease is the most common problem in developed countries.

Prompt recognition of the development of heart disease is limited by two key factors. Firstly, it is often latent; coronary artery disease can proceed to an advanced stage before the patient notices any symptoms. Secondly, the diversity of symptoms attributable to heart disease is limited, so different pathologies may frequently present with the same symptoms.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Anatomy

The heart acts as two serial pumps that share several electrical and mechanical components. The right heart circulates blood to the lungs where it is oxygenated, and the left heart receives this and circulates it to the rest of the

body (Fig. 18.1). The atria are thin-walled structures that act as priming pumps for the ventricles, which provide most of the energy to the circulation. Within the mediastinum, the atria are situated posteriorly and the left atrium (LA) sits anterior to the oesophagus and descending aorta. The interatrial septum separates the two atria. In 20% of adults a patent foramen ovale is found; this communication in the fetal circulation between the right and left atria normally closes at birth (p. 629). The right atrium (RA) receives blood from the superior and inferior venae cavae and the coronary sinus. The LA receives blood from four pulmonary veins, two from each of the left and right lungs. The ventricles are thick-walled structures, adapted to circulating blood through large vascular beds under pressure. The atria and ventricles are separated by the annulus fibrosus, which forms the skeleton for the atrioventricular (AV) valves and which electrically insulates the atria from the ventricles. The right ventricle (RV) is roughly triangular in shape and extends from the annulus fibrosus to near the cardiac apex, which is situated to the left of the midline. Its anterosuperior surface is rounded and convex, and its posterior extent is bounded by the interventricular septum, which bulges into the chamber. Its upper extent is conical, forming the conus arteriosus or outflow tract, from which the pulmonary artery arises. The RV sits anterior to and to the right of the left ventricle (LV). The LV is more conical in shape and in cross-section is nearly circular. It extends from the LA to the apex of the heart. The LV myocardium is normally around 10 mm thick (c.f. RV thickness of 2–3 mm) because it pumps blood at a higher pressure.

The normal heart occupies less than 50% of the transthoracic diameter in the frontal plane, as seen on a chest X-ray. On the patient's left, the cardiac silhouette is formed by the aortic arch, the pulmonary trunk, the left atrial appendage and the LV. On the right, the RA is joined by superior and inferior venae cavae, and

Fig. 18.1 Direction of blood flow through the heart. The blue arrows show deoxygenated blood moving through the right heart to the lungs. The red arrows show oxygenated blood moving from the lungs to the systemic circulation. The normal pressures are shown for each chamber in mmHg.

Fig. 18.2 Surface anatomy of the heart. The positions of the major cardiac chambers and heart valves are shown.

the lower right border is made up by the RV (Fig. 18.2). In disease states or congenital cardiac abnormalities, the silhouette may change as a result of hypertrophy or dilatation.

The coronary circulation

The left main and right coronary arteries arise from the left and right coronary sinuses of the aortic root, distal to the aortic valve (Fig. 18.3). Within 2.5cm of its origin, the left main coronary artery divides into the left anterior descending artery (LAD), which runs in the anterior interventricular groove, and the left circumflex artery (CX), which runs posteriorly in the atrioventricular groove. The LAD gives branches to supply the anterior part of the septum (septal perforators) and the anterior, lateral and apical walls of the LV. The CX gives marginal branches that supply the lateral, posterior and inferior segments

Fig. 18.3 The coronary arteries of the heart. Diagram of the anterior view.

of the LV. The right coronary artery (RCA) runs in the right atrioventricular groove, giving branches that supply the RA, RV and inferoposterior aspects of the LV. The posterior descending artery runs in the posterior interventricular groove and supplies the inferior part of the interventricular septum. This vessel is a branch of the RCA in approximately 90% of people (dominant right system) and is supplied by the CX in the remainder (dominant left system). The coronary anatomy varies greatly from person to person and there are many 'normal variants'.

The RCA supplies the sinoatrial (SA) node in about 60% of individuals and the AV node in about 90%. Proximal occlusion of the RCA therefore often results in sinus bradycardia and may also cause AV nodal block. Abrupt occlusions in the RCA, due to coronary thrombosis, result in infarction of the inferior part of the LV and often the RV. Abrupt occlusion of the LAD or CX causes infarction in the corresponding territory of the LV, and occlusion of the left main coronary artery is usually fatal.

The venous system follows the coronary arteries but drains into the coronary sinus in the atrioventricular groove, and then to the RA. An extensive lymphatic system drains into vessels that travel with the coronary vessels and then into the thoracic duct.

Conducting system of the heart

The SA node is situated at the junction of the superior vena cava and RA (Fig. 18.4). It comprises specialised atrial cells that depolarise at a rate influenced by the autonomic nervous system and by circulating catecholamines. During normal (sinus) rhythm, this depolarisation wave propagates through both atria via sheets of atrial myocytes. The annulus fibrosus forms a conduction barrier between atria and ventricles, and the only pathway through it is the AV node. This is a midline structure, extending from the right side of the interatrial septum, penetrating the annulus fibrosus anteriorly. The AV node conducts relatively slowly, producing a necessary time delay between atrial and ventricular contraction. The His-Purkinje system is comprised of the bundle of His extending from the AV node into the interventricular septum, the right and left bundle branches passing along the ventricular septum and into

Fig. 18.4 The cardiac conduction system. Depolarisation starts in the sinoatrial node and spreads through the atria (blue arrows), and then through the atrioventricular node (black arrows). Depolarisation then spreads through the bundle of His and the bundle branches to reach the ventricular muscle (red arrows). Repolarisation spreads from epicardium to endocardium (green arrows).

the respective ventricles, the anterior and posterior fascicles of the left bundle branch, and the smaller Purkinje fibres that ramify through the ventricular myocardium. The tissues of the His–Purkinje system conduct very rapidly and allow near-simultaneous depolarisation of the entire ventricular myocardium.

Nerve supply of the heart

The heart is innervated by both sympathetic and parasympathetic fibres. Adrenergic nerves from the cervical sympathetic chain supply muscle fibres in the atria and ventricles and the electrical conducting system. Positive inotropic and chronotropic effects are mediated by β_1 -adrenoceptors, whereas β_2 -adrenoceptors predominate in vascular smooth muscle and mediate vasodilatation. Parasympathetic pre-ganglionic fibres and sensory fibres reach the heart through the vagus nerves. Cholinergic nerves supply the AV and SA nodes via muscarinic (M2) receptors. Under resting conditions, vagal inhibitory activity predominates and the heart rate is slow. Adrenergic stimulation associated with exercise, emotional stress, fever and so on causes the heart rate to increase. In disease states the nerve supply to the heart may be affected. For example, in heart failure the sympathetic system may be up-regulated, and in diabetes mellitus the nerves themselves may be damaged (autonomic neuropathy, p. 831) so that there is little variation in heart rate.

Physiology

The circulation

The RA receives deoxygenated blood from the superior and inferior venae cavae and discharges blood to the RV, which in turn pumps it into the pulmonary artery. Blood passes through the pulmonary arterial and alveolar capillary bed where it is oxygenated, then drains via four pulmonary veins into the LA. This in turn fills the LV, which delivers blood into the aorta (see Fig. 18.1). During ventricular contraction (systole), the tricuspid valve in the right heart and the mitral valve in the left heart close, and the pulmonary and aortic valves open. In diastole, the pulmonary and aortic valves close, and the two AV valves open. Collectively, these atrial and ventricular events constitute the cardiac cycle of filling and ejection of blood from one heartbeat to the next.

Myocardial contraction

Myocardial cells (myocytes) are about 50–100 μm long; each cell branches and interdigitates with adjacent cells. An intercalated disk permits electrical conduction via gap junctions, and mechanical conduction via the fascia adherens, to adjacent cells. The basic unit of contraction is the sarcomere (2 μm long), which is aligned to those of adjacent myofibrils, giving a striated appearance due to the Z-lines (Fig. 18.5). Actin filaments are attached at

Fig. 18.5 Schematic of myocytes and a muscle fibre. The arrangement of myofibrils, and longitudinal and transverse tubules extending from the sarcoplasmic reticulum are shown. The expanded section shows a schematic of an individual sarcomere with thick filaments composed of myosin and thin filaments composed primarily of actin.

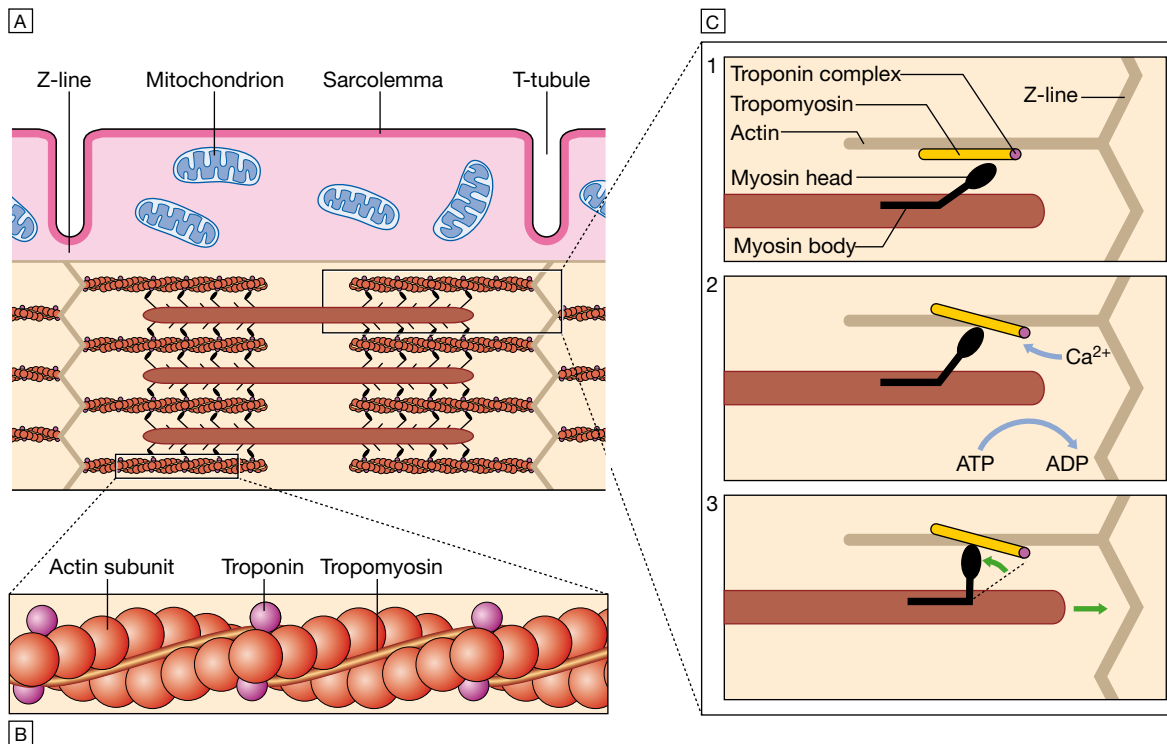

Fig. 18.6 Contraction process within the muscle fibre. **A** Schematic of a sarcomere showing the overlapping of actin and myosin filaments. **B** Enlarged diagram of the structure of an actin filament. **C** The three stages of contraction resulting in shortening of the sarcomere. (1) The actin binding site is blocked by tropomyosin. (2) ATP-dependent release of calcium ions which bind to troponin, displacing tropomyosin. The binding site is exposed. (ADP = adenosine diphosphate; ATP = adenosine triphosphate) (3) Tilting of the angle of attachment of the myosin head, resulting in fibre shortening.

right angles to the Z-lines and interdigitate with thicker parallel myosin filaments. The cross-links between actin and myosin molecules contain myofibrillar ATPase, which breaks down adenosine triphosphate (ATP) to provide the energy for contraction. Two chains of actin molecules form a helical structure, with a second molecule, tropomyosin, in the grooves of the actin helix, and a further molecule complex, troponin, attached to every seventh actin molecule (Fig. 18.6).

During the plateau phase of the action potential, calcium ions enter the cell and are mobilised from the sarcoplasmic reticulum. They bind to troponin and thereby precipitate contraction by shortening of the sarcomere through the interdigitation of the actin and myosin molecules. The force of cardiac muscle contraction, or inotropic state, is regulated by the influx of calcium ions through 'slow calcium channels'. The extent to which the sarcomere can shorten determines stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or marked exercise. However, the enlargement of the heart seen in heart failure is due to slippage of the myofibrils and adjacent cells rather than lengthening of the sarcomere.

Cardiac output

Cardiac output is the product of stroke volume and heart rate. Stroke volume is the volume of blood ejected in each cardiac cycle (see Fig. 18.36, p. 559), and is dependent upon end-diastolic volume and pressure (preload), myocardial contractility and systolic aortic pressure (afterload). Stretch of cardiac muscle (from increased end-diastolic volume) causes an increase in the force

of contraction, producing a greater stroke volume: Starling's Law of the heart (see Fig. 18.22, p. 544).

The contractile state of the myocardium is controlled by neuro-endocrine factors, such as adrenaline (epinephrine), and can be influenced by inotropic drugs and their antagonists. The response to a physiological change or to a drug can be predicted on the basis of its combined influence on preload, afterload and contractility (see Fig. 18.26, p. 548).

Blood flow

Blood passes from the heart through the large central elastic arteries into muscular arteries before encountering the resistance vessels, and ultimately the capillary bed where there is exchange of nutrients, oxygen and waste products of metabolism. The central arteries, such as the aorta, are predominantly composed of elastic tissue with little or no vascular smooth muscle cells. When blood is ejected from the heart, the compliant aorta expands to accommodate the volume of blood before the elastic recoil sustains blood pressure (BP) and flow following cessation of cardiac contraction. This 'Windkessel effect' prevents excessive rises in systolic BP whilst sustaining diastolic BP, thereby reducing cardiac afterload and maintaining coronary perfusion. These benefits are lost with progressive arterial stiffening: a feature of ageing and advanced renal disease.

Passing down the arterial tree, vascular smooth muscle cells progressively play a greater role until the resistance arterioles are encountered. Although all vessels contribute, the resistance vessels (diameter 50–200 μm) provide the greatest contribution to systemic vascular resistance, with small changes in radius having a marked

influence on blood flow; resistance is proportional to the fourth power of the radius (Poiseuille's Law). The tone of these resistance vessels is tightly regulated by humoral, neuronal and mechanical factors. Neurogenic constriction operates via α -adrenoceptors on vascular smooth muscle, and dilatation via muscarinic and β_2 -adrenoceptors. In addition, systemic and locally released vasoactive substances influence tone; vasoconstrictors include noradrenaline (norepinephrine), angiotensin II and endothelin-1, whereas adenosine, bradykinin, prostaglandins and nitric oxide are vasodilators. Resistance to blood flow rises with viscosity and is mainly influenced by red cell concentration (haematocrit).

Coronary blood vessels receive sympathetic and parasympathetic innervation. Stimulation of α -adrenoceptors causes vasoconstriction; stimulation of β_2 -adrenoceptors causes vasodilatation; the predominant effect of sympathetic stimulation in coronary arteries is vasodilatation. Parasympathetic stimulation also causes modest dilatation of normal coronary arteries. As a result of vascular regulation, an atheromatous narrowing (stenosis) in a coronary artery does not limit flow, even during exercise, until the cross-sectional area of the vessel is reduced by at least 70%.

Endothelial function

The endothelium plays a vital role in the control of vascular homeostasis. It synthesises and releases many vasoactive mediators that cause vasodilatation, including nitric oxide, prostacyclin and endothelium-derived hyperpolarising factor, and vasoconstriction, including endothelin-1 and angiotensin II. A balance exists whereby the release of such factors contributes to the maintenance and regulation of vascular tone and BP. Damage to the endothelium may disrupt this balance and lead to vascular dysfunction, tissue ischaemia and hypertension.

The endothelium also has a major influence on key regulatory steps in the recruitment of inflammatory cells and on the formation and dissolution of thrombus. Once activated, the endothelium expresses surface receptors such as E-selectin, intercellular adhesion molecule type 1 (ICAM-1) and platelet endothelial cell adhesion molecule type 1 (PECAM-1), which mediate rolling, adhesion and migration of inflammatory leucocytes into the subintima. The endothelium also stores and releases the multimeric glycoprotein, von Willebrand factor, which promotes thrombus formation by linking platelet adhesion to denuded surfaces, especially in the arterial vasculature. In contrast, once intravascular thrombus forms, tissue plasminogen activator is rapidly released from a dynamic storage pool within the endothelium to induce fibrinolysis and thrombus dissolution. These processes are critically involved in the development and progression of atherosclerosis, and endothelial function and injury is seen as central to the pathogenesis of many cardiovascular disease states.

Effects of respiration

There is a fall in intrathoracic pressure during inspiration that tends to promote venous flow into the chest, producing an increase in the flow of blood through the right heart. However, a substantial volume of blood is sequestered in the chest as the lungs expand; the increase in the capacitance of the pulmonary vascular bed usually exceeds any increase in the output of the right heart and there is therefore a reduction in the flow of blood into the left heart

18.1 Haemodynamic effects of respiration

	Inspiration	Expiration
Jugular venous pressure	Falls	Rises
Blood pressure	Falls (up to 10 mmHg)	Rises
Heart rate	Accelerates	Slows
Second heart sound	Splits*	Fuses*

*Inspiration prolongs RV ejection, delaying P₂, and shortens LV ejection, bringing forward A₂; expiration produces the opposite effects.

during inspiration. In contrast, expiration is accompanied by a fall in venous return to the right heart, a reduction in the output of the right heart, a rise in the venous return to the left heart (as blood is squeezed out of the lungs) and an increase in the output of the left heart (Box 18.1).

Pulsus paradoxus

This term is used to describe the exaggerated fall in BP during inspiration that is characteristic of cardiac tamponade (pp. 542 and 639) and severe airways obstruction. In airways obstruction, it is due to accentuation of the change in intrathoracic pressure with respiration. In cardiac tamponade, compression of the right heart prevents the normal increase in flow through the right heart on inspiration, which exaggerates the usual drop in venous return to the left heart and produces a marked fall in BP.

INVESTIGATION OF CARDIOVASCULAR DISEASE

Specific investigations may be required to confirm a diagnosis of cardiac disease. Basic tests, such as electrocardiography, chest X-ray and echocardiography, can be performed in an outpatient clinic or at the bedside. Procedures such as cardiac catheterisation, radionuclide imaging, computed tomography (CT) and magnetic resonance imaging (MRI) require specialised facilities.

Electrocardiogram (ECG)

The ECG is used to assess cardiac rhythm and conduction. It provides information about chamber size and is the main test used to assess for myocardial ischaemia and infarction.

The basis of an ECG recording is that the electrical depolarisation of myocardial tissue produces a small dipole current which can be detected by electrode pairs on the body surface. To produce an ECG, these signals are amplified and either printed or displayed on a monitor (Fig. 18.7). During sinus rhythm, the SA node triggers atrial depolarisation, producing a P wave. Depolarisation proceeds slowly through the AV node, which is too small to produce a depolarisation wave detectable from the body surface. The bundle of His, bundle branches and Purkinje system are then activated, initiating ventricular myocardial depolarisation, which produces the QRS complex. The muscle mass of the ventricles is much larger than that of the atria, so the QRS

Fig. 18.7 The electrocardiograph. The components correspond to depolarisation and repolarisation, as depicted in Figure 18.4. The upper limit of the normal range for each interval is given in brackets.

complex is larger than the P wave. The interval between the onset of the P wave and the onset of the QRS complex is termed the 'PR interval' and largely reflects the duration of AV nodal conduction. Injury to the left or right bundle branch delays ventricular depolarisation, widening the QRS complex. Selective injury of one of the left fascicles (hemiblock, p. 570) affects the electrical axis. Repolarisation is a slower process that spreads from the epicardium to the endocardium. Atrial repolarisation does not cause a detectable signal but ventricular repolarisation produces the T wave. The QT interval represents the total duration of ventricular depolarisation and repolarisation.

The standard 12-lead ECG

The 12-lead ECG (Box 18.2) is generated from ten physical electrodes that are attached to the skin. One electrode is attached to each limb and six electrodes are attached to the chest. In addition the left arm, right arm and left leg electrodes are attached to a central terminal acting as an additional virtual electrode in the centre of the chest (the right leg electrode acts as an earthing electrode). The twelve 'leads' of the ECG refer to recordings made from pairs or sets of these electrodes. They comprise three groups: three dipole limb leads, three augmented voltage limb leads and six unipole chest leads.

Leads I, II and III are the dipole limb leads and refer to recordings obtained from pairs of limb electrodes. Lead I records the signal between the right (-ve) and left (+ve) arms. Lead II records the signal between the right arm (-ve) and left leg (+ve). Lead III records the signal between the left arm (-ve) and left leg (+ve). These three leads thus record electrical activity along three different axes in the frontal plane. Leads aVR, aVL and aVF are the augmented voltage limb leads. These record electrical activity between a limb electrode and a modified central terminal. For example, lead aVL records the signal between the left arm (+ve) and a central (-ve) terminal formed by connecting the right arm and left leg electrodes (Fig. 18.8). Similarly augmented signals are obtained from the right arm (aVR) and left leg (aVF). These leads also record electrical activity in the frontal plane, with each lead 120° apart. Lead

18.2 How to read a 12-lead ECG: examination sequence

Rhythm strip (lead II)	To determine heart rate and rhythm
Cardiac axis	Normal if QRS complexes +ve in leads I and II
P-wave shape	Tall P waves denote right atrial enlargement (P pulmonale) and notched P waves denote left atrial enlargement (P mitrale)
PR interval	Normal = 0.12–0.20 secs. Prolongation denotes impaired AV nodal conduction. A short PR interval occurs in Wolff–Parkinson–White syndrome (p. 565)
QRS duration	If > 0.12 secs then ventricular conduction is abnormal (left or right bundle branch block)
QRS amplitude	Large QRS complexes occur in slim young patients and in patients with left ventricular hypertrophy
Q waves	May signify previous myocardial infarction (MI)
ST segment	ST elevation may signify MI, pericarditis or left ventricular aneurysm; ST depression may signify myocardial ischaemia or infarction)
T waves	T-wave inversion has many causes, including myocardial ischaemia or infarction, and electrolyte disturbances
QT interval	Normal < 0.42 secs. QT prolongation may occur with congenital long QT syndrome, low K ⁺ , Mg ²⁺ or Ca ²⁺ , and some drugs (see Box 18.35, p. 568)
ECG conventions	Depolarisation towards electrode: positive deflection Depolarisation away from electrode: negative deflection Sensitivity: 10 mm = 1 mV Paper speed: 25 mm per second Each large (5 mm) square = 0.2 s Each small (1 mm) square = 0.04 s Heart rate = 1500/RR interval (mm) (i.e. 300 ÷ number of large squares between beats)

aVF thus examines activity along the axis +90°, and lead aVL along the axis -30° etc.

When depolarisation moves towards a positive electrode, it produces a positive deflection in the ECG; depolarisation in the opposite direction produces a negative deflection. The average vector of ventricular depolarisation is known as the frontal cardiac axis. When the vector is at right angles to a lead, the depolarisation in that lead is equally negative and positive (isoelectric). In Figure 18.8, the QRS complex is isoelectric in aVL, negative in aVR and most strongly positive in lead II; the main vector or axis of depolarisation is therefore 60°. The normal cardiac axis lies between -30° and +90°. Examples of left and right axis deviation are shown in Figures 18.8B and C.

There are six chest leads, V₁–V₆, derived from electrodes placed on the anterior and lateral left side of the chest, over the heart. Each lead records the signal between the corresponding chest electrode (+ve) and the central terminal (-ve). Leads V₁ and V₂ lie approximately over the RV, V₃ and V₄ over the interventricular septum, and V₅ and V₆ over the LV (Fig. 18.9). The LV has the greater muscle mass and contributes the major component of the

Fig. 18.8 The appearance of the ECG from different leads in the frontal plane. **A** Normal. **B** Left axis deviation, with negative deflection in lead II and positive in lead I. **C** Right axis deviation, with negative deflection in lead I and positive in lead II.

QRS complex. Depolarisation of the interventricular septum occurs first and moves from left to right; this generates a small initial negative deflection in lead V_6 (Q wave) and an initial positive deflection in lead V_1 (R wave). The second phase of depolarisation is activation of the body of the LV, which creates a large positive deflection or R wave in V_6 (with reciprocal changes in V_1). The third and final phase of depolarisation involves the RV and produces a small negative deflection or S wave in V_6 .

The ECG in ischaemia and infarction

When an area of the myocardium is ischaemic or undergoing infarction, repolarisation and depolarisation become abnormal relative to the surrounding myocardium. In transmural infarction there is initial ST segment elevation (the current of injury) in the leads facing or overlying the infarct; Q waves (negative deflections)

will then appear as the entire thickness of the myocardial wall becomes electrically neutral relative to the adjacent myocardium. The changes occurring in infarction are described in more detail on page 588, and shown in Figures 18.70–18.74 (pp. 590–591). In myocardial ischaemia, the ECG typically shows ST segment depression and/or T-wave inversion; it is usually the subendocardium that most readily becomes ischaemic. Other conditions, such as left ventricular hypertrophy and electrolyte disturbances, can cause similar ST and T-wave changes.

Exercise (stress) ECG

Exercise electrocardiography is used to detect myocardial ischaemia during physical stress and is helpful in the diagnosis of coronary artery disease. A 12-lead ECG is recorded during exercise on a treadmill or bicycle ergometer. The limb electrodes are placed on the shoulders and hips rather than the wrists and ankles. The Bruce Protocol is the most commonly used protocol for treadmill testing (Box 18.3). BP is recorded and symptoms assessed throughout the test. Common indications for exercise testing are shown in Box 18.4. A test is 'positive' if anginal pain occurs, BP falls or fails to increase, or if there are ST segment shifts of > 1 mm (see Fig. 18.63, p. 583). Exercise testing is useful in confirming the diagnosis in patients with suspected angina, and in such patients has good sensitivity and specificity (see Box 18.4). False negative results can occur in patients with

18.3 The Bruce Protocol for exercise tolerance testing

	Speed		Gradient (% incline)
	(mph)	(kph)	
Stage 1*	1.7	2.7	10
Stage 2	2.5	4.0	12
Stage 3	3.4	5.4	14
Stage 4	4.2	6.7	16
Stage 5	5.0	8.0	18

*Each stage lasts for 3 mins.

18.4 Exercise testing

Indications

- To confirm the diagnosis of angina
- To evaluate stable angina
- To assess prognosis following MI
- To assess outcome after coronary revascularisation, e.g. coronary angioplasty
- To diagnose and evaluate the treatment of exercise-induced arrhythmias

High-risk findings

- Low threshold for ischaemia (i.e. within stage 1 or 2 of the Bruce Protocol)
- Fall in BP on exercise
- Widespread, marked or prolonged ischaemic ECG changes
- Exercise-induced arrhythmia

Fig. 18.9 The sequence of activation of the ventricles. **A** Activation of the septum occurs first (red arrows), followed by spreading of the impulse through the LV (blue arrows) and then the RV (green arrows). **B** Normal electrocardiographic complexes from leads V_1 and V_6 .

coronary artery disease, and some patients with a positive test will not have coronary disease (false positive). Exercise testing is an unreliable population screening tool because in low-risk individuals (e.g. asymptomatic young or middle-aged women) an abnormal response is more likely to represent a false positive than a true positive test.

Stress testing is contraindicated in the presence of acute coronary syndrome, decompensated heart failure and severe hypertension.

Ambulatory ECG

Continuous (ambulatory) ECG recordings can be obtained using a portable digital recorder. These devices usually provide limb lead ECG recordings only, and can record for between 1 and 7 days. Ambulatory ECG recording is principally used in the investigation of patients with suspected arrhythmia, such as those with intermittent palpitation, dizziness or syncope. For these patients, a 12-lead ECG provides only a snapshot of the cardiac rhythm and is unlikely to detect an intermittent arrhythmia, so a longer period of recording is useful (see Fig. 18.50, p. 569). These devices can also be used to assess rate control in patients with atrial fibrillation, and are sometimes used to detect transient myocardial ischaemia using ST segment analysis. For patients with more infrequent symptoms, small patient-activated ECG recorders can be issued for several weeks until a symptom episode occurs. The patient places the device on the chest to record the rhythm during the episode. With some devices the recording can be transmitted to the hospital via telephone. Implantable 'loop recorders' are small devices that resemble a leadless pacemaker and are implanted subcutaneously. They have a lifespan of 1–3 years and are used to investigate patients with infrequent but potentially serious symptoms, such as syncope.

Cardiac biomarkers

Plasma or serum biomarkers can be measured to assess myocardial dysfunction and ischaemia.

Brain natriuretic peptide

This is a 32 amino acid peptide and is secreted by the LV along with an inactive 76 amino acid N-terminal fragment (NT-proBNP). The latter is diagnostically more useful, as it has a longer half-life. It is elevated principally in conditions associated with left ventricular systolic dysfunction and may aid the diagnosis and assess prognosis and response to therapy in patients with heart failure (p. 543).

Cardiac troponins

Troponin I and troponin T are structural cardiac muscle proteins (see Fig. 18.6, p. 527) that are released during myocyte damage and necrosis, and represent the cornerstone of the diagnosis of acute myocardial infarction (MI, p. 590). However, modern assays are extremely sensitive and can detect very low levels of myocardial damage, so that elevated plasma troponin concentrations are seen in other acute conditions, such as pulmonary embolus, septic shock and acute pulmonary oedema. The diagnosis of MI therefore relies on the patient's clinical presentation (see Box 18.63, p. 588).

Chest X-ray

This is useful for determining the size and shape of the heart, and the state of the pulmonary blood vessels and lung fields. Most information is given by a postero-anterior (PA) projection taken in full inspiration. Anteroposterior (AP) projections are convenient when

patient movement is restricted but result in magnification of the cardiac shadow.

An estimate of overall heart size can be made by comparing the maximum width of the cardiac outline with the maximum internal transverse diameter of the thoracic cavity. 'Cardiomegaly' is the term used to describe an enlarged cardiac silhouette where the 'cardiothoracic ratio' is > 0.5 . It can be caused by chamber dilatation, especially left ventricular dilatation, or by a pericardial effusion. Artefactual cardiomegaly may be due to a mediastinal mass or pectus excavatum (p. 730), and cannot be reliably assessed from an AP film. Cardiomegaly is not a sensitive indicator of left ventricular systolic dysfunction since the cardiothoracic ratio is normal in many affected patients.

Dilatation of individual cardiac chambers can be recognised by the characteristic alterations to the cardiac silhouette:

- Left atrial dilatation results in prominence of the left atrial appendage, creating the appearance of a straight left heart border, a double cardiac shadow to the right of the sternum, and widening of the angle of the carina (bifurcation of the trachea) as the left main bronchus is pushed upwards (Fig. 18.10).
- Right atrial enlargement projects from the right heart border towards the right lower lung field.
- Left ventricular dilatation causes prominence of the left heart border and enlargement of the cardiac silhouette. Left ventricular hypertrophy produces rounding of the left heart border (Fig. 18.11).
- Right ventricular dilatation increases heart size, displaces the apex upwards and straightens the left heart border.

Lateral or oblique projections may be useful for detecting pericardial calcification in patients with constrictive pericarditis (p. 639) or a calcified thoracic aortic aneurysm, as these abnormalities may be obscured by the spine on the PA view.

Fig. 18.10 Chest X-ray of a patient with mitral stenosis and regurgitation indicating enlargement of the LA and prominence of the pulmonary artery trunk.

Fig. 18.11 Chest X-ray of a patient with aortic regurgitation, left ventricular enlargement and dilatation of the ascending aorta.

The lung fields on the chest X-ray may show congestion and oedema in patients with heart failure (see Fig. 18.25, p. 547), and an increase in pulmonary blood flow ('pulmonary plethora') in those with left-to-right shunt. Pleural effusions may also occur in heart failure.

Echocardiography (echo)

Two-dimensional echocardiography

Echocardiography, or cardiac ultrasound, is obtained by placing an ultrasound transducer on the chest wall to image the heart structures as a real-time two-dimensional 'slice'. This permits the rapid assessment of cardiac structure and function. Left ventricular wall thickness and ejection fraction can be estimated from two-dimensional images. Common indications are shown in Box 18.5.

Doppler echocardiography

This depends on the Doppler principle that sound waves reflected from moving objects, such as intracardiac red blood cells, undergo a frequency shift. The speed and direction of the red cells, and thus of blood, can be detected in the heart chambers and great vessels. The greater the frequency shift, the faster the blood is moving. The derived information can be presented either as a plot of blood velocity against time for a particular point in the heart (Fig. 18.12) or as a colour overlay on a two-dimensional real-time echo picture (colour-flow Doppler, Fig. 18.13). Doppler echocardiography can be used to detect valvular regurgitation, where the direction of blood flow is reversed and turbulence is seen, and

18.5 Common indications for echocardiography

- Assessment of left ventricular function
- Diagnosis and quantification of severity of valve disease
- Identification of vegetations in endocarditis
- Identification of structural heart disease in atrial fibrillation, cardiomyopathies or congenital heart disease
- Detection of pericardial effusion
- Identification of structural heart disease or intracardiac thrombus in systemic embolism

Fig. 18.12 Doppler echocardiography in aortic stenosis. **A** The aortic valve is imaged and a Doppler beam passed directly through the left ventricular outflow tract and the aorta into the turbulent flow beyond the stenosed valve. **B** The velocity of the blood cells is recorded to determine the maximum velocity and hence the pressure gradient across the valve. In this example the peak velocity is approximately 450 cm/sec (4.5 m/sec), indicating severe aortic stenosis (peak gradient of 81 mmHg).

Fig. 18.13 Echocardiographic illustration of the principal cardiac structures in the 'four-chamber' view. **A** The major chambers and valves. **B** Colour-flow Doppler has been used to demonstrate mitral regurgitation: a flame-shaped (yellow/blue) turbulent jet into the LA.

is also used to detect the high pressure gradients associated with stenosed valves. For example, the normal resting systolic flow velocity across the aortic valve is approximately 1 m/sec; in the presence of aortic stenosis, this velocity is increased as blood accelerates through the narrow orifice. In severe aortic stenosis the peak aortic velocity may be increased to 5 m/sec (see Fig. 18.12). An estimate of the pressure gradient across a valve or lesion is given by the modified Bernoulli equation:

$$\text{Pressure gradient (mmHg)} = 4 \times (\text{peak velocity in m/sec})^2$$

Advanced techniques include three-dimensional echocardiography, intravascular ultrasound (defines vessel wall abnormalities and guides coronary intervention), intracardiac ultrasound (provides high-resolution images of cardiac structures) and tissue Doppler imaging (quantifies myocardial contractility and diastolic function).

Transoesophageal echocardiography

Transthoracic echocardiography sometimes produces poor images, especially if the patient is overweight or has obstructive airways disease. Some structures are difficult to visualise in transthoracic views, such as the

left atrial appendage, pulmonary veins, thoracic aorta and interatrial septum. Transoesophageal echocardiography (TOE) uses an endoscope-like ultrasound probe which is passed into the oesophagus under light sedation and positioned immediately behind the LA. This produces high-resolution images, which makes the technique particularly valuable for investigating patients with prosthetic (especially mitral) valve dysfunction, congenital abnormalities (e.g. atrial septal defect), aortic dissection, infective endocarditis (vegetations that are too small to be detected by transthoracic echocardiography) and systemic embolism.

Stress echocardiography

Stress echocardiography is used to investigate patients with suspected coronary heart disease who are unsuitable for exercise stress testing, such as those with mobility problems or pre-existing bundle branch block. A two-dimensional echo is performed before and after infusion of a moderate to high dose of an inotrope such as dobutamine. Myocardial segments with poor perfusion become ischaemic and contract poorly under stress, showing as a wall motion abnormality on the scan.

Stress echocardiography is sometimes used to examine myocardial viability in patients with impaired left ventricular function. Low-dose dobutamine can induce contraction in 'hibernating' myocardium; such patients may benefit from bypass surgery or percutaneous coronary intervention.

Computed tomographic (CT) imaging

This is useful for imaging the cardiac chambers, great vessels, pericardium, and mediastinal structures and masses. Multidetector scanners can acquire up to 320 slices per rotation, allowing very high-resolution imaging. CT is often performed using a timed injection of X-ray contrast to produce clear images of blood vessels and associated pathologies. Contrast scans are very useful for imaging the aorta in suspected aortic dissection (see Fig. 18.82, p. 605), and the pulmonary arteries and branches in suspected pulmonary embolism (p. 717).

Multidetector scanning allows non-invasive imaging of the epicardial coronary arteries with a spatial resolution approaching that of conventional coronary arteriography. Coronary artery bypass grafts are also well seen (see Fig. 18.67, p. 587), and in some centres, multidetector scanning is routinely used to assess graft patency. It is likely that CT will supplant invasive coronary angiography for the initial elective assessment of patients with suspected coronary artery disease. Some centres use cardiac CT scans for quantification of coronary artery calcification, which may serve as an index of cardiovascular risk.

Magnetic resonance imaging (MRI)

This requires no ionising radiation and can be used to generate cross-sectional images of the heart, lungs and mediastinal structures. MRI provides better differentiation of soft tissue structures than CT but is poor at demonstrating calcification. MRI scans can be 'gated' to the ECG, allowing the scanner to produce moving images of the heart and mediastinal structures throughout the

cardiac cycle. MRI is very useful for imaging the aorta, including suspected dissection (see Fig. 18.81, p. 605), and can define the anatomy of the heart and great vessels in patients with congenital heart disease. It is also useful for detecting infiltrative conditions affecting the heart.

Physiological data can be obtained from the signal returned from moving blood that allows quantification of blood flow across regurgitant or stenotic valves. It is also possible to analyse regional wall motion in patients with suspected coronary disease or cardiomyopathy. The RV is difficult to assess using echocardiography because of its retrosternal position but is readily visualised with MRI.

MRI can also be employed to assess myocardial perfusion and viability. When a contrast agent such as gadolinium is injected, areas of myocardial hypoperfusion can be identified with better spatial resolution than nuclear medicine techniques. Later redistribution of this contrast, so-called delayed enhancement, can be used to identify myocardial scarring and fibrosis. This can help in selecting patients for revascularisation procedures, or in identifying those with myocardial infiltration such as that seen with sarcoid heart disease and right ventricular dysplasia.

Cardiac catheterisation

This involves passage of a preshaped catheter via a vein or artery into the heart under X-ray guidance, which allows the measurement of pressure and oxygen saturation in the cardiac chambers and great vessels, and the performance of angiograms by injecting contrast media into a chamber or blood vessel.

Left heart catheterisation involves accessing the arterial circulation via the radial or femoral artery, to allow catheterisation of the aorta, LV and coronary arteries. Coronary angiography is the most widely performed procedure, in which the left and right coronary arteries are selectively cannulated and imaged, providing information about the extent and severity of coronary stenoses, thrombus and calcification (Fig. 18.14). This permits planning of percutaneous coronary intervention and coronary artery bypass graft surgery. Left ventriculography can be performed during the procedure to determine the size

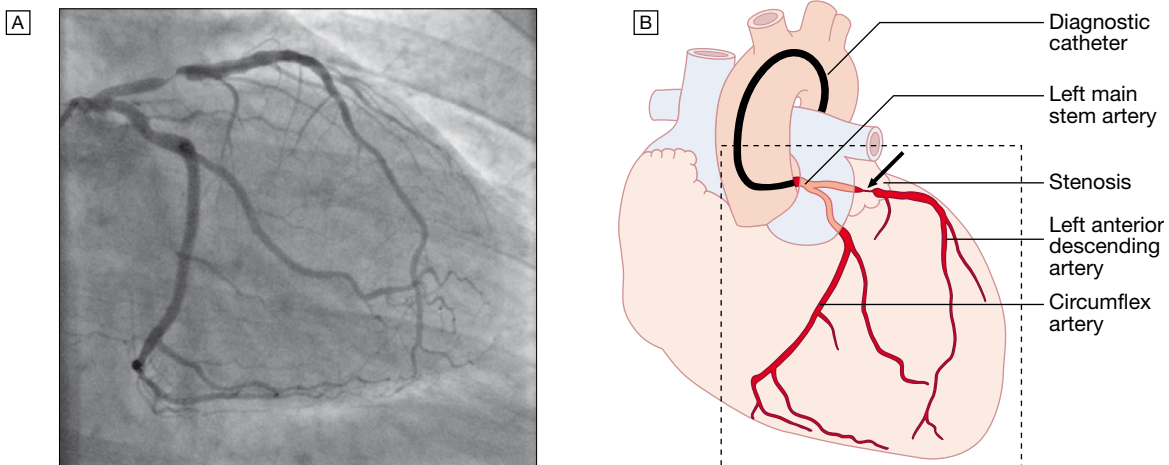

Fig. 18.14 The left anterior descending and circumflex coronary arteries with a stenosis in the left anterior descending vessel. **A** Coronary artery angiogram. **B** Schematic of the vessels and branches.

and function of the LV and to demonstrate mitral regurgitation. Aortography helps define the size of the aortic root and thoracic aorta, and can help quantify aortic regurgitation. Left heart catheterisation can be completed as a day-case procedure and is relatively safe, with serious complications occurring in fewer than 1 in 1000 cases.

Right heart catheterisation is used to assess right heart and pulmonary artery pressures, and to detect intracardiac shunts by measuring oxygen saturations in different chambers. For example, a step up in oxygen saturation from 65% in the RA to 80% in the pulmonary artery is indicative of a large left-to-right shunt that might be due to a ventricular septal defect. Cardiac output can also be measured using thermodilution techniques. Left atrial pressure can be measured directly by puncturing the interatrial septum from the RA with a special catheter. For most purposes, however, a satisfactory approximation to left atrial pressure can be obtained by 'wedging' an end-hole or balloon catheter in a branch of the pulmonary artery. Swan-Ganz balloon catheters are often used to monitor pulmonary 'wedge' pressure as a guide to left heart filling pressure in critically ill patients (p. 190).

Radionuclide imaging

The availability of gamma-emitting radionuclides with a short half-life has made it possible to study cardiac function non-invasively. Two techniques are available.

Blood pool imaging

The isotope is injected intravenously and mixes with the circulating blood. A gamma camera detects the amount of isotope-emitting blood in the heart at different phases of the cardiac cycle, and also the size and 'shape' of the cardiac chambers. By linking the gamma camera to the ECG, information can be collected over multiple cardiac cycles, allowing 'gating' of the systolic and diastolic phases of the cardiac cycle; the left (and right) ventricular ejection fraction (the proportion of blood ejected during each beat) can then be calculated. The reference value for left ventricular ejection fraction depends on the method used but is usually > 60%.

Myocardial perfusion imaging

This technique involves obtaining scintiscans of the myocardium at rest and during stress after the administration of an intravenous radioactive isotope such as ^{99m}technetium tetrofosmin (see Fig. 18.64, p. 584). More sophisticated quantitative information is obtained with positron emission tomography (PET), which can be used to assess myocardial metabolism, but this is only available in a few centres.

THERAPEUTIC PROCEDURES

Catheters can be passed into the arterial circulation with X-ray guidance to permit balloon dilatation and/or stenting of diseased arteries (Fig. 18.15, overleaf). Percutaneous coronary intervention (PCI) involves placement of a balloon catheter into one of the coronary arteries via a guide catheter, which is engaged in the coronary ostium. This allows balloon angioplasty and coronary stenting. This technique can also be used to treat stenoses in larger arteries, such as aortic coarctation (p. 631). Balloon valvuloplasty is some-

times used to treat mitral or pulmonary valve stenosis. Patients with congenital heart defects, such as atrial septal defect and patent ductus arteriosus, can have these closed by devices delivered to the heart via a catheter.

Pacemakers are implanted to correct bradycardias or AV block (p. 575). Implantable cardiac defibrillators have similar capabilities to pacemakers and, in addition, can deliver an internal shock to defibrillate the heart if a life-threatening rhythm such as ventricular fibrillation occurs. Cardiac resynchronisation therapy or biventricular pacemakers can improve cardiac function in some patients with heart failure (see Fig. 18.28, p. 550).

Recurrent arrhythmias can be treated by catheter ablation (see Fig. 18.15). Electrode catheters are placed in the heart and can locate re-entry pathways or automatic foci which cause tachycardias. Radiofrequency current is passed through the catheter tip to heat the tissues and cauterise the culprit tissue.

PRESENTING PROBLEMS IN CARDIOVASCULAR DISEASE

Cardiovascular disease gives rise to a relatively limited range of symptoms. Differential diagnosis depends on careful analysis of the factors that provoke symptoms, the subtle differences in how they are described by the patient, the clinical findings and appropriate investigations. A close relationship between symptoms and exercise is the hallmark of heart disease. The New York Heart Association (NYHA) functional classification is used to grade disability (Box 18.6).

18.6 New York Heart Association (NYHA) functional classification

- **Class I** No limitation during ordinary activity
- **Class II** Slight limitation during ordinary activity
- **Class III** Marked limitation of normal activities without symptoms at rest
- **Class IV** Unable to undertake physical activity without symptoms; symptoms may be present at rest

Chest pain

Chest pain is a common presentation of cardiac disease but can also be a manifestation of anxiety or disease of the lungs or musculoskeletal or gastrointestinal systems (see Box 18.7 below). Some patients deny 'pain' in favour of 'discomfort' but the significance remains the same.

Characteristics of ischaemic cardiac pain

Several key characteristics help to distinguish cardiac pain from that of other causes (Fig. 18.16). Diagnosis may be difficult and it is helpful to classify pain as possible, probable or definite ischaemic cardiac pain, based on the balance of evidence (Fig. 18.17).

- **Site.** Cardiac pain is typically located in the centre of the chest because of the derivation of the nerve supply to the heart and mediastinum.
- **Radiation.** Ischaemic cardiac pain may radiate to the neck, jaw, and upper or even lower arms. Occasionally, cardiac pain may be experienced only at the sites of radiation or in the back. Pain situated

Fig. 18.15 Percutaneous therapeutic procedures in cardiology. (IVC/SVC = inferior/superior vena cava)

over the left anterior chest and radiating laterally is unlikely to be due to cardiac ischaemia and may have many causes including pleural or lung disorders, musculoskeletal problems and anxiety.

- **Character.** Cardiac pain is typically dull, constricting, choking or 'heavy', and is usually described as squeezing, crushing, burning or aching but not sharp, stabbing, pricking or knife-like. The sensation can be described as breathlessness. Patients often emphasise that it is a discomfort rather than a pain. They typically use characteristic hand gestures (e.g. open hand or clenched fist) when describing ischaemic pain (see Fig. 18.16).
- **Provocation.** Anginal pain occurs during (not after) exertion and is promptly relieved (in less than 5 minutes) by rest. The pain may also be precipitated or exacerbated by emotion but tends to occur more readily during exertion, after a large meal or in a cold wind. In crescendo or unstable angina, similar pain may be precipitated by minimal exertion or at rest. The increase in venous return or preload induced by lying down may also be sufficient to provoke pain in

vulnerable patients (decubitus angina). The pain of MI may be preceded by a period of stable or unstable angina but may occur de novo. In contrast, pleural or pericardial pain is usually described as a 'sharp' or 'catching' sensation that is exacerbated by breathing, coughing or movement. Pain associated with a specific movement (bending, stretching, turning) is likely to be musculoskeletal in origin.

- **Onset.** The pain of MI typically takes several minutes or even longer to develop; similarly, angina builds up gradually in proportion to the intensity of exertion. Pain that occurs after rather than during exertion is usually musculoskeletal or psychological in origin. The pain of aortic dissection, massive pulmonary embolism or pneumothorax is usually very sudden or instantaneous in onset.
- **Associated features.** The pain of MI, massive pulmonary embolism or aortic dissection is often accompanied by autonomic disturbance including sweating, nausea and vomiting. Breathlessness, due to pulmonary congestion arising from transient ischaemic left ventricular dysfunction, is often a prominent and

Fig. 18.16 Typical ischaemic cardiac pain. Characteristic hand gestures used to describe cardiac pain. Typical radiation of pain is shown in the schematic.

occasionally the dominant feature of MI or angina (angina equivalent). Breathlessness may also accompany any of the respiratory causes of chest pain and can be associated with cough, wheeze or other respiratory symptoms. Classical gastrointestinal symptoms, such as oesophageal reflux, oesophagitis, peptic ulceration or biliary disease, may indicate non-cardiac chest pain but effort-related 'indigestion' is usually due to heart disease.

Differential diagnosis of chest pain (Box 18.7)

Psychological aspects of chest pain

Emotional distress is a common cause of atypical chest pain. This diagnosis should be considered if there are

18.7 Common causes of chest pain

Anxiety/emotion

Cardiac

- Myocardial ischaemia (angina)
- MI
- Myocarditis
- Pericarditis
- Mitral valve prolapse

Aortic

- Aortic dissection
- Aortic aneurysm

Oesophageal

- Oesophagitis
- Oesophageal spasm
- Mallory–Weiss syndrome

Lungs/pleura

- Bronchospasm
- Pulmonary infarct
- Pneumonia
- Tracheitis
- Pneumothorax
- Pulmonary embolism
- Malignancy
- Tuberculosis
- Connective tissue disorders (rare)

Musculoskeletal

- Osteoarthritis
- Rib fracture/injury
- Costochondritis (Tietze's syndrome)
- Intercostal muscle injury
- Epidemic myalgia (Bornholm disease)

Neurological

- Prolapsed intervertebral disc
- Herpes zoster
- Thoracic outlet syndrome

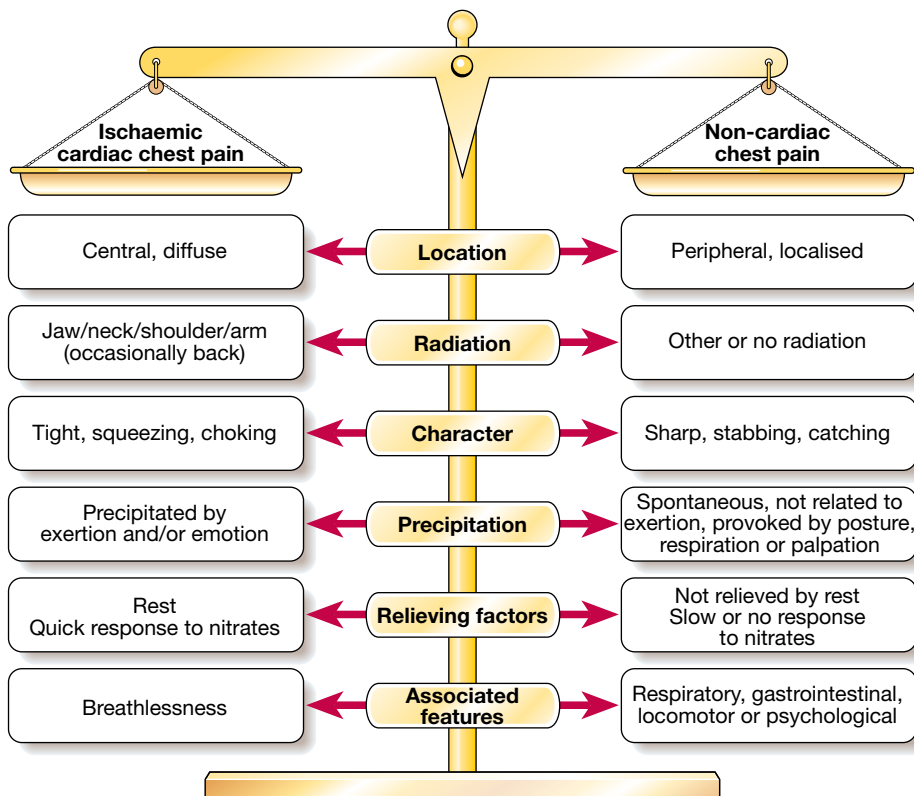

Fig. 18.17 Identifying ischaemic cardiac pain: the 'balance' of evidence.

features of anxiety and the pain lacks a predictable relationship with exercise. However, the prospect of heart disease is a frightening experience, particularly when it has been responsible for the death of a close friend or relative; psychological and organic features therefore often coexist. Anxiety may amplify the effects of organic disease and can create a very confusing picture. Patients who believe they are suffering from heart disease are sometimes afraid to take exercise and this may make it difficult to establish their true effort tolerance; assessment may also be complicated by the impact of physical deconditioning.

Myocarditis and pericarditis

Pain is characteristically felt retrosternally, to the left of the sternum, or in the left or right shoulder, and typically varies in intensity with movement and the phase of respiration. The pain is usually described as 'sharp' and may 'catch' the patient during inspiration, coughing or lying flat; there is occasionally a history of a prodromal viral illness.

Mitral valve prolapse

Sharp left-sided chest pain that is suggestive of a musculoskeletal problem may be a feature of mitral valve prolapse (p. 617).

Aortic dissection

This pain is severe, sharp and tearing, is often felt in or penetrating through to the back, and is typically very abrupt in onset (p. 603). The pain follows the path of the dissection.

Oesophageal pain

This can mimic the pain of angina very closely, is sometimes precipitated by exercise and may be relieved by nitrates. However, it is usually possible to elicit a history relating chest pain to supine posture or eating, drinking or oesophageal reflux. It often radiates to the back.

Bronchospasm

Patients with reversible airways obstruction, such as asthma, may describe exertional chest tightness that

is relieved by rest. This may be difficult to distinguish from ischaemic chest tightness. Bronchospasm may be associated with wheeze, atopy and cough (p. 652).

Musculoskeletal chest pain

This is a common problem that is very variable in site and intensity but does not usually fall into any of the patterns described above. The pain may vary with posture or movement of the upper body and is sometimes accompanied by local tenderness over a rib or costal cartilage. There are numerous causes, including arthritis, costochondritis, intercostal muscle injury and Coxsackie viral infection (epidemic myalgia or Bornholm disease). Many minor soft tissue injuries are related to everyday activities such as driving, manual work and sport. The differential diagnosis of peripheral or pleural chest pain is discussed on page 656.

Initial evaluation of suspected cardiac pain

A careful history is crucial in determining whether pain is cardiac or not. Although the physical findings and subsequent investigations may help to confirm the diagnosis, they are of more value in determining the nature and extent of any underlying heart disease, the risk of a serious adverse event, and the best course of management.

Stable angina

Effort-related chest pain is the hallmark of stable angina (Fig. 18.18). The reproducibility, predictability and relationship to physical exertion (and occasionally emotion) of the chest pain are the most important features. The duration of symptoms should be noted because patients with recent-onset angina are at greater risk than those with long-standing and unchanged symptoms.

Physical examination is often normal but may reveal evidence of risk factors (e.g. xanthoma indicating hyperlipidaemia), left ventricular dysfunction (e.g. dyskinetic apex beat, gallop rhythm), other manifestations of arterial disease (e.g. bruits, signs of peripheral vascular disease)

	Stable angina	Unstable angina

Fig. 18.18 Pathophysiology, clinical features and risk assessment of patients with stable or unstable angina.

and unrelated conditions that may exacerbate angina (e.g. anaemia, thyroid disease). Stable angina is usually a symptom of coronary artery disease but may be a manifestation of other forms of heart disease, particularly aortic valve disease and hypertrophic cardiomyopathy. In patients with angina in whom a murmur is found, echocardiography should be performed.

A full blood count, fasting blood glucose, lipids, thyroid function tests and a 12-lead ECG are the most important baseline investigations. Exercise testing may help to confirm the diagnosis and is also used to identify high-risk patients who require further investigation and treatment (p. 530).

Acute coronary syndromes

Prolonged and severe cardiac chest pain may be due to unstable angina (which comprises recent-onset limiting angina, rapidly worsening or crescendo angina, and angina at rest) or acute MI; these are known collectively as the acute coronary syndromes. Although there may be a history of antecedent chronic stable angina, an episode of chest pain at rest is often the first presentation of coronary disease. The diagnosis depends on analysis of the character of the pain and its associated features. Physical examination may reveal signs of important comorbidity, such as peripheral or cerebrovascular disease, autonomic disturbance (such as pallor or sweating) and complications (such as arrhythmia or heart failure).

Patients presenting with symptoms consistent with an acute coronary syndrome require urgent evaluation because there is a high risk of avoidable complications, such as sudden death and MI. Signs of haemodynamic compromise (hypotension, pulmonary oedema), ECG changes (ST segment elevation or depression) and biochemical markers of cardiac damage, such as elevated troponin I or T, are powerful indicators of short-term risk. A 12-lead ECG is mandatory and is the most useful method of initial triage (Fig. 18.19). The release of markers such as creatine kinase, troponin and myoglobin is relatively slow (p. 590) but can help guide immediate management and treatment.

If the diagnosis is unclear, patients with a suspected acute coronary syndrome should be observed in hospital. Repeated ECG recordings are valuable, particularly if obtained during an episode of pain. Plasma troponin concentrations should be measured and, if normal, repeated 12 hours after the onset of symptoms or hospital admission. New ECG changes or an elevated plasma troponin concentration confirm the diagnosis of an acute coronary syndrome. The subsequent management is described on pages 592–595.

If the pain has not recurred 12 hours after the onset of symptoms, plasma troponin concentrations are not elevated and there are no new ECG changes, the patient may be discharged from hospital. At this stage, an exercise test may help to diagnose underlying coronary heart disease but does not reliably exclude the future risk of MI.

Breathlessness (dyspnoea)

Dyspnoea of cardiac origin may vary in severity from an uncomfortable awareness of breathing to a frightening sensation of 'fighting for breath'. The sensation of dyspnoea originates in the cerebral cortex and is described in detail on page 652.

There are several causes of cardiac dyspnoea: acute left heart failure, chronic heart failure, arrhythmia and angina equivalent (Box 18.8). The assessment and treatment of heart failure is described on pages 543–551, and arrhythmias on pages 559–568.

Acute left heart failure

Acute left heart failure may be triggered by a major event such as MI in a previously healthy heart, or by a relatively minor event such as the onset of atrial fibrillation in a diseased heart. An increase in the left ventricular diastolic pressure causes the pressure in the LA, pulmonary veins and pulmonary capillaries to rise. When the hydrostatic pressure of the pulmonary capillaries exceeds the oncotic pressure of plasma (about 25–30 mmHg), fluid moves from the capillaries

18.8 Some causes of dyspnoea

System	Acute dyspnoea	Chronic exertional dyspnoea
Cardiovascular system	*Acute pulmonary oedema	*Chronic congestive cardiac failure Myocardial ischaemia
Respiratory system	*Acute severe asthma *Acute exacerbation of chronic obstructive pulmonary disease *Pneumothorax *Pneumonia *Pulmonary embolus Acute respiratory distress syndrome Inhaled foreign body (especially in a child) Lobar collapse Laryngeal oedema (e.g. anaphylaxis)	*Chronic obstructive pulmonary disease *Chronic asthma Chronic pulmonary thromboembolism Bronchial carcinoma Interstitial lung diseases: sarcoidosis, fibrosing alveolitis, extrinsic allergic alveolitis, pneumoconiosis Lymphatic carcinomatosis (may cause intolerable dyspnoea) Large pleural effusion(s)
Others	Metabolic acidosis (e.g. diabetic ketoacidosis, lactic acidosis, uraemia, overdose of salicylates, ethylene glycol poisoning) Hyperventilation	Severe anaemia Obesity

*Common cause.

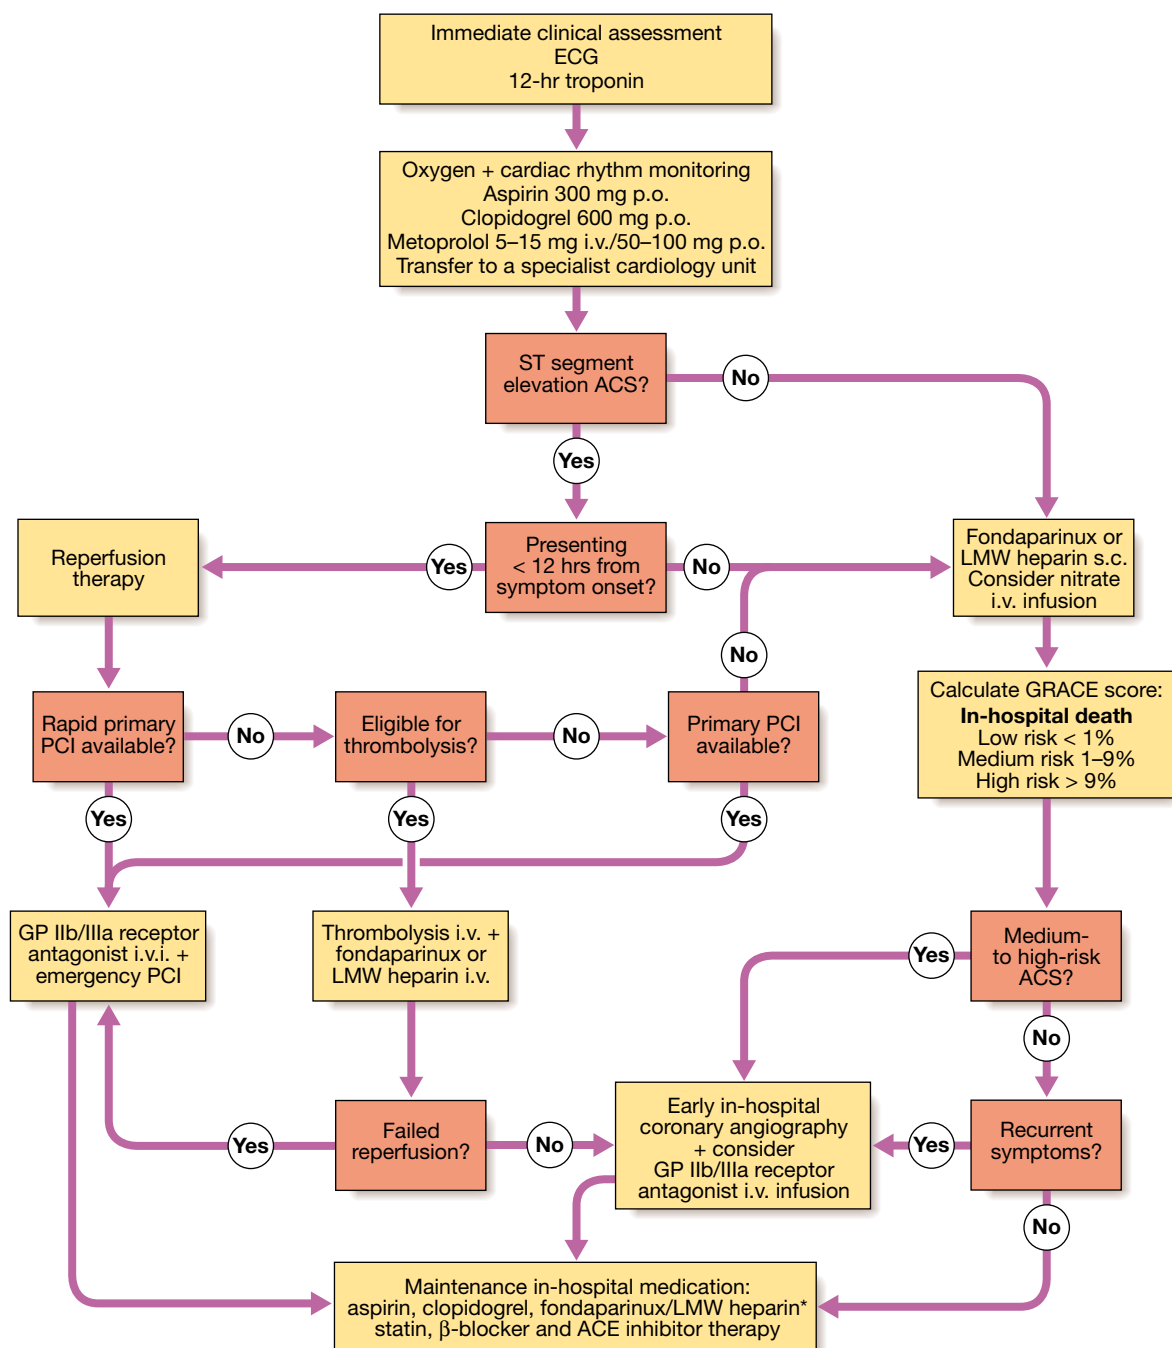

Fig. 18.19 Summary of treatment for acute coronary syndrome (ACS). *Not required following PCI. Amended from SIGN 93. For details of the GRACE score, see Figure 18.69, p. 589. (LMW = low molecular weight; PCI = percutaneous coronary intervention)

into alveoli. This stimulates respiration through a series of autonomic reflexes, producing rapid shallow respiration. Congestion of the bronchial mucosa may cause wheeze (cardiac asthma).

Acute pulmonary oedema is a terrifying experience with the sensation of 'fighting for breath'. Sitting upright or standing may provide some relief by helping to reduce congestion at the apices of the lungs. The patient may be unable to speak and is typically distressed, agitated, sweaty and pale. Respiration is rapid with recruitment of accessory muscles, coughing and wheezing. Sputum may be profuse, frothy and blood-streaked or pink. Extensive

crepitations and rhonchi are usually audible in the chest and there may also be signs of right heart failure.

Chronic heart failure

Chronic heart failure is the most common cardiac cause of chronic dyspnoea. Symptoms may first present on moderate exertion, such as walking up a steep hill, and may be described as a difficulty in 'catching my breath'. As heart failure progresses, the dyspnoea is provoked by less exertion and ultimately the patient may be breathless walking from room to room, washing, dressing or trying to hold a conversation. Other symptoms may include:

- *Orthopnoea*. Lying down increases the venous return to the heart and provokes breathlessness. Patients may prop themselves up with pillows to prevent this.
- *Paroxysmal nocturnal dyspnoea*. In patients with severe heart failure, fluid shifts from the interstitial tissues of the peripheries into the circulation within 1–2 hours of lying down. Pulmonary oedema supervenes, causing the patient to wake and sit upright, profoundly breathless.
- *Cheyne–Stokes respiration*. This cyclical pattern of respiration is due to impaired responsiveness of the respiratory centre to carbon dioxide and occurs in severe left ventricular failure. The pattern of slowly diminishing respiration, leading to apnoea, followed by progressively increasing respiration and hyperventilation, may be accompanied by a sensation of breathlessness and panic during the period of hyperventilation. The Cheyne–Stokes cycle length is a function of the circulation time. The condition can also occur in diffuse cerebral atherosclerosis, stroke or head injury, and may be exaggerated by sleep, barbiturates and opiates.

Arrhythmia

Any arrhythmia may cause breathlessness but usually does so only if the heart is structurally abnormal, such

as with the onset of atrial fibrillation in a patient with mitral stenosis.

Angina equivalent

Breathlessness is a common feature of angina. Patients will sometimes describe chest tightness as 'breathlessness'. However, myocardial ischaemia may also induce true breathlessness by provoking transient left ventricular dysfunction or heart failure. When breathlessness is the dominant or sole feature of myocardial ischaemia, it is known as 'angina equivalent'. A history of chest tightness, the close correlation with exercise, and objective evidence of myocardial ischaemia from stress testing may all help to establish the diagnosis.

Acute circulatory failure (cardiogenic shock)

'Shock' is used to describe the clinical syndrome that develops when there is critical impairment of tissue perfusion due to some form of acute circulatory failure. There are numerous causes of shock, described in detail on page 186. The important features and causes (Fig. 18.20) of acute heart failure or cardiogenic shock are described here.

18

Fig. 18.20 Some common causes of cardiogenic shock.

Myocardial infarction

Shock in acute MI is due to left ventricular dysfunction in more than 70% of cases. However, it may also be due to infarction of the RV and a variety of mechanical complications, including tamponade (due to infarction and rupture of the free wall), an acquired ventricular septal defect (due to infarction and rupture of the septum) and acute mitral regurgitation (due to infarction or rupture of the papillary muscles).

Severe myocardial systolic dysfunction causes a fall in cardiac output, BP and coronary perfusion pressure. Diastolic dysfunction causes a rise in left ventricular end-diastolic pressure, pulmonary congestion and oedema, leading to hypoxaemia that worsens myocardial ischaemia. This is further exacerbated by peripheral vasoconstriction. These factors combine to create the 'downward spiral' of cardiogenic shock (Fig. 18.21).

Hypotension, oliguria, confusion and cold clammy peripheries are the manifestations of a low cardiac output, whereas breathlessness, hypoxaemia, cyanosis and inspiratory crackles at the lung bases are typical features of pulmonary oedema. A chest X-ray (see Fig. 18.25, p. 547) may reveal signs of pulmonary congestion when clinical examination is normal. If necessary, a Swan-Ganz catheter can be used to measure the pulmonary artery wedge pressure to guide fluid replacement. The findings can be used to categorise patients with acute MI into four haemodynamic subsets (Box 18.9). Those with cardiogenic shock should be considered for immediate intra-aortic balloon counterpulsation and coronary revascularisation.

The viable myocardium surrounding a fresh infarct may contract poorly for a few days and then recover. This phenomenon is known as myocardial stunning and means that acute heart failure should be treated inten-

Fig. 18.21 The downward spiral of cardiogenic shock.

18.9 Acute myocardial infarction: haemodynamic subsets

Cardiac output	Pulmonary oedema	
	No	Yes
Normal	Good prognosis and requires no treatment for heart failure	Due to moderate left ventricular dysfunction. Treat with vasodilators and diuretics
Low	Due to right ventricular dysfunction or concomitant hypovolaemia. Give fluid challenge and consider pulmonary artery catheter to guide therapy	Extensive MI and poor prognosis. Consider intra-aortic balloon pump, vasodilators, diuretics and inotropes

sively because overall cardiac function may subsequently improve.

Acute massive pulmonary embolism

This may complicate leg or pelvic vein thrombosis and usually presents with sudden collapse. The clinical features and treatment are discussed on page 717. Bedside echocardiography may demonstrate a small underfilled vigorous LV with a dilated RV; it is sometimes possible to see thrombus in the right ventricular outflow tract or main pulmonary artery. CT pulmonary angiography usually provides a definitive diagnosis.

Cardiac tamponade

This is due to a collection of fluid or blood in the pericardial sac, compressing the heart; the effusion may be small and is sometimes < 100 mL. Sudden deterioration (Box 18.10) may be due to bleeding into the pericardial space. Tamponade may complicate any form of pericarditis but can be due to malignant disease. Other causes include trauma and rupture of the free wall of the myocardium following MI.

An ECG may show features of the underlying disease, such as pericarditis or acute MI. When there is a large pericardial effusion, the ECG complexes are small and there may be electrical alternans: a changing axis with alternate beats caused by the heart swinging from side to side in the pericardial fluid. A chest X-ray shows an enlarged globular heart but can look normal. Echocardiography is the best way of confirming the diagnosis and helps to identify the optimum site for aspiration of the fluid.

18.10 Clinical features of pericardial tamponade

- Dyspnoea
- Collapse
- Tachycardia
- Hypotension
- Gross elevation of the JVP
- Soft heart sounds with an early third heart sound
- Pulsus paradoxus (a large fall in BP during inspiration when the pulse may be impalpable)
- Kussmaul's sign (a paradoxical rise in the JVP during inspiration)

Prompt recognition of tamponade is important because the patient usually responds dramatically to percutaneous pericardiocentesis (p. 639) or surgical drainage.

Valvular heart disease

Acute left ventricular failure and shock may be due to the sudden onset of aortic regurgitation, mitral regurgitation or prosthetic valve dysfunction (Box 18.11).

The clinical diagnosis of acute valvular dysfunction is sometimes difficult. Murmurs are often unimpressive because there is usually a tachycardia and a low cardiac output. Transthoracic echocardiography will establish the diagnosis in most cases; however, transoesophageal

echocardiography is sometimes required, especially in patients with prosthetic mitral valves.

Patients with acute valve failure usually require cardiac surgery and should be referred for urgent assessment in a cardiac centre.

Aortic dissection may lead to shock by causing aortic regurgitation, coronary dissection, tamponade or blood loss (p. 603).

Management of shock

This is discussed in detail on page 186.

Heart failure

Heart failure describes the clinical syndrome that develops when the heart cannot maintain an adequate cardiac output, or can do so only at the expense of an elevated filling pressure. In mild to moderate forms of heart failure, cardiac output is adequate at rest and only becomes inadequate when the metabolic demand increases during exercise or some other form of stress. In practice, heart failure may be diagnosed whenever a patient with significant heart disease develops the signs or symptoms of a low cardiac output, pulmonary congestion or systemic venous congestion.

Almost all forms of heart disease can lead to heart failure. An accurate aetiological diagnosis (Box 18.12) is important because in some situations a specific remedy may be available.

18.11 Causes of acute valve failure

Aortic regurgitation

- Aortic dissection
- Infective endocarditis

Mitral regurgitation

- Papillary muscle rupture due to acute MI
- Infective endocarditis
- Rupture of chordae due to myxomatous degeneration

Prosthetic valve failure

- Mechanical valves: fracture, jamming, thrombosis, dehiscence
- Biological valves: degeneration with cusp tear

18.12 Mechanisms of heart failure

Cause	Examples	Features
Reduced ventricular contractility	MI (segmental dysfunction)	In coronary artery disease, 'akinetic' or 'dyskinetic' segments contract poorly and may impede the function of normal segments by distorting their contraction and relaxation patterns
	Myocarditis/cardiomyopathy (global dysfunction)	Progressive ventricular dilatation
Ventricular outflow obstruction (pressure overload)	Hypertension, aortic stenosis (left heart failure) Pulmonary hypertension, pulmonary valve stenosis (right heart failure)	Initially, concentric ventricular hypertrophy allows the ventricle to maintain a normal output by generating a high systolic pressure. Later, secondary changes in the myocardium and increasing obstruction lead to failure with ventricular dilatation and rapid clinical deterioration
Ventricular inflow obstruction	Mitral stenosis, tricuspid stenosis	Small vigorous ventricle, dilated hypertrophied atrium. Atrial fibrillation is common and often causes marked deterioration because ventricular filling depends heavily on atrial contraction
Ventricular volume overload	Ventricular septal defect Right ventricular volume overload (e.g. atrial septal defect) Increased metabolic demand (high output)	Dilatation and hypertrophy allow the ventricle to generate a high stroke volume and help to maintain a normal cardiac output. However, secondary changes in the myocardium lead to impaired contractility and worsening heart failure
Arrhythmia	Atrial fibrillation Tachycardia cardiomyopathy Complete heart block	Tachycardia does not allow for adequate filling of the heart, resulting in reduced cardiac output and back pressure Incessant tachycardia causes myocardial fatigue Bradycardia limits cardiac output even if stroke volume is normal
Diastolic dysfunction	Constrictive pericarditis Restrictive cardiomyopathy Left ventricular hypertrophy and fibrosis Cardiac tamponade	Marked fluid retention and peripheral oedema, ascites, pleural effusions and elevated jugular veins Bi-atrial enlargement (restrictive filling pattern and high atrial pressures). Atrial fibrillation may cause deterioration Good systolic function but poor diastolic filling Hypotension, elevated jugular veins, pulsus paradoxus, poor urine output

Heart failure is frequently due to coronary artery disease, tends to affect elderly people and often leads to prolonged disability. The prevalence of heart failure rises from 1% in those aged 50–59 years to over 10% in those aged 80–89 years. In the UK, most patients admitted to hospital with heart failure are > 70 years old and remain hospitalised for a week or more.

Although the outlook depends to some extent on the underlying cause of the problem, heart failure carries a very poor prognosis; approximately 50% of patients with severe heart failure due to left ventricular dysfunction will die within 2 years. Many patients die suddenly from malignant ventricular arrhythmias or MI.

Pathophysiology

Cardiac output is a function of the preload (the volume and pressure of blood in the ventricle at the end of diastole), the afterload (the volume and pressure of blood in the ventricle during systole) and myocardial contractility; this is the basis of Starling's Law (Fig. 18.22).

In patients without valvular disease, the primary abnormality is impairment of ventricular function leading to a fall in cardiac output. This activates counter-regulatory neurohumoral mechanisms that in normal physiological circumstances would support cardiac function, but in the setting of impaired ventricular function can lead to a deleterious increase in both afterload and preload (Fig. 18.23). A vicious circle may be established because any additional fall in cardiac output will cause further neurohumoral activation and increasing peripheral vascular resistance.

Stimulation of the renin-angiotensin-aldosterone system leads to vasoconstriction, salt and water retention, and sympathetic nervous system activation. This is mediated by angiotensin II, a potent constrictor of arterioles in both the kidney and the systemic circulation (see Fig. 18.23). Activation of the sympathetic nervous system may initially maintain cardiac output through an increase in myocardial contractility, heart rate and peripheral vasoconstriction. However, prolonged sympathetic stimulation leads to cardiac myocyte apoptosis, hypertrophy and focal myocardial necrosis. Salt and

Fig. 18.22 Starling's Law. Normal (A), mild (B), moderate (C) and severe (D) heart failure. Ventricular performance is related to the degree of myocardial stretching. An increase in preload (end-diastolic volume, end-diastolic pressure, filling pressure or atrial pressure) will therefore enhance function; however, overstretching causes marked deterioration. In heart failure the curve moves to the right and becomes flatter. An increase in myocardial contractility or a reduction in afterload will shift the curve upwards and to the left (green arrow).

water retention is promoted by the release of aldosterone, endothelin-1 (a potent vasoconstrictor peptide with marked effects on the renal vasculature) and, in severe heart failure, antidiuretic hormone (ADH). Natriuretic peptides are released from the atria in response to atrial stretch, and act as physiological antagonists to the fluid-conserving effect of aldosterone.

After MI, cardiac contractility is impaired and neurohumoral activation causes hypertrophy of non-infarcted segments, with thinning, dilatation and expansion of the infarcted segment (remodelling; see Fig. 18.77, p. 596). This leads to further deterioration in ventricular function and worsening heart failure.

The onset of pulmonary and peripheral oedema is due to high atrial pressures compounded by salt and water retention caused by impaired renal perfusion and secondary hyperaldosteronism.

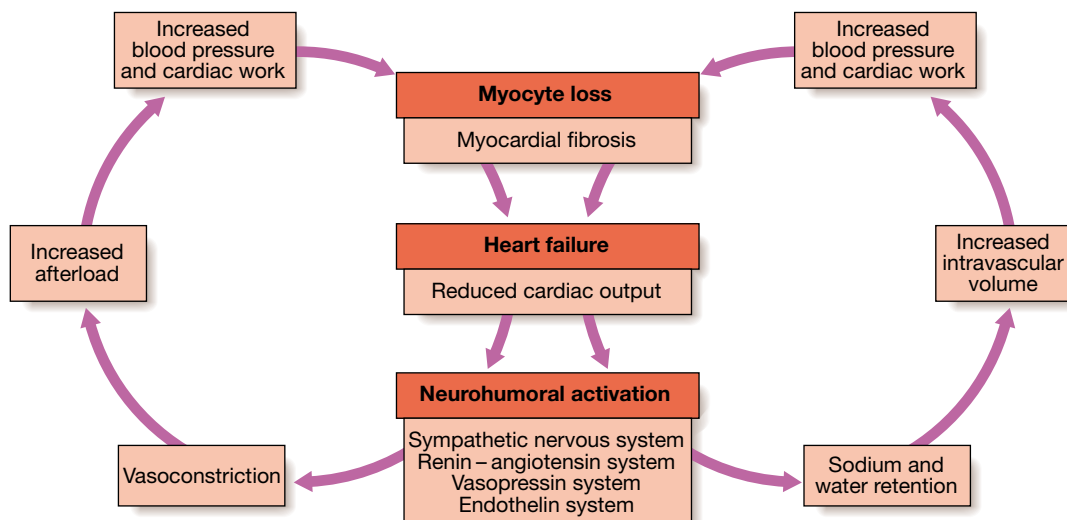

Fig. 18.23 Neurohumoral activation and compensatory mechanisms in heart failure. There is a vicious circle in progressive heart failure.

Types of heart failure

Left, right and biventricular heart failure

The left side of the heart comprises the functional unit of the LA and LV, together with the mitral and aortic valves; the right heart comprises the RA, RV, and tricuspid and pulmonary valves.

- *Left-sided heart failure.* There is a reduction in the left ventricular output and an increase in the left atrial or pulmonary venous pressure. An acute increase in left atrial pressure causes pulmonary congestion or pulmonary oedema; a more gradual increase in left atrial pressure, as occurs with mitral stenosis, leads to reflex pulmonary vasoconstriction, which protects the patient from pulmonary oedema at the cost of increasing pulmonary hypertension.
- *Right-sided heart failure.* There is a reduction in right ventricular output for any given right atrial pressure. Causes of isolated right heart failure include chronic lung disease (cor pulmonale), multiple pulmonary emboli and pulmonary valvular stenosis.
- *Biventricular heart failure.* Failure of the left and right heart may develop because the disease process, such as dilated cardiomyopathy or ischaemic heart disease, affects both ventricles or because disease of the left heart leads to chronic elevation of the left atrial pressure, pulmonary hypertension and right heart failure.

Diastolic and systolic dysfunction

Heart failure may develop as a result of impaired myocardial contraction (systolic dysfunction) but can also be due to poor ventricular filling and high filling pressures caused by abnormal ventricular relaxation (diastolic dysfunction). The latter is caused by a stiff non-compliant ventricle and is commonly found in patients with left ventricular hypertrophy. Systolic and diastolic dysfunction often coexist, particularly in patients with coronary artery disease.

High-output failure

Conditions such as large arteriovenous shunt, beri-beri (p. 126), severe anaemia or thyrotoxicosis can occasionally cause heart failure due to an excessively high cardiac output.

Acute and chronic heart failure

Heart failure may develop suddenly, as in MI, or gradually, as in progressive valvular heart disease. When there is gradual impairment of cardiac function, a variety of compensatory changes may take place.

The term 'compensated heart failure' is sometimes used to describe those with impaired cardiac function in whom adaptive changes have prevented the development of overt heart failure. A minor event, such as an intercurrent infection or development of atrial fibrillation, may precipitate overt or acute heart failure (Box 18.13). Acute left heart failure occurs either de novo or as an acute decompensated episode on a background of chronic heart failure, so-called acute-on-chronic heart failure.

Clinical assessment

Acute left heart failure

Acute de novo left ventricular failure presents with a sudden onset of dyspnoea at rest that rapidly progresses to acute respiratory distress, orthopnoea and prostra-

18.13 Factors that may precipitate or aggravate heart failure in patients with pre-existing heart disease

- Myocardial ischaemia or infarction
- Intercurrent illness, e.g. infection
- Arrhythmia, e.g. atrial fibrillation
- Inappropriate reduction of therapy
- Administration of a drug with negative inotropic properties (e.g. β -blocker) or fluid-retaining properties (e.g. non-steroidal anti-inflammatory drugs (NSAIDs), corticosteroids)
- Pulmonary embolism
- Conditions associated with increased metabolic demand, e.g. pregnancy, thyrotoxicosis, anaemia
- I.v. fluid overload, e.g. post-operative i.v. infusion

tion. The precipitant, such as acute MI, is often apparent from the history.

The patient appears agitated, pale and clammy. The peripheries are cool to the touch and the pulse is rapid. Inappropriate bradycardia or excessive tachycardia should be identified promptly, as this may be the precipitant for the acute episode of heart failure. The BP is usually high because of sympathetic nervous system activation, but may be normal or low if the patient is in cardiogenic shock.

The jugular venous pressure (JVP) is usually elevated, particularly with associated fluid overload or right heart failure. In acute de novo heart failure, there has been no time for ventricular dilatation and the apex is not displaced. Auscultation occasionally identifies the murmur of a catastrophic valvular or septal rupture, or reveals a triple 'gallop' rhythm. Crepitations are heard at the lung bases, consistent with pulmonary oedema.

Acute-on-chronic heart failure will have additional features of long-standing heart failure (see below). Potential precipitants, such as an upper respiratory tract infection or inappropriate cessation of diuretic medication, should be identified.

Chronic heart failure

Patients with chronic heart failure commonly follow a relapsing and remitting course, with periods of stability and episodes of decompensation leading to worsening symptoms that may necessitate hospitalisation. The clinical picture depends on the nature of the underlying heart disease, the type of heart failure that it has evoked, and the neurohumoral changes that have developed (see Box 18.12 and Fig. 18.24).

A low cardiac output causes fatigue, listlessness and a poor effort tolerance; the peripheries are cold and the BP is low. To maintain perfusion of vital organs, blood flow is diverted away from skeletal muscle and this may contribute to fatigue and weakness. Poor renal perfusion leads to oliguria and uraemia.

Pulmonary oedema due to left heart failure presents as described above and with inspiratory crepitations over the lung bases. In contrast, right heart failure produces a high JVP with hepatic congestion and dependent peripheral oedema. In ambulant patients, the oedema affects the ankles, whereas in bed-bound patients it collects around the thighs and sacrum. Ascites or pleural effusion occurs in some cases (see Fig. 18.24). Heart failure is not the only cause of oedema (Box 18.14).

Chronic heart failure is sometimes associated with marked weight loss (cardiac cachexia) caused by a

Fig. 18.24 Clinical features of left and right heart failure. (JVP = jugular venous pressure)

combination of anorexia and impaired absorption due to gastrointestinal congestion, poor tissue perfusion due to a low cardiac output, and skeletal muscle atrophy due to immobility.

Complications

In advanced heart failure, the following may occur:

- *Renal failure* is caused by poor renal perfusion due to a low cardiac output and may be exacerbated by diuretic therapy, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers.
- *Hypokalaemia* may be the result of treatment with potassium-losing diuretics or hyperaldosteronism

caused by activation of the renin-angiotensin system and impaired aldosterone metabolism due to hepatic congestion. Most of the body's potassium is intracellular and there may be substantial depletion of potassium stores, even when the plasma potassium concentration is in the normal range.

- *Hyperkalaemia* may be due to the effects of drug treatment, particularly the combination of ACE inhibitors and spironolactone (which both promote potassium retention), and renal dysfunction.
- *Hyponatraemia* is a feature of severe heart failure and is a poor prognostic sign. It may be caused by diuretic therapy, inappropriate water retention due to high ADH secretion, or failure of the cell membrane ion pump.
- *Impaired liver function* is caused by hepatic venous congestion and poor arterial perfusion, which frequently cause mild jaundice and abnormal liver function tests; reduced synthesis of clotting factors can make anticoagulant control difficult.
- *Thromboembolism*. Deep vein thrombosis and pulmonary embolism may occur due to the effects of a low cardiac output and enforced immobility, whereas systemic emboli may be related to arrhythmias, atrial flutter or fibrillation, or intracardiac thrombus complicating conditions such as mitral stenosis, MI or left ventricular aneurysm.
- *Atrial and ventricular arrhythmias* are very common and may be related to electrolyte changes (e.g. hypokalaemia, hypomagnesaemia), the underlying

18.14 Differential diagnosis of peripheral oedema

- Cardiac failure: right or combined left and right heart failure, pericardial constriction, cardiomyopathy
- Chronic venous insufficiency: varicose veins
- Hypoalbuminaemia: nephrotic syndrome, liver disease, protein-losing enteropathy; often widespread, can affect arms and face
- Drugs:
 - Sodium retention: fludrocortisone, NSAIDs
 - Increasing capillary permeability: nifedipine, amlodipine
- Idiopathic: women > men
- Chronic lymphatic obstruction

structural heart disease, and the pro-arrhythmic effects of increased circulating catecholamines or drugs. Sudden death occurs in up to 50% of patients with heart failure and is often due to a ventricular arrhythmia. Frequent ventricular ectopic beats and runs of non-sustained ventricular tachycardia are common findings in patients with heart failure and are associated with an adverse prognosis.

Investigations

Serum urea and electrolytes, haemoglobin, thyroid function, ECG and chest X-ray may help to establish the nature and severity of the underlying heart disease and detect any complications. Brain natriuretic peptide (BNP) is elevated in heart failure and is a marker of risk; it is useful in the investigation of patients with breathlessness or peripheral oedema.

Echocardiography is very useful and should be considered in all patients with heart failure in order to:

- determine the aetiology
- detect hitherto unsuspected valvular heart disease, such as occult mitral stenosis, and other conditions that may be amenable to specific remedies
- identify patients who will benefit from long-term therapy with drugs, such as ACE inhibitors (see below).

Chest X-ray

A rise in pulmonary venous pressure from left-sided heart failure first shows on the chest X-ray (Fig. 18.25) as an abnormal distension of the upper lobe pulmonary veins (with the patient in the erect position). The vascularity of the lung fields becomes more prominent, and the right and left pulmonary arteries dilate. Subsequently, interstitial oedema causes thickened interlobular septa and dilated lymphatics. These are evident as horizontal lines in the costophrenic angles (septal or 'Kerley B' lines). More advanced changes due to alveolar oedema cause a hazy opacification spreading from the hilar regions, and pleural effusions.

Management of acute pulmonary oedema

This is urgent:

- Sit the patient up in order to reduce pulmonary congestion.
- Give oxygen (high-flow, high-concentration). Non-invasive positive pressure ventilation (continuous positive airways pressure (CPAP) of 5–10 mmHg) by a tight-fitting facemask results in a more rapid improvement in the patient's clinical state.
- Administer nitrates, such as i.v. glyceryl trinitrate 10–200 µg/min or buccal glyceryl trinitrate 2–5 mg, titrated upwards every 10 minutes, until clinical improvement occurs or systolic BP falls to < 110 mmHg.
- Administer a loop diuretic such as furosemide 50–100 mg i.v.

The patient should initially be kept on strict bed rest with continuous monitoring of cardiac rhythm, BP and pulse oximetry. Intravenous opiates may be cautiously used when patients are in extremis. They reduce sympathetically mediated peripheral vasoconstriction but may cause respiratory depression and exacerbation of hypoxaemia and hypercapnia.

Fig. 18.25 Radiological features of heart failure. **A** Chest X-ray of a patient with pulmonary oedema. **B** Enlargement of lung base showing septal or 'Kerley B' lines (arrow).

If these measures prove ineffective, inotropic agents may be required to augment cardiac output, particularly in hypotensive patients. Insertion of an intra-aortic balloon pump can be very beneficial in patients with acute cardiogenic pulmonary oedema, especially when secondary to myocardial ischaemia.

Management of chronic heart failure

General measures

Education of patients and their relatives about the causes and treatment of heart failure can help adherence to a management plan (Box 18.15). Some patients may need to weigh themselves daily and adjust their diuretic therapy accordingly.

In patients with coronary heart disease, secondary preventative measures, such as low-dose aspirin and lipid-lowering therapy, are required (p. 579). However, statins do not appear to be effective in patients with severe heart failure.

Drug therapy

Cardiac function can be improved by increasing contractility, optimising preload or decreasing afterload

18.15 General measures for the management of heart failure
Education
<ul style="list-style-type: none"> Explanation of nature of disease, treatment and self-help strategies
Diet
<ul style="list-style-type: none"> Good general nutrition and weight reduction for the obese Avoidance of high-salt foods and added salt, especially for patients with severe congestive heart failure
Alcohol
<ul style="list-style-type: none"> Moderation or elimination of alcohol consumption. Alcohol-induced cardiomyopathy requires abstinence
Smoking
<ul style="list-style-type: none"> Cessation
Exercise
<ul style="list-style-type: none"> Regular moderate aerobic exercise within limits of symptoms
Vaccination
<ul style="list-style-type: none"> Influenza and pneumococcal vaccination should be considered

(see Fig. 18.23). Drugs that reduce preload are appropriate in patients with high end-diastolic filling pressures and evidence of pulmonary or systemic venous congestion. Those that reduce afterload or increase myocardial contractility are more useful in patients with signs and symptoms of a low cardiac output.

Diuretic therapy

In heart failure, diuretics produce an increase in urinary sodium and water excretion, leading to a reduction in blood and plasma volume (p. 433). Diuretic therapy reduces preload and improves pulmonary and systemic venous congestion. It may also reduce afterload and ventricular volume, leading to a fall in wall tension and increased cardiac efficiency.

Although a fall in preload (ventricular filling pressure) tends to reduce cardiac output, the 'Starling curve' in heart failure is flat, so there may be a substantial and beneficial fall in filling pressure with little change in cardiac output (see Figs 18.22 and 18.26). Nevertheless, excessive diuretic therapy may cause an undesirable fall in cardiac output, with a rising serum urea, hypotension and increasing lethargy, especially in patients with a marked diastolic component to their heart failure.

18.16 Congestive cardiac failure in old age
<ul style="list-style-type: none"> Incidence: rises with age and affects 5–10% of those in their eighties. Common causes: coronary artery disease, hypertension and calcific degenerative valvular disease. Diastolic dysfunction: often prominent, particularly in those with a history of hypertension. ACE inhibitors: improve symptoms and mortality but are more frequently associated with postural hypotension and renal impairment than in younger patients. Loop diuretics: usually required but may be poorly tolerated in those with urinary incontinence and men with prostate enlargement.

Fig. 18.26 The effect of treatment on ventricular performance curves in heart failure. Diuretics and venodilators (A), angiotensin-converting enzyme (ACE) inhibitors and mixed vasodilators (B), and positive inotropic agents (C).

In some patients with severe chronic heart failure, particularly in the presence of chronic renal impairment, oedema may persist despite oral loop diuretics. In such patients an intravenous infusion of furosemide 10mg/hr may initiate a diuresis. Combining a loop diuretic with a thiazide (e.g. bendroflumethiazide 5mg daily) or a thiazide-like diuretic (e.g. metolazone 5mg daily) may prove effective, but this can cause an excessive diuresis.

Aldosterone receptor antagonists, such as spironolactone and eplerenone, are potassium-sparing diuretics that are of particular benefit in patients with heart failure. They may cause hyperkalaemia, particularly when used with an ACE inhibitor. They improve long-term clinical outcome in patients with severe heart failure or heart failure following acute MI.

Vasodilator therapy

These drugs are valuable in chronic heart failure. Venodilators, such as nitrates, reduce preload, and arterial dilators, such as hydralazine, reduce afterload (Fig. 18.26). Their use is limited by pharmacological tolerance and hypotension.

Angiotensin-converting enzyme (ACE) inhibition therapy

This interrupts the vicious circle of neurohumoral activation that is characteristic of moderate and severe heart failure by preventing the conversion of angiotensin I to angiotensin II, thereby preventing salt and water retention, peripheral arterial and venous vasoconstriction, and activation of the sympathetic nervous system (Fig. 18.27). These drugs also prevent the undesirable activation of the renin-angiotensin system caused by diuretic therapy.

Whilst the major benefit of ACE inhibition in heart failure is a reduction in afterload, it also reduces preload and causes a modest rise in the plasma potassium concentrations. Treatment with a combination of a loop diuretic and an ACE inhibitor therefore has many potential advantages.

In moderate and severe heart failure, ACE inhibitors can produce a substantial improvement in effort tolerance and in mortality. They can also improve outcome and prevent the onset of overt heart failure in patients with poor residual left ventricular function following MI (Box 18.17).

Fig. 18.27 Neurohumoral activation and sites of action of drugs used in the treatment of heart failure.

They can cause symptomatic hypotension and impairment of renal function, especially in patients with bilateral renal artery stenosis or those with pre-existing renal disease. Short-acting ACE inhibitors can cause marked falls in BP, particularly in the elderly or when started in the presence of hypotension, hypovolaemia or hyponatraemia. In stable patients without hypotension (systolic BP > 100 mmHg), ACE inhibitors can usually be safely started in the community. However, in other patients, it is usually advisable to withhold diuretics for 24 hours before starting treatment with a small dose of a long-acting agent, preferably given at night (Box 18.18). Renal function must be monitored and should be checked 1–2 weeks after starting therapy.

EBM 18.17 ACE inhibitors and treatment of chronic heart failure

'ACE inhibitors in chronic heart failure due to ventricular dysfunction reduce mortality and readmission rates; average NNT₅ for 3 years to prevent one death = 26 and for the combined endpoint of death or readmission = 19.'

• Flather M, et al. *Lancet* 2000; 355:1575–1581.

	Starting dose	Target dose
ACE inhibitors		
Enalapril	2.5 mg 12-hourly	10 mg 12-hourly
Lisinopril	2.5 mg daily	20 mg daily
Ramipril	1.25 mg daily	10 mg daily
Angiotensin receptor blockers		
Losartan	25 mg daily	100 mg daily
Candesartan	4 mg daily	32 mg daily
Valsartan	40 mg daily	160 mg daily

Angiotensin receptor blocker (ARB) therapy

These drugs (see Box 18.18) act by blocking the action of angiotensin II on the heart, peripheral vasculature and kidney. In heart failure, they produce beneficial haemodynamic changes that are similar to the effects of ACE inhibitors (see Fig. 18.27) but are generally better tolerated. They have comparable effects on mortality and are a useful alternative for patients who cannot tolerate ACE inhibitors (Box 18.19). Unfortunately, they share all the more serious adverse effects of ACE inhibitors, including renal dysfunction and hyperkalaemia. They may be considered in combination with ACE inhibitors, especially in those with recurrent hospitalisations for heart failure.

Beta-adrenoceptor blocker therapy

Beta-blockade helps to counteract the deleterious effects of enhanced sympathetic stimulation and reduces the risk of arrhythmias and sudden death. When initiated in standard doses, they may precipitate acute-on-chronic heart failure, but when given in small incremental doses (e.g. bisoprolol started at a dose of 1.25 mg daily, and increased gradually over a 12-week period to a target maintenance dose of 10 mg daily), they can increase ejection fraction, improve symptoms, reduce the frequency

EBM 18.19 ARBs and chronic heart failure

'Compared with ACE inhibitors, ARBs are better tolerated and have similar efficacy in reducing cardiovascular events. ARBs reduce cardiovascular morbidity and mortality in patients with symptomatic heart failure who are intolerant of ACE inhibitors. NNT₅ for 5 years to prevent one death or hospitalisation for heart failure = 8. The addition of an ARB to an ACE inhibitor produces further additional benefit. NNT₅ for 5 years to prevent one death or hospitalisation for heart failure = 16.'

• Granger CB, et al. *Lancet* 2003; 362:772–776.
• McMurray JJV, et al. *Lancet* 2003; 362:767–771.

EBM 18.20 β -blockers and treatment of chronic heart failure

'Adding oral β -blockers gradually in small incremental doses to standard therapy including ACE inhibitors in people with heart failure reduces the rate of death or hospital admission. NNT₆ for 1 year to prevent one death = 21.'

- Lechat P, et al. *Circulation* 1998; 98:1184–1191.
- Shibata MC, et al. *Eur J Heart Fail* 2001; 34:351–357.

For further information:  www.escardio.org

of hospitalisation and reduce mortality in patients with chronic heart failure (Box 18.20). Beta-blockers are more effective at reducing mortality than ACE inhibitors: relative risk reduction of 33% versus 20% respectively.

Digoxin

Digoxin (p. 574) can be used to provide rate control in patients with heart failure and atrial fibrillation. In patients with severe heart failure (NYHA class III–IV, see Box 18.6, p. 535), digoxin reduces the likelihood of hospitalisation for heart failure, although it has no effect on long-term survival.

Amiodarone

This is a potent anti-arrhythmic drug (p. 572) that has little negative inotropic effect and may be valuable in patients with poor left ventricular function. It is only effective in the treatment of symptomatic arrhythmias, and should not be used as a preventative agent in asymptomatic patients.

Implantable cardiac defibrillators and resynchronisation therapy

Patients with symptomatic ventricular arrhythmias and heart failure have a very poor prognosis. Irrespective of their response to anti-arrhythmic drug therapy, all should be considered for implantation of a cardiac defibrillator (p. 576). In patients with marked intraventricular conduction delay, prolonged depolarisation may lead to uncoordinated left ventricular contraction. When this is associated with severe symptomatic heart failure, cardiac resynchronisation therapy should be considered. Here, both the LV and RV are paced simultaneously (Fig. 18.28) in an attempt to generate a more coordinated left ventricular contraction and improve cardiac output.

Coronary revascularisation

Coronary artery bypass surgery or percutaneous coronary intervention may improve function in areas of the myocardium that are 'hibernating' because of inadequate blood supply, and can be used to treat carefully selected patients with heart failure and coronary artery disease. If necessary, 'hibernating' myocardium can be identified by stress echocardiography and specialised nuclear or MR imaging.

Heart transplantation

Cardiac transplantation is an established and successful form of treatment for patients with intractable heart failure. Coronary artery disease and dilated cardiomyopathy are the most common indications. The introduction of ciclosporin for immunosuppression (p. 94) has improved survival, which is around 80% at 1 year. The use of trans-

Fig. 18.28 Chest X-ray of a biventricular pacemaker and defibrillator. The right ventricular lead (RV) is in position in the ventricular apex and is used for both pacing and defibrillation. The left ventricular lead (LV) is placed via the coronary sinus and the right atrial lead (RA) is placed in the right atrial appendage; both are used for pacing only.

plantation is limited by the efficacy of modern drug and device therapies, as well as the availability of donor hearts, so it is generally reserved for young patients with severe symptoms despite optimal therapy.

Conventional heart transplantation is contraindicated in patients with pulmonary vascular disease due to long-standing left heart failure, complex congenital heart disease (e.g. Eisenmenger's syndrome) or primary pulmonary hypertension because the RV of the donor heart may fail in the face of high pulmonary vascular resistance. However, heart-lung transplantation can be successful in patients with Eisenmenger's syndrome. Lung transplantation has been used for primary pulmonary hypertension.

Although cardiac transplantation usually produces a dramatic improvement in the recipient's quality of life, serious complications may occur:

- **Rejection.** In spite of routine therapy with ciclosporin A, azathioprine and corticosteroids, episodes of rejection are common and may present with heart failure, arrhythmias or subtle ECG changes; cardiac biopsy is often used to confirm the diagnosis before starting treatment with high-dose corticosteroids.
- **Accelerated atherosclerosis.** Recurrent heart failure is often due to progressive atherosclerosis in the coronary arteries of the donor heart. This is not confined to patients who were transplanted for coronary artery disease and is probably a manifestation of chronic rejection. Angina is rare because the heart has been denervated.
- **Infection.** Opportunistic infection with organisms such as cytomegalovirus or *Aspergillus* remains a major cause of death in transplant recipients.

Ventricular assist devices

Because of the limited supply of donor organs, ventricular assist devices (VADs) have been employed as:

- a bridge to cardiac transplantation
- potential long-term 'destination' therapy
- short-term restoration therapy following a potentially reversible insult such as viral myocarditis.

VADs assist cardiac output by using a roller, centrifugal or pulsatile pump that in some cases is implantable and portable. They withdraw blood through cannulae inserted in the atria or ventricular apex and pump it into the pulmonary artery or aorta. They are designed not only to unload the ventricles but also to provide support to the pulmonary and systemic circulations. Their more widespread application is limited by high complication rates (haemorrhage, systemic embolism, infection, neurological and renal sequelae), although some improvements in survival and quality of life have been demonstrated in patients with severe heart failure.

Hypertension

High BP is a trait as opposed to a specific disease and represents a quantitative rather than a qualitative deviation from the norm. Any definition of hypertension is therefore arbitrary.

Systemic BP rises with age, and the incidence of cardiovascular disease (particularly stroke and coronary artery disease) is closely related to average BP at all ages, even when BP readings are within the so-called 'normal range'. Randomised controlled trials have demonstrated that antihypertensive therapy can reduce the incidence of stroke and, to a lesser extent, coronary artery disease (see Box 18.93, p. 608).

The cardiovascular risks associated with a given BP are dependent upon the combination of risk factors in an individual, such as age, gender, weight, physical activity, smoking, family history, serum cholesterol, diabetes mellitus and pre-existing vascular disease. Effective management of hypertension requires a holistic approach, based on the identification of those at highest cardiovascular risk and the use of multifactorial interventions, targeting not only BP but all modifiable cardiovascular risk factors.

Thus a practical definition of hypertension is 'the level of BP at which the benefits of treatment outweigh the costs and hazards'. The British Hypertension Society classification of hypertension is provided in Box 18.87 (p. 606) and is consistent with those defined by the European Society of Hypertension and the World Health Organization–International Society of Hypertension.

Approach to newly diagnosed hypertension

Hypertension is predominantly an asymptomatic condition and the diagnosis is usually made at routine examination or when a complication arises. A BP check is advisable every 5 years in adults.

The objectives of the initial evaluation of a patient with high BP readings are:

- to obtain accurate and representative measurements of BP
- to identify contributory factors and any underlying cause (secondary hypertension)
- to assess other risk factors and quantify cardiovascular risk
- to detect any complications (target organ damage) that are already present
- to identify comorbidity that may influence the choice of antihypertensive therapy.

These goals are attained by a careful history, clinical examination and some simple investigations. Details of these, along with pathophysiology and management, are discussed on pages 606–612.

Syncope and presyncope

The term 'syncope' refers to sudden loss of consciousness due to reduced cerebral perfusion. 'Presyncope' refers to lightheadedness where the individual thinks he or she may black out. Syncope affects around 20% of the population at some time and accounts for more than 5% of hospital admissions. Dizziness and presyncope are very common in old age (p. 173). Symptoms are disabling, undermine confidence and independence,

18.21 Typical features of cardiac syncope, vasovagal syncope and seizures

	Cardiac syncope	Neuro-cardiogenic syncope	Seizures
Premonitory symptoms	Often none Lightheadedness Palpitation Chest pain Breathlessness	Nausea Lightheadedness Sweating	Confusion Hyperexcitability Olfactory hallucinations 'Aura'
Unconscious period	Extreme 'death-like' pallor	Pallor	Prolonged (> 1 min) unconsciousness Motor seizure activity* Tongue-biting Urinary incontinence
Recovery	Rapid recovery (< 1 min) Flushing	Slow Nausea Lightheadedness	Prolonged confusion (> 5 mins) Headache Focal neurological signs

*N.B. Cardiac syncope can also cause convulsions by inducing cerebral anoxia.

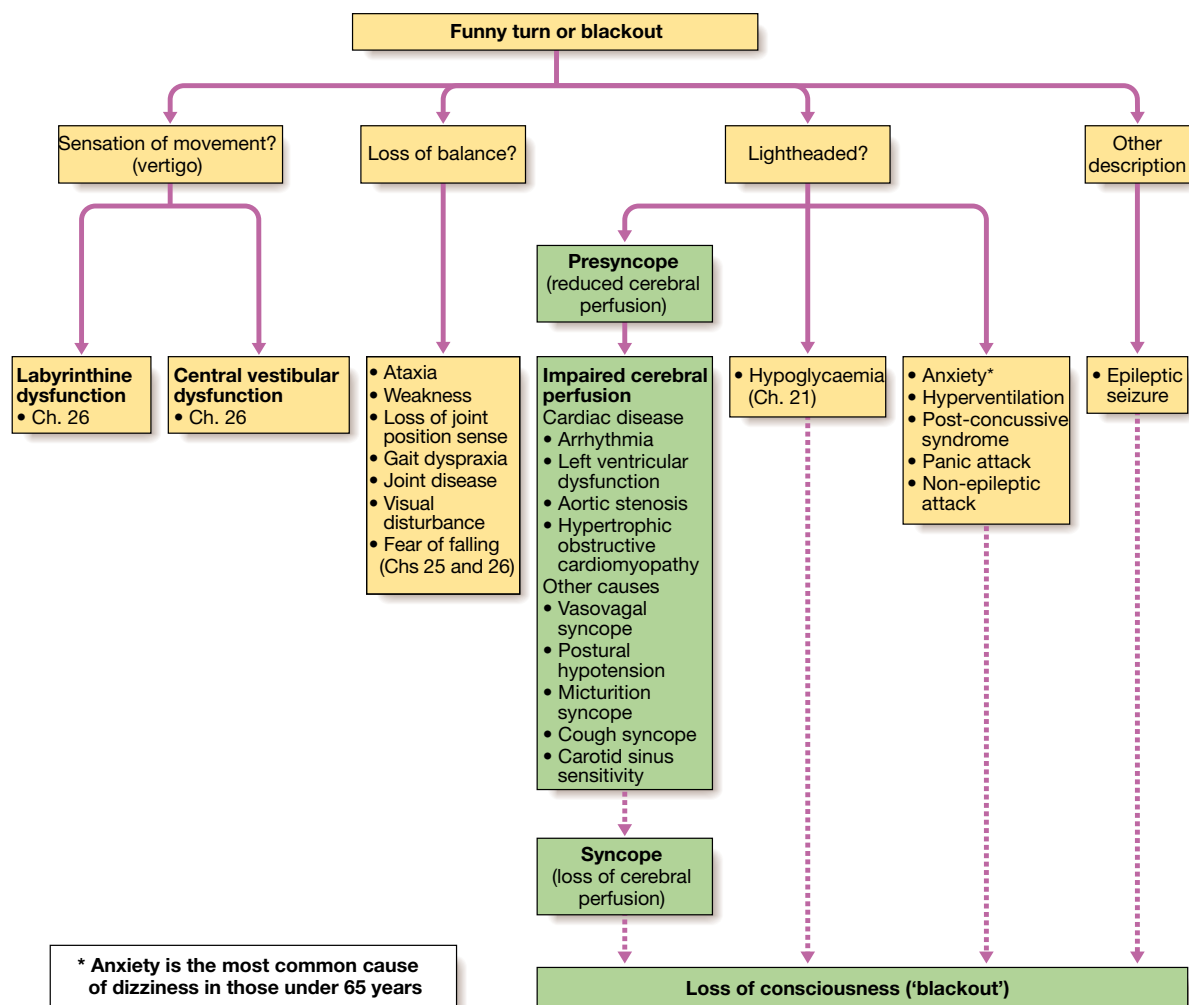

Fig. 18.29 The differential diagnosis of syncope and presyncope.

and can affect an individual's ability to work or to drive. There are several mechanisms that underlie recurrent presyncope or syncope:

- *cardiac syncope* due to mechanical cardiac dysfunction or arrhythmia
- *neurocardiogenic syncope* in which an abnormal autonomic reflex causes bradycardia and/or hypotension.

Blackouts can also be caused by non-cardiac pathology such as epilepsy, cerebrovascular ischaemia or hypoglycaemia (Fig. 18.29).

Differential diagnosis

History-taking, from the patient or a witness, is the key to establishing a diagnosis. Attention should be given to potential triggers (e.g. medication, exertion, posture), the victim's appearance (e.g. colour, seizure activity), the duration of the episode and the speed of recovery (Box 18.21). Cardiac syncope is usually sudden but can be associated with premonitory lightheadedness, palpitation or chest discomfort. The blackout is usually brief and recovery rapid. Neurocardiogenic syncope will often be associated with a situational trigger, and the patient may experience flushing, nausea and malaise for

several minutes afterwards. Patients with seizures do not exhibit pallor, may have abnormal movements, usually take more than 5 minutes to recover and are often confused. A history of rotational vertigo is suggestive of a labyrinthine or vestibular disorder (p. 1149). The pattern and description of the patient's symptoms should indicate the probable mechanism and help to determine subsequent investigations (Fig. 18.30).

Arrhythmia

Lightheadedness may occur with many arrhythmias, but blackouts (Stokes–Adams attacks, p. 570) are usually due to profound bradycardia or malignant ventricular tachyarrhythmias. The 12-lead ECG may show evidence of conducting system disease (e.g. sinus bradycardia, AV block, bundle branch block or axis deviation) which would predispose a patient to bradycardia, but the key to establishing a diagnosis is to obtain an ECG recording *during symptoms*. Since minor rhythm disturbances are common, especially in old age, symptoms must occur at the same time as a recorded arrhythmia before a diagnosis can be made. Ambulatory ECG recordings are helpful only if symptoms occur several times per week. Patient-activated ECG recorders are useful for examining the rhythm in patients with recurrent dizziness, but are not

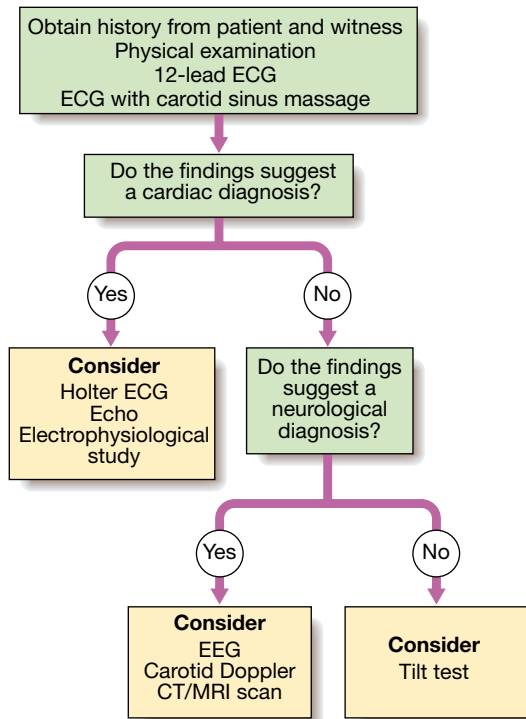

Fig. 18.30 A simple guide to the investigation and diagnosis of recurrent presyncope and syncope.

useful in assessing sudden blackouts. In patients with presyncope or syncope in whom these investigations fail to establish a cause, an implantable 'loop recorder' can be placed subcutaneously in the upper chest. This device continuously records the cardiac rhythm and will activate automatically if extreme bradycardia or tachycardia occurs. The ECG memory can also be frozen by the patient using a hand-held activator. Stored ECGs can be accessed by the implanting centre, using a telemetry device.

Structural heart disease

Severe aortic stenosis, hypertrophic obstructive cardiomyopathy and severe coronary artery disease can cause lightheadedness or syncope on exertion. This is caused by profound hypotension due to a fall in cardiac output, or failure to increase output during exertion, coupled with exercise-induced peripheral vasodilatation. Exertional arrhythmias also occur in these patients.

Neurocardiogenic syncope

This encompasses a family of syndromes in which bradycardia and/or hypotension occur because of a series of abnormal autonomic reflexes. The two main conditions are hypersensitive carotid sinus syndrome (HCSS) and malignant vasovagal syncope.

Situational syncope

This is the collective name given to some variants of neurocardiogenic syncope that occur in the presence of identifiable triggers (e.g. cough syncope, micturition syncope).

Vasovagal syncope

This is normally triggered by a reduction in venous return due to prolonged standing, excessive heat or a large meal. It is mediated by the Bezold-Jarisch reflex, in which there is an initial sympathetic activation that leads to vigorous contraction of the relatively under-filled ventricles. This stimulates ventricular mechanoreceptors, producing parasympathetic (vagal) activation and sympathetic withdrawal, and causing bradycardia, vasodilatation or both. Head-up tilt-table testing is a provocation test used to establish the diagnosis, and involves asking the patient to lie on a table that is then tilted to an angle of 60–70° for up to 45 minutes, while the ECG and BP are monitored. A positive test is characterised by bradycardia (cardio-inhibitory response) and/or hypotension (vasodepressor response) associated with typical symptoms. Initial management involves lifestyle modification (salt supplementation and avoiding prolonged standing, dehydration or missing meals). In resistant cases, drug therapy can be used; fludrocortisone, which causes sodium and water retention and expands plasma volume, β -blockers, which inhibit the initial sympathetic activation, disopyramide (a vagolytic agent) or midodrine (a vasoconstrictor α -adrenoceptor agonist) may be helpful. A dual-chamber pacemaker can be useful if symptoms are predominantly due to bradycardia. Patients with a urinary sodium excretion of less than 170 mmol/day may respond to salt loading.

Carotid sinus hypersensitivity

This causes presyncope or syncope because of reflex bradycardia and vasodilatation. Carotid baroreceptors are involved in BP regulation and are activated by increased BP, resulting in a vagal discharge that causes a compensatory drop in BP. In HCSS the baroreceptor is sensitive to external pressure (e.g. during neck movement or if a tight collar is worn), so that pressure over the carotid artery causes an inappropriate and intense vagal discharge. The diagnosis can be established by monitoring the ECG and BP during carotid sinus massage for 6 seconds. This manoeuvre should not be attempted in patients with a carotid bruit or with a history of cerebrovascular disease because of the risk of embolic stroke. A positive cardio-inhibitory response is defined as a sinus pause of 3 seconds or more; a positive vasodepressor response is defined as a fall in systolic BP of more than 50 mmHg. Carotid sinus pressure will produce positive findings in about 10% of elderly individuals but less than 25% of these experience spontaneous syncope. Symptoms should not therefore be attributed to HCSS unless they are reproduced by carotid sinus pressure. Dual-chamber pacing usually prevents syncope in patients with the more common cardio-inhibitory response.

Postural hypotension

This is caused by a failure of the normal compensatory mechanisms. Relative hypovolaemia (often due to excessive diuretic therapy), sympathetic degeneration (diabetes mellitus, Parkinson's disease, ageing) and drug therapy (vasodilators, antidepressants) can all cause or aggravate the problem. Treatment is often ineffective; however, withdrawing unnecessary medication and advising the patient to wear graduated elastic stockings and get up slowly may be helpful. Fludrocortisone, which can expand blood volume through sodium and water retention, may be of value.

Palpitation

Palpitation is a very common and sometimes frightening symptom. Patients use the term to describe a wide variety of sensations including an unusually erratic, fast, slow or forceful heart beat, or even chest pain or breathlessness. Initial evaluation should concentrate on determining its likely mechanism, and whether or not there is significant underlying heart disease.

A detailed description of the sensation is essential and patients should be asked to tap out the heart beat they experience, on their chest or a table. A provisional diagnosis can usually be made on the basis of a thorough history (Box 18.22 and Fig. 18.31). It helps to obtain an ECG recording during an episode using an ambulatory monitor or a patient-activated ECG recorder.

18.22 How to evaluate palpitation

- Is the palpitation continuous or intermittent?
- Is the heart beat regular or irregular?
- What is the approximate heart rate?
- Do symptoms occur in discrete attacks?
Is the onset abrupt?
How do attacks terminate?
- Are there any associated symptoms?
e.g. Chest pain
Lightheadedness
Polyuria (a feature of supraventricular tachycardia, p. 564)
- Are there any precipitating factors, e.g. exercise, alcohol?
- Is there a history of structural heart disease, e.g. coronary artery disease, valvular heart disease?

Fig. 18.31 A simple approach to the diagnosis of palpitation.

Recurrent but short-lived bouts of an irregular heart beat are usually due to atrial or ventricular extrasystoles (ectopic beats). Some patients will describe the experience as a 'flip' or a 'jolt' in the chest, while others report dropped or missed beats. Extrasystoles are often more frequent during periods of stress or debility; they can be triggered by alcohol or nicotine.

Episodes of a pounding, forceful and relatively fast (90–120/min) heart beat are a common manifestation of anxiety. They may also reflect a hyperdynamic circulation, such as anaemia, pregnancy and thyrotoxicosis, and can occur in some forms of valve disease (e.g. aortic regurgitation). Discrete bouts of a very rapid (> 120/min) heart beat are more likely to be due to a paroxysmal tachyarrhythmia. Supraventricular and ventricular tachycardias may all present in this way. In contrast, episodes of atrial fibrillation typically present with irregular and usually rapid palpitation.

Palpitation is usually benign and, even if the patient's symptoms are due to an arrhythmia, the outlook is good if there is no underlying structural heart disease. Most cases are due to an awareness of the normal heart beat, a sinus tachycardia or benign extrasystoles, in which case an explanation and reassurance may be all that is required. Palpitation associated with presyncope or syncope may reflect more serious structural or electrical disease and should be investigated promptly.

The diagnosis and management of individual arrhythmias are considered on pages 559–577.

Cardiac arrest and sudden cardiac death

Cardiac arrest describes the sudden and complete loss of cardiac output due to asystole, ventricular tachycardia or ventricular fibrillation, or loss of mechanical cardiac contraction (pulseless electrical activity). The clinical diagnosis is based on the victim being unconscious and pulseless; breathing may take some time to stop completely after cardiac arrest. Death is virtually inevitable unless effective treatment is given promptly.

Sudden cardiac death is usually caused by a catastrophic arrhythmia and accounts for 25–30% of deaths

18.23 Common causes of sudden arrhythmic death

Coronary artery disease (85%)

- Myocardial ischaemia
- Acute MI
- Prior MI with myocardial scarring

Structural heart disease (10%)

- Aortic stenosis (p. 619)
- Hypertrophic cardiomyopathy (p. 635)
- Dilated cardiomyopathy (p. 635)
- Arrhythmogenic right ventricular dysplasia (p. 637)
- Congenital heart disease (p. 628)

No structural heart disease (5%)

- Long QT syndrome (p. 567)
- Brugada syndrome (p. 568)
- Wolff–Parkinson–White syndrome (p. 565)
- Adverse drug reactions (torsades de pointes, p. 567)
- Severe electrolyte abnormalities

from cardiovascular disease, claiming an estimated 70 000–90 000 lives each year in the UK. Many of these deaths are potentially preventable. Arrhythmias complicate many types of heart disease and can sometimes occur in the absence of recognisable structural abnormalities (Box 18.23). Sudden death less often occurs because of an acute mechanical catastrophe such as cardiac rupture or aortic dissection (pp. 595 and 603).

Coronary artery disease, especially acute MI, is the most common condition leading to cardiac arrest. Ventricular fibrillation or ventricular tachycardia is common in the first few hours of MI and many victims die before medical help is sought. Up to one-third of people developing MI die before reaching hospital, emphasising the importance of educating the public to recognise symptoms and to seek medical help quickly. Acute myocardial ischaemia (in the absence of infarction) can also cause these arrhythmias, although less commonly. Patients with a history of MI may be at risk of sudden arrhythmic death, especially if left ventricular function is impaired or there is ongoing myocardial ischaemia. In these patients, the risk is reduced by the appropriate treatment of heart failure with β -blockers and ACE inhibitors, and by coronary revascularisation, and many require implantation of a cardiac defibrillator (p. 576).

Aetiology of cardiac arrest

Cardiac arrest may be caused by ventricular fibrillation, pulseless ventricular tachycardia, asystole or pulseless electrical activity.

Ventricular fibrillation and pulseless ventricular tachycardia

These are the most common and most easily treatable cardiac arrest rhythms. Ventricular fibrillation produces rapid ineffective uncoordinated movement of the ventricles, which therefore produce no pulse. The ECG (Fig. 18.32) shows rapid, bizarre and irregular ventricular complexes. Ventricular tachycardia (p. 566) can cause

Fig. 18.32 Ventricular fibrillation. A bizarre chaotic rhythm initiated in this case by two ventricular ectopic beats in rapid succession.

cardiac arrest if the ventricular rate is so rapid that effective mechanical contraction and relaxation cannot occur, especially if it occurs in the presence of severe left ventricular impairment. It may degenerate into ventricular fibrillation. Defibrillation will restore cardiac output in more than 80% of patients if delivered immediately. However, the chances of survival fall by at least 10% with each minute's delay, and by more if basic life support is not given (see below); thus provision of these is the key to survival.

Asystole

This occurs when there is no electrical activity within the ventricles and is usually due to failure of the conducting tissue or massive ventricular damage complicating MI. A precordial thump, external cardiac massage, or administration of intravenous atropine or adrenaline (epinephrine) may restore cardiac activity. When due to conducting tissue failure, permanent pacemaker implantation will be required if the individual survives.

Pulseless electrical activity

This occurs when there is no effective cardiac output despite the presence of organised electrical activity. It may be caused by reversible conditions, such as hypovolaemia, cardiac tamponade or tension pneumothorax (see Fig. 18.35 below), but is often due to a catastrophic event such as cardiac rupture or massive pulmonary embolism, and therefore carries an extremely poor prognosis.

Management of cardiac arrest

The Chain of Survival

This term refers to the sequence of events that are necessary to maximise the chances of a cardiac arrest victim surviving (Fig. 18.33). Survival is most likely if all links in the chain are strong, i.e. if the arrest is witnessed, help is called immediately, basic life support is administered by a trained individual, the emergency medical services respond promptly, and defibrillation is achieved within a few minutes. Good training in both basic and advanced life support is essential and should be maintained by regular refresher courses. In recent years, public access defibrillation has been introduced in places of high population density, particularly where traffic congestion may impede the response of emergency services, e.g. railway stations, airports and sports stadia. Designated individuals can respond to a cardiac arrest using basic life support and an automated external defibrillator.

Fig. 18.33 The Chain of Survival in cardiac arrest. (CPR = cardiopulmonary resuscitation; ALS = advanced life support)

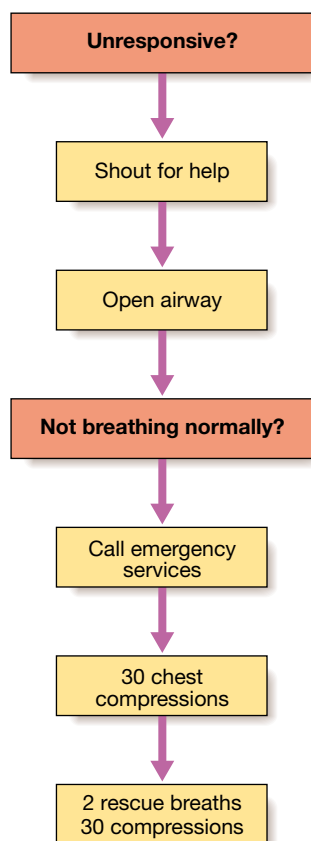

Fig. 18.34 Algorithm for adult basic life support. For further information see www.resus.org.uk.

Basic life support (BLS)

BLS encompasses manoeuvres that aim to maintain a low level of circulation until more definitive treatment with advanced life support can be given. Management of the collapsed patient requires prompt assessment and restoration of the airway, maintenance of breathing using rescue breathing ('mouth-to-mouth' breathing) and maintenance of the circulation using chest compressions (Fig. 18.34).

Advanced life support (ALS)

ALS (Fig. 18.35) aims to restore normal cardiac rhythm by defibrillation when the cause of cardiac arrest is due to a tachyarrhythmia, or to restore cardiac output by correcting other reversible causes of cardiac arrest. ALS can also involve administration of intravenous drugs to support the circulation, and endotracheal intubation to ventilate the lungs.

If cardiac arrest is witnessed, a precordial thump may sometimes convert ventricular fibrillation or tachycardia to normal rhythm, but this is futile if cardiac arrest has lasted longer than a few seconds. The priority is to assess the patient's cardiac rhythm by attaching a defibrillator/monitor. Ventricular fibrillation or pulseless ventricular tachycardia is treated with immediate defibrillation. Defibrillation is more likely to be effective if a biphasic shock defibrillator is used, where the polarity of the shock is reversed midway through its delivery. Defibrillation is usually administered using

a 150 Joule biphasic shock, and CPR resumed immediately for 2 minutes without attempting to confirm restoration of a pulse, because restoration of mechanical cardiac output rarely occurs immediately after successful defibrillation. If after 2 minutes a pulse is not restored, a further biphasic shock of 150–200 joules is given. Thereafter, additional biphasic shocks of 150–200 joules are given every 2 minutes after each cycle of cardiopulmonary resuscitation (CPR). During resuscitation, adrenaline (epinephrine, 1 mg i.v.) should be given every 3–5 minutes and consideration given to the use of intravenous amiodarone, especially if ventricular fibrillation or ventricular tachycardia reinitiates after successful defibrillation.

Ventricular fibrillation of low amplitude, or 'fine VF', may mimic asystole. If asystole cannot be confidently diagnosed, the patient should be regarded as having 'fine VF' and defibrillated. If an electrical rhythm is present that would be expected to produce a cardiac output, 'pulseless electrical activity' is present. There are several potentially reversible causes that can be easily remembered as a list of four Hs and four Ts (see Fig. 18.35). Pulseless electrical activity is treated by continuing CPR and adrenaline (epinephrine) administration whilst seeking such causes. Asystole is treated similarly, with the additional support of atropine and sometimes external or transvenous pacing in an attempt to generate an electrical rhythm.

Survivors of cardiac arrest

Patients who survive a cardiac arrest caused by acute MI need no specific treatment beyond that given to those recovering from an uncomplicated infarct, since their prognosis is similar (p. 598). Those with reversible causes, such as exercise-induced ischaemia or aortic stenosis, should have the underlying cause treated if possible. Survivors of ventricular tachycardia or ventricular fibrillation arrest in whom no reversible cause can be identified may be at risk of another episode, and should be considered for an implantable cardiac defibrillator (p. 576) and anti-arrhythmic drug therapy.

Abnormal heart sounds and murmurs

The first clinical manifestation of heart disease may be the discovery of an abnormal sound on auscultation (Box 18.24). This may be incidental—for example, during a routine childhood examination—or may be prompted by symptoms of heart disease. Clinical evaluation is helpful but an echocardiogram is often necessary to confirm the nature of an abnormal heart sound or murmur.

Is the sound cardiac?

Additional heart sounds and murmurs demonstrate a consistent relationship to a specific part of the cardiac cycle but extracardiac sounds (e.g. pleural rub or venous hum) do not. Pericardial friction produces a characteristic scratching or crunching noise, which often has two components corresponding to atrial and ventricular systole, and may vary with posture and respiration.

Is the sound pathological?

Pathological sounds and murmurs are the product of turbulent blood flow or rapid ventricular filling due to abnormal loading conditions. Some added sounds

Fig. 18.35 Algorithm for adult advanced life support. For further information see www.resus.org.uk. (CPR = cardiopulmonary resuscitation; PEA = pulseless electrical activity; VF = ventricular fibrillation; VT = pulseless ventricular tachycardia)

are physiological but may also occur in pathological conditions; for example, a third sound is common in young people and in pregnancy but is also a feature of heart failure (see Box 18.24). Similarly, a systolic murmur due to turbulence across the right ventricular outflow tract may occur in hyperdynamic states (e.g. anaemia, pregnancy) but may also be due to pulmonary stenosis or an intracardiac shunt leading to volume overload of the RV (e.g. atrial septal defect).

Benign murmurs do not occur in diastole (Box 18.25), and systolic murmurs that radiate or are associated with a thrill are almost always pathological.

Auscultatory evaluation of a heart murmur

Timing, intensity, location, radiation and quality are all useful clues to the origin and nature of a heart murmur (Box 18.26). Radiation of a murmur is determined by the direction of turbulent blood flow and is only detectable when there is a high-velocity jet, such as in

mitral regurgitation (radiation from apex to axilla) or aortic stenosis (radiation from base to neck). Similarly, the pitch and quality of the sound can help to distinguish the murmur, such as the 'blowing' murmur of mitral regurgitation or the 'rasping' murmur of aortic stenosis.

The position of a murmur in relation to the cardiac cycle is crucial and should be assessed by timing it with the heart sounds, carotid pulse and apex beat (Figs 18.36 and 18.37).

Systolic murmurs associated with ventricular outflow tract obstruction

These occur in mid-systole and have a crescendo-decrescendo pattern, reflecting the changing velocity of blood flow (Box 18.27). Pansystolic murmurs maintain a constant intensity and extend from the first heart sound throughout systole (up to and beyond the second heart sound). They occur when blood leaks from a ventricle

18.24 Normal and abnormal heart sounds				
Sound	Timing	Characteristics	Mechanisms	Variable features
First heart sound (S1)	Onset of systole	Usually single or narrowly split	Closure of mitral and tricuspid valves	Loud: hyperdynamic circulation (anaemia, pregnancy, thyrotoxicosis); mitral stenosis Soft: heart failure; mitral regurgitation
Second heart sound (S2)	End of systole	Split on inspiration Single on expiration (p. 528)	Closure of aortic and pulmonary valve A ₂ first P ₂ second	Fixed wide splitting with atrial septal defect Wide but variable splitting with delayed right heart emptying (e.g. right bundle branch block) Reversed splitting due to delayed left heart emptying (e.g. left bundle branch block)
Third heart sound (S3)	Early in diastole, just after S2	Low pitch, often heard as 'gallop'	From ventricular wall due to abrupt cessation of rapid filling	Physiological: young people, pregnancy Pathological: heart failure, mitral regurgitation
Fourth heart sound (S4)	End of diastole, just before S1	Low pitch	Ventricular origin (stiff ventricle and augmented atrial contraction) related to atrial filling	Absent in atrial fibrillation A feature of severe left ventricular hypertrophy (e.g. hypertrophic cardiomyopathy)
Systolic clicks	Early or mid-systole	Brief, high-intensity sound	Valvular aortic stenosis Valvular pulmonary stenosis Floppy mitral valve Prosthetic heart sounds from opening and closing of normally functioning mechanical valves	Click may be lost when stenotic valve becomes thickened or calcified Prosthetic clicks lost when valve obstructed by thrombus or vegetations
Opening snap (OS)	Early in diastole	High pitch, brief duration	Opening of stenosed leaflets of mitral valve Prosthetic heart sounds	Moves closer to S2 as mitral stenosis becomes more severe. May be absent in calcific mitral stenosis

18.25 Features of a benign or innocent heart murmur

- Soft
- Mid-systolic
- Heard at left sternal edge
- No radiation
- No other cardiac abnormalities

into a low-pressure chamber at an even or constant velocity. Mitral regurgitation, tricuspid regurgitation and ventricular septal defect are the only causes of a pansystolic murmur. Late systolic murmurs are unusual but may occur in mitral valve prolapse, if the mitral regurgitation is confined to late systole, hypertrophic obstructive cardiomyopathy if dynamic obstruction occurs late in systole.

Mid-diastolic murmurs

These are due to accelerated or turbulent flow across the mitral or tricuspid valves. They are low-pitched noises that are often difficult to hear and should be evaluated with the bell of the stethoscope. A mid-diastolic murmur may be due to mitral stenosis (located at the apex and axilla), tricuspid stenosis (located at the left sternal edge), increased flow across the mitral valve (e.g. the to-and-fro murmur of severe mitral regurgitation) or increased flow across the tricuspid valve (e.g. left-to-right shunt

18.26 How to assess a heart murmur

When does it occur?	Time the murmur using heart sounds, carotid pulse and the apex beat. Is it systolic or diastolic? Does the murmur extend throughout systole or diastole or is it confined to a shorter part of the cardiac cycle?
How loud is it? (intensity)	Grade 1: very soft (only audible in ideal conditions) Grade 2: soft Grade 3: moderate Grade 4: loud with associated thrill Grade 5: very loud Grade 6: heard without stethoscope N.B. Diastolic murmurs are sometimes graded 1–4
Where is it heard best? (location)	Listen over the apex and base of the heart, including the aortic and pulmonary areas
Where does it radiate?	Listen at the neck, axilla or back
What does it sound like? (pitch and quality)	Pitch is determined by flow (high pitch indicates high-velocity flow) Is the intensity constant or variable?

18.27 Features of some common systolic murmurs

Condition	Timing and duration	Quality	Location and radiation	Associated features
Aortic stenosis	Mid-systolic	Loud rasping	Base and left sternal edge, radiating to suprasternal notch and carotids	Single second heart sound Ejection click (in young patients) Slow rising pulse Left ventricular hypertrophy (pressure overload)
Mitral regurgitation	Pansystolic	Blowing	Apex, radiating to axilla	Soft first heart sound Third heart sound Left ventricular hypertrophy (volume overload)
Ventricular septal defect (VSD)	Pansystolic	Harsh	Lower left sternal edge, radiating to whole precordium	Thrill Biventricular hypertrophy
Benign	Mid-systolic	Soft	Left sternal edge, no radiation	No other signs of heart disease

Fig. 18.36 The relationship of the cardiac cycle to the ECG, the left ventricular pressure wave and the position of heart sounds.

through a large atrial septal defect). Early diastolic murmurs have a soft, blowing quality with a decrescendo pattern and should be evaluated with the diaphragm of the stethoscope. They are due to regurgitation across the aortic or pulmonary valves and are best heard at the left sternal edge with the patient sitting forwards in held expiration.

Ejection systolic murmur (aortic stenosis, pulmonary stenosis, aortic or pulmonary flow murmurs)

Pansystolic murmur (mitral regurgitation, tricuspid regurgitation, ventricular septal defect)

Late systolic murmur (mitral valve prolapse)

Early diastolic murmur (aortic or pulmonary regurgitation)

Mid-diastolic murmur (mitral stenosis, tricuspid stenosis, mitral or tricuspid flow murmurs)

Fig. 18.37 The timing and pattern of cardiac murmurs.

Continuous murmurs

These result from a combination of systolic and diastolic flow (e.g. persistent ductus arteriosus), and must be distinguished from extracardiac noises such as bruits from arterial shunts, venous hums (high rates of venous flow in children) and pericardial friction rubs.

The characteristics of specific valve defects and congenital anomalies are described on pages 612–635.

DISORDERS OF HEART RATE, RHYTHM AND CONDUCTION

The heart beat is normally initiated by an electrical discharge from the sinoatrial (sinus) node. The atria and ventricles then depolarise sequentially as electrical depolarisation passes through specialised conducting tissues (see Fig. 18.4, p. 525). The sinus node acts as a

pacemaker and its intrinsic rate is regulated by the autonomic nervous system; vagal activity slows the heart rate, and sympathetic activity accelerates it via cardiac sympathetic nerves and circulating catecholamines.

If the sinus rate becomes unduly slow, a lower centre may assume the role of pacemaker. This is known as an escape rhythm and may arise in the AV node or His bundle (junctional rhythm) or the ventricles (idioventricular rhythm).

A cardiac arrhythmia is a disturbance of the electrical rhythm of the heart. Arrhythmias are often a manifestation of structural heart disease but may also occur because of abnormal conduction or depolarisation in an otherwise healthy heart. A heart rate $> 100/\text{min}$ is called a tachycardia and a heart rate $< 60/\text{min}$ is called a bradycardia.

There are three main mechanisms of tachycardia:

- **Increased automaticity.** The tachycardia is produced by repeated spontaneous depolarisation of an ectopic focus, often in response to catecholamines.
 - **Re-entry.** The tachycardia is initiated by an ectopic beat and sustained by a re-entry circuit (Fig. 18.38). Most tachyarrhythmias are due to re-entry.
 - **Triggered activity.** This can cause ventricular arrhythmias in patients with coronary heart disease. It is a form of secondary depolarisation arising from an incompletely repolarised cell membrane.
- Bradycardia may be due to:
- **Reduced automaticity,** e.g. sinus bradycardia.
 - **Blocked or abnormally slow conduction,** e.g. AV block.

An arrhythmia may be 'supraventricular' (sinus, atrial or junctional) or ventricular. Supraventricular rhythms usually produce narrow QRS complexes because the ventricles are depolarised normally through the AV node and bundle of His. In contrast, ventricular rhythms produce broad, bizarre QRS complexes because the ventricles are activated in an abnormal sequence. However, occasionally a supraventricular rhythm can produce broad or wide QRS complexes due to coexisting bundle

branch block or the presence of accessory conducting tissue (see below).

Bradycardias tend to cause symptoms that reflect low cardiac output: fatigue, lightheadedness and syncope. Tachycardias cause rapid palpitation, dizziness, chest discomfort or breathlessness. Extreme tachycardias can cause syncope because the heart is unable to contract or relax properly at extreme rates. Extreme bradycardias or tachycardias can precipitate sudden death or cardiac arrest.

Sinus rhythms

Sinus arrhythmia

Phasic alteration of the heart rate during respiration (the sinus rate increases during inspiration and slows during expiration) is a consequence of normal parasympathetic nervous system activity and can be pronounced in children. Absence of this normal variation in heart rate with breathing or with changes in posture may be a feature of autonomic neuropathy (p. 831).

Sinus bradycardia

A sinus rate $< 60/\text{min}$ may occur in healthy people at rest and is a common finding in athletes. Some pathological causes are listed in Box 18.28. Asymptomatic sinus bradycardia requires no treatment. Symptomatic acute sinus bradycardia usually responds to intravenous atropine 0.6–1.2 mg. Patients with recurrent or persistent symptomatic sinus bradycardia should be considered for pacemaker implantation.

Sinus tachycardia

This is defined as a sinus rate $> 100/\text{min}$, and is usually due to an increase in sympathetic activity associated with exercise, emotion, pregnancy or pathology (see Box 18.28). Young adults can produce a rapid sinus rate, up to 200/min, during intense exercise.

Fig. 18.38 The mechanism of re-entry. Re-entry can occur when there are two alternative pathways with different conducting properties (e.g. the AV node and an accessory pathway, or an area of normal and an area of ischaemic tissue). Here, pathway A conducts slowly and recovers quickly, while pathway B conducts rapidly and recovers slowly. (1) In sinus rhythm each impulse passes down both pathways before entering a common distal pathway. (2) As the pathways recover at different rates, a premature impulse may find pathway A open and B closed. (3) Pathway B may recover while the premature impulse is travelling selectively down pathway A. The impulse can then travel retrogradely up pathway B, setting up a closed loop or re-entry circuit. (4) This may initiate a tachycardia that continues until the circuit is interrupted by a change in conduction rates or electrical depolarisation.

18.28 Some pathological causes of sinus bradycardia and tachycardia

Sinus bradycardia

- MI
- Sinus node disease (sick sinus syndrome)
- Hypothermia
- Hypothyroidism
- Cholestatic jaundice
- Raised intracranial pressure
- Drugs, e.g. β -blockers, digoxin, verapamil

Sinus tachycardia

- Anxiety
- Fever
- Anaemia
- Heart failure
- Thyrotoxicosis
- Pheochromocytoma
- Drugs, e.g. β -agonists (bronchodilators)

Atrial tachyarrhythmias

Atrial ectopic beats (extrasystoles, premature beats)

These usually cause no symptoms but can give the sensation of a missed beat or an abnormally strong beat. The ECG (Fig. 18.39) shows a premature but otherwise normal QRS complex; if visible, the preceding P wave has a different morphology because the atria activate from an abnormal site. In most cases these are of no consequence, although very frequent atrial ectopic beats may herald the onset of atrial fibrillation. Treatment is rarely necessary but β -blockers can be used if symptoms are intrusive.

Fig. 18.39 Atrial ectopic beats. The first, second and fifth complexes are normal sinus beats. The third, fourth and sixth complexes are atrial ectopic beats with identical QRS complexes and abnormal (sometimes barely visible) P waves.

Atrial tachycardia

Atrial tachycardia may be a manifestation of increased atrial automaticity, sinoatrial disease or digoxin toxicity. It produces a narrow complex tachycardia with abnormal P-wave morphology, sometimes associated with AV block if the atrial rate is rapid. It may respond to β -blockers which reduce automaticity, or class I or III anti-arrhythmic drugs (see Box 18.40, p. 573). The ventricular response in rapid atrial tachycardias may be controlled by AV node-blocking drugs. Catheter ablation (p. 575) can be used to target the ectopic site and should be offered as an alternative to anti-arrhythmic drugs in patients with recurrent atrial tachycardia.

Atrial flutter

Atrial flutter is characterised by a large (macro) re-entry circuit, usually within the RA encircling the tricuspid annulus. The atrial rate is approximately 300/min, and is usually associated with 2:1, 3:1 or 4:1 AV block (with corresponding heart rates of 150, 100 or 75/min). Rarely, in young patients, every beat is conducted, producing a heart rate of 300/min and potentially haemodynamic compromise. The ECG shows saw-toothed flutter waves (Fig. 18.40). When there is regular 2:1 AV block, it may be difficult to identify flutter waves which are buried in the QRS complexes and T waves. Atrial flutter should always be suspected when there is a narrow complex tachycardia of 150/min. Carotid sinus pressure or intravenous adenosine may help to establish the diagnosis by temporarily increasing the degree of AV block and revealing the flutter waves (Fig. 18.41).

Fig. 18.40 Atrial flutter. Simultaneous recording showing atrial flutter with 3:1 AV block; flutter waves are only visible in leads II and III.

Fig. 18.41 Carotid sinus pressure in atrial flutter: continuous trace. The diagnosis of atrial flutter with 2:1 block was established when carotid sinus pressure produced temporary AV block revealing the flutter waves.

Management

Digoxin, β -blockers or verapamil can be used to control the ventricular rate (pp. 571–573). However, in many cases it may be preferable to try to restore sinus rhythm by direct current (DC) cardioversion or by using intravenous amiodarone. Beta-blockers or amiodarone can also be used to prevent recurrent episodes of atrial flutter. Although flecainide can also be used for acute treatment or prophylaxis, it should be avoided because there is a risk of slowing the flutter circuit and facilitating 1:1 AV nodal conduction. This can cause a paradoxical tachycardia and haemodynamic compromise. If used, it should always be prescribed along with an AV node-blocking drug, such as a β -blocker. Catheter ablation offers a 90% chance of complete cure and is the treatment of choice for patients with persistent, troublesome symptoms.

Atrial fibrillation

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia, with an overall prevalence of 0.5% in the adult population of the UK. The prevalence rises with age, affecting 2–5% and 8% of those aged over 70 and 80 years respectively. Atrial fibrillation is a complex arrhythmia characterised by both abnormal automatic firing and the presence of multiple interacting re-entry circuits looping around the atria. Episodes of atrial fibrillation are usually initiated by rapid bursts of ectopic beats arising from conducting tissue in the pulmonary veins or from diseased atrial tissue. AF becomes sustained because of initiation of re-entrant conduction within the atria or sometimes because of continuous ectopic firing (Fig. 18.42). Re-entry is more likely to occur in atria that are enlarged, or in which conduction is slow (as is the case in many forms of heart disease). During episodes of AF, the atria beat rapidly but in an uncoordinated and ineffective manner. The ventricles are activated irregularly at a rate determined by conduction through the AV node. This produces the characteristic 'irregularly irregular' pulse. The ECG (Fig. 18.43) shows normal but irregular QRS complexes; there are no P waves but the baseline may show irregular fibrillation waves.

AF can be classified as paroxysmal (intermittent, self-terminating episodes), persistent (prolonged episodes

Fig 18.42 Mechanisms of the initiation of atrial fibrillation.

(1) Ectopic beats, often arising from the pulmonary veins, trigger atrial fibrillation. (2) Re-entry within the atria maintains atrial fibrillation, with multiple interacting re-entry circuits operating simultaneously.

Fig. 18.43 Two examples of atrial fibrillation. The QRS complexes are irregular and there are no P waves. **A** There is usually a fast ventricular rate, e.g. between 120 and 160/min, at the onset of atrial fibrillation. **B** In chronic AF, the ventricular rate may be much slower due to the effects of medication and AV nodal fatigue.

that can be terminated by electrical or chemical cardioversion) or permanent. In patients with AF seen for the first time, it can be difficult to identify which of these is present. Unfortunately for many patients, paroxysmal AF will become permanent as the underlying disease process that predisposes to AF progresses. Electrophysiological changes occur in the atria within a few hours of the onset of AF that tend to maintain fibrillation: electrical remodelling. When AF persists for a period of months, structural remodelling occurs with atrial fibrosis and dilatation that further predispose to AF. Thus early treatment of AF will prevent this and reinitiation of the arrhythmia.

AF may be the first manifestation of many forms of heart disease (Box 18.29), particularly those that are associated with enlargement or dilatation of the atria. Alcohol excess, hyperthyroidism and chronic lung disease are also common causes of AF, although multiple aetiological factors often coexist such as the combination of alcohol, hypertension and coronary disease. About 50% of all patients with paroxysmal AF and 20% of patients with persistent or permanent AF have structurally normal hearts; this is known as 'lone atrial fibrillation'.

AF can cause palpitation, breathlessness and fatigue. In patients with poor ventricular function or valve disease it may precipitate or aggravate cardiac failure because of loss of atrial function and heart rate control. A fall in BP may cause lightheadedness, and chest pain may occur with underlying coronary disease. However, AF is often completely asymptomatic, in which case it is usually discovered as a result of a routine examination or ECG.

AF is associated with significant morbidity and a two-fold increase in mortality that are largely attributable to the effects of the underlying heart disease and the risk of cerebral embolism. Careful assessment, risk stratification and therapy can improve the prognosis.

18.29 Common causes of atrial fibrillation

- Coronary artery disease (including acute MI)
- Valvular heart disease, especially rheumatic mitral valve disease
- Hypertension
- Sinoatrial disease
- Hyperthyroidism
- Alcohol
- Cardiomyopathy
- Congenital heart disease
- Chest infection
- Pulmonary embolism
- Pericardial disease
- Idiopathic (lone AF)

Management

Assessment of patients with newly diagnosed AF includes a full history, physical examination, 12-lead ECG, echocardiogram and thyroid function tests. Additional investigations such as exercise testing may be needed to determine the nature and extent of any underlying heart disease. Biochemical evidence of hyperthyroidism is found in a small minority of patients with otherwise unexplained AF.

When AF complicates an acute illness (e.g. chest infection, pulmonary embolism), effective treatment of the primary disorder will often restore sinus rhythm. Otherwise, the main objectives are to restore sinus rhythm as soon as possible, prevent recurrent episodes of AF, optimise the heart rate during periods of AF, minimise the risk of thromboembolism and treat any underlying disease.

Paroxysmal atrial fibrillation

Occasional attacks that are well tolerated do not necessarily require treatment. Beta-blockers are normally used as first-line therapy if symptoms are troublesome, and are particularly useful for treating patients with AF associated with ischaemic heart disease, hypertension and cardiac failure. Beta-blockers reduce the ectopic firing that normally initiates AF. Class Ic drugs (see Box 18.40, p. 573), such as propafenone or flecainide, are also effective at preventing episodes but should not be given to patients with coronary disease or left ventricular dysfunction. Flecainide is usually prescribed along with a rate limiting β -blocker because it occasionally precipitates atrial flutter. Amiodarone is the most effective agent for preventing AF but its side-effects restrict its use to patients in whom other measures fail. Digoxin and verapamil are not effective drugs for preventing paroxysms of AF, although they serve to limit the heart rate when AF occurs by blocking the AV node. In patients with AF in whom β -blockers or class Ic drugs are ineffective or cause side-effects, catheter ablation can be considered. Ablation is used to isolate electrically the pulmonary veins from the LA, preventing ectopic triggering of AF. Sometimes ablation is used to create lines of conduction block within the atria to prevent re-entry. Ablation prevents AF in approximately 70% of patients with prior drug-resistant episodes, although drugs may subsequently be needed to maintain sinus rhythm. Ablation for AF is an evolving treatment which is associated with a small risk of embolic stroke or cardiac tamponade. Specialised 'AF suppression' pacemakers have been developed which pace the atria to prevent paroxysms but this has not proved to be as effective as was initially hoped.

Persistent and permanent atrial fibrillation

There are two options for treating persistent AF:

- **rhythm control:** attempting to restore and maintain sinus rhythm
- **rate control:** accepting that AF will be permanent and using treatments to control the ventricular rate and to prevent embolic complications.

Rhythm control. An attempt to restore sinus rhythm is particularly appropriate if the arrhythmia has precipitated troublesome symptoms and there is a modifiable or treatable underlying cause. Electrical cardioversion (p. 574) is initially successful in three-quarters of patients but relapse is frequent (25–50% at 1 month and 70–90% at 1 year). Attempts to restore and maintain

18.30 Atrial fibrillation in old age

- **Prevalence:** rises with age, reaching more than 10% in those > 80 yrs of age.
- **Symptoms:** sometimes asymptomatic but often accompanied by diastolic heart failure.
- **Hyperthyroidism:** AF may be the dominant feature of otherwise silent or occult hyperthyroidism.
- **Cardioversion:** followed by high rates (~70% at 1 yr) of recurrent AF.
- **Stroke:** AF is an important cause of cerebral embolism, found in 15% of all stroke patients and 2–8% of those with transient ischaemic attacks (TIAs).
- **Anticoagulation:** although the risk of thromboembolism rises, the hazards of anticoagulation also rise with age because of increased comorbidity, particularly cognitive impairment and falls.
- **Target INR:** if anticoagulation is recommended in those > 75 yrs, care should be taken to maintain an INR < 3.0 because of the increased risk of intracranial haemorrhage.
- **Aspirin:** a safer alternative if anticoagulation cannot be recommended, but its benefits in reducing the risk of stroke are less significant and consistent than with warfarin.

sinus rhythm are most successful if AF has been present for < 3 months, the patient is young and there is no important structural heart disease.

Immediate DC cardioversion after the administration of intravenous heparin is appropriate if AF has been present for < 48 hours. An attempt to restore sinus rhythm by infusing intravenous flecainide (2 mg/kg over 30 minutes, maximum dose 150 mg) is a safe alternative to electrical cardioversion if there is no underlying structural heart disease. In other situations, DC cardioversion should be deferred until the patient has been established on warfarin, with an international normalised ratio (INR) > 2.0 for a minimum of 4 weeks, and any underlying problems, such as hypertension or alcohol excess, have been eliminated. Anticoagulation should be maintained for at least 3 months following successful cardioversion; if relapse occurs, a second (or third) cardioversion may be appropriate. Concomitant therapy with amiodarone or β -blockers may reduce the risk of recurrence. Catheter ablation is sometimes used to help restore and maintain sinus rhythm in resistant cases, but it is a less effective treatment for persistent AF than for paroxysmal AF.

Rate control. If sinus rhythm cannot be restored, treatment should be directed at maintaining an appropriate heart rate. Digoxin, β -blockers or rate-limiting calcium antagonists such as verapamil or diltiazem (pp. 571–573) will reduce the ventricular rate by increasing the degree of AV block. This alone may produce a striking improvement in overall cardiac function, particularly in patients with mitral stenosis. Beta-blockers and rate-limiting calcium antagonists are often more effective than digoxin at controlling the heart rate during exercise and may have additional benefits in patients with hypertension or structural heart disease. Combination therapy (e.g. digoxin + atenolol) is often advisable.

In exceptional cases, poorly controlled and symptomatic AF can be treated by deliberately inducing complete AV nodal block with catheter ablation; a permanent pacemaker must be implanted beforehand. This is known as the 'pace and ablate' strategy.

Prevention of thromboembolism

Loss of atrial contraction and left atrial dilatation cause stasis of blood in the LA and may lead to thrombus formation in the left atrial appendage. This predisposes patients to stroke and other forms of systemic embolism. The annual risk of these events in patients with persistent AF is approximately 5% but it is influenced by many factors (Box 18.31) and may range from less than 1% to 12% (Box 18.32).

Several large randomised trials have shown that treatment with adjusted-dose warfarin (target INR 2.0–3.0) reduces the risk of stroke by about two-thirds, at the cost of an annual risk of bleeding of approximately 1–1.5%, whereas treatment with aspirin reduces the risk of stroke by only one-fifth (Box 18.33). Warfarin is thus indicated for patients with AF who have specific risk factors for stroke. For patients with intermittent AF, the risk of stroke is proportionate to the frequency and duration of AF episodes. Those with frequent, prolonged (> 24 hours) episodes of AF should be considered for warfarin anticoagulation.

An assessment of the risk of embolism helps to define the possible benefits of antithrombotic therapy (see Box 18.31), which must be balanced against its potential hazards. Echocardiography is valuable in risk stratification. Warfarin is indicated in patients at high or very high risk of stroke, unless anticoagulation poses unacceptable risks. Comorbid conditions that may be complicated by bleeding, such as peptic ulcer, uncontrolled hypertension, alcohol misuse, frequent falls, poor drug compliance and potential drug interactions, are all relative contraindications to warfarin. Patients at moderate risk of stroke may be treated with warfarin or aspirin after discussing the balance of risk and benefit with the individual. Young

18.31 How to assess risk of thromboembolism in atrial fibrillation: the CHADS score		
<ul style="list-style-type: none"> • Congestive heart failure (1 point) • Hypertension (1 point) • Age > 75 (1 point) • Diabetes mellitus (1 point) • Stroke or transient ischaemic attack (2 points) 		
CHADS score	Stroke risk/yr (%)	95% CI
0	1.9	1.2–3.0
1	2.8	2.0–3.8
2	4.0	3.1–5.1
3	5.9	4.6–7.3
4	8.5	6.3–11.1
5	12.5	8.2–17.5
6	18.2	10.5–27.4
Score: 0 = aspirin therapy only, 1 = warfarin or aspirin, ≥ 2 = warfarin		

18.32 Effect of risk status and treatment on annual risk of stroke in non-rheumatic atrial fibrillation			
Risk group	Untreated	Aspirin	Warfarin
Very high	12%	10%	5%
High	6.5%	5%	2.5%
Moderate	4%	3%	1.5%
Low	1.2%	1%	0.5%
N.B. In most studies the annual risk of significant bleeding during warfarin therapy is between 1.0 and 1.5%.			

EBM 18.33 Anticoagulation in atrial fibrillation

'Anticoagulation with warfarin reduces the risk of ischaemic stroke in non-rheumatic atrial fibrillation by about 62% (absolute risk reduction 2.7% for primary prevention and 8.4% for secondary prevention), while aspirin reduces the risk by only 22% (absolute risk reduction 1.5% for primary prevention and 2.5% for secondary prevention). NNT₆ for 1 year (warfarin vs placebo) = 18.'

• Hart RG, et al. *Ann Intern Med* 1999; 131:492–501.

For further information:  www.sign.ac.uk

patients (under 65 years) with no evidence of structural heart disease have a very low risk of stroke; they do not require warfarin but may benefit from aspirin.

'Supraventricular' tachycardias

The term 'supraventricular tachycardia' (SVT) is commonly used to describe a range of regular tachycardias that have a similar appearance on an ECG. These are usually associated with a narrow QRS complex and are characterised by a re-entry circuit or automatic focus involving the atria. The term SVT is misleading, as in many cases the ventricles also form part of the re-entry circuit, such as in patients with AV re-entrant tachycardia.

Atrioventricular nodal re-entrant tachycardia (AVNRT)

This is due to re-entry in a circuit involving the AV node and its two right atrial input pathways: a superior 'fast' pathway and an inferior 'slow' pathway (see Fig. 18.45A below). This produces a regular tachycardia with a rate of 120–240/min. It tends to occur in hearts that are otherwise normal and episodes may last from a few seconds to many hours. The patient is usually aware of a fast heart beat and may feel faint or breathless. Polyuria, mainly due to the release of atrial natriuretic peptide, is sometimes a feature, and cardiac pain or heart failure may occur if there is coexisting structural heart disease. The ECG (Fig. 18.44) usually shows a tachycardia with normal QRS complexes but occasionally there may be rate-dependent bundle branch block.

Fig. 18.44 Supraventricular tachycardia. The rate is 180/min and the QRS complexes are normal.

Management

Treatment is not always necessary. However, an episode may be terminated by carotid sinus pressure or other measures that increase vagal tone (e.g. Valsalva manoeuvre). Intravenous adenosine or verapamil will restore sinus rhythm in most cases. Suitable alternative drugs include β -blockers or flecainide. In rare cases when there is severe haemodynamic compromise, the tachycardia should be terminated by DC cardioversion (p. 574).

If episodes are frequent or disabling, prophylactic oral therapy with a β -blocker or verapamil may be indicated. Catheter ablation (p. 575) offers a high chance of complete cure and is usually preferable to long-term drug treatment.

Wolff–Parkinson–White syndrome and atrioventricular re-entrant tachycardia

In these conditions, an abnormal band of conducting tissue connects the atria and ventricles. It resembles

Purkinje tissue in that it conducts very rapidly, and is known as an accessory pathway. In around half of cases, this pathway only conducts in the retrograde direction (from ventricles to atria) and thus does not alter the appearance of the ECG in sinus rhythm. This is known as a concealed accessory pathway. In the remainder, conduction takes place partly through the AV node and partly through the accessory pathway. Premature activation of ventricular tissue via the pathway produces a short PR interval and a 'slurring' of the QRS complex, called a delta wave (Fig. 18.45B). This is known as a manifest accessory pathway. As the AV node and

Fig. 18.45 AV nodal re-entrant tachycardia (AVNRT) and Wolff–Parkinson–White (WPW) syndrome. **A** AV node re-entrant tachycardia. The mechanism of AVNRT occurs via two right atrial AV nodal input pathways: the slow (S) and fast (F) pathways. Antegrade conduction occurs via the slow pathway; the wavefront enters the AV node and passes into the ventricles, at the same time re-entering the atria via the fast pathway.

In WPW syndrome there is a strip of accessory conducting tissue that allows electricity to bypass the AV node and spread from the atria to the ventricles rapidly and without delay. When the ventricles are depolarised through the AV node the ECG is normal, but when the ventricles are depolarised through the accessory conducting tissue the ECG shows a very short PR interval and a broad QRS complex **B** Sinus rhythm. In sinus rhythm the ventricles are depolarised through (1) the AV node and (2) the accessory pathway, producing an ECG with a short PR interval and broadened QRS complexes; the characteristic slurring of the upstroke of the QRS complex is known as a delta wave. The degree of pre-excitation (the proportion of activation passing down the accessory pathway) and therefore the ECG appearances may vary a lot, and at times the ECG can look normal. **C** Orthodromic tachycardia. This is the most common form of tachycardia in WPW. The re-entry circuit passes antegradely through the AV node and retrogradely through the accessory pathway. The ventricles are therefore depolarised in the normal way, producing a narrow-complex tachycardia that is indistinguishable from other forms of SVT. **D** Atrial fibrillation. In this rhythm the ventricles are largely depolarised through the accessory pathway, producing an irregular broad-complex tachycardia which is often more rapid than the example shown.

accessory pathway have different conduction speeds and refractory periods, a re-entry circuit can develop, causing tachycardia (Fig. 18.45C); when this is associated with symptoms, the condition is known as Wolff-Parkinson-White syndrome. The ECG appearance of this tachycardia may be indistinguishable from that of AVNRT (Fig. 18.45A). Carotid sinus pressure or intravenous adenosine can terminate the tachycardia. If atrial fibrillation occurs, it may produce a dangerously rapid ventricular rate because the accessory pathway lacks the rate-limiting properties of the AV node (Fig. 18.45D). This is known as pre-excited atrial fibrillation and may cause collapse, syncope and even death. It should be treated as an emergency, usually with DC cardioversion.

Catheter ablation is first-line treatment in symptomatic patients and is nearly always curative. Prophylactic anti-arrhythmic drugs, such as flecainide, propafenone or amiodarone (p. 573), can also be used. These slow the conduction rate and prolong the refractory period of the accessory pathway. Digoxin and verapamil shorten the refractory period of the accessory pathway and should be avoided.

Ventricular tachyarrhythmias

Ventricular ectopic beats (extrasystoles, premature beats)

QRS complexes in sinus rhythm are normally narrow because the ventricles are activated rapidly and simultaneously via the His-Purkinje system. The complexes of ventricular ectopic beats are premature, broad and bizarre because the ventricles are activated one after the other, rather than simultaneously. The complexes may be unifocal (identical beats arising from a single ectopic focus) or multifocal (varying morphology with multiple foci, Fig. 18.46). 'Couplet' and 'triplet' are terms used to describe two or three successive ectopic beats, whereas a run of alternate sinus and ectopic beats is known as ventricular 'bigeminy'. Ectopic beats produce a low stroke volume because left ventricular contraction occurs before filling is complete. The pulse is therefore irregular, with weak or missed beats (see Fig. 18.46). Patients are usually asymptomatic but may complain of an irregular heart

beat, missed beats or abnormally strong beats (due to the increased output of the post-ectopic sinus beat). The significance of ventricular ectopic beats (VEBs) depends on the presence or absence of underlying heart disease.

Ventricular ectopic beats in otherwise healthy subjects

VEBs are frequently found in healthy people and their prevalence increases with age. Ectopic beats in patients with otherwise normal hearts are more prominent at rest and disappear with exercise. Treatment is not necessary unless the patient is highly symptomatic, in which case β -blockers can be used.

VEBs are sometimes a manifestation of otherwise subclinical heart disease, particularly coronary artery disease. There is no evidence that anti-arrhythmic therapy improves prognosis but the discovery of very frequent VEBs should prompt investigations such as an echocardiogram (looking for structural heart disease) and an exercise stress test (to detect underlying ischaemic heart disease).

Ventricular ectopic beats associated with heart disease

Frequent VEBs often occur during acute MI but need no treatment. Persistent, frequent ($> 10/\text{hour}$) ventricular ectopic beats in patients who have survived the acute phase of MI indicate a poor long-term outcome. Other than β -blockers, anti-arrhythmic drugs do not improve and may even worsen prognosis.

VEBs are common in patients with heart failure, when they are associated with an adverse prognosis, but again the outlook is no better if they are suppressed with anti-arrhythmic drugs. Effective treatment of the heart failure may suppress the ectopic beats.

VEBs are also a feature of digoxin toxicity, are sometimes found in mitral valve prolapse, and may occur as 'escape beats' in the presence of an underlying bradycardia. Treatment should be directed at the underlying condition.

Ventricular tachycardia (VT)

The common causes of VT include acute MI, cardiomyopathy and chronic ischaemic heart disease,

Fig. 18.46 Ventricular ectopic beats. **A** There are broad bizarre QRS complexes (arrows) with no preceding P wave in between normal sinus beats. Their configuration varies, so these are multifocal ectopics. **B** A simultaneous arterial pressure trace is shown. The ectopic beats result in a weaker pulse (arrows), which may be perceived as a 'dropped beat'.

particularly when it is associated with a ventricular aneurysm or poor left ventricular function. In these settings it is serious because it may cause haemodynamic compromise or degenerate into ventricular fibrillation (p. 555). It is caused by abnormal automaticity or triggered activity in ischaemic tissue, or by re-entry within scarred ventricular tissue. Patients may complain of palpitation or symptoms of low cardiac output, such as dizziness, dyspnoea or syncope. The ECG shows tachycardia with broad, abnormal QRS complexes with a rate $> 120/\text{min}$ (Fig. 18.47). VT may be difficult to distinguish from SVT with bundle branch block or pre-excitation (WPW syndrome). Features in favour of a diagnosis of VT are listed in Box 18.34. A 12-lead (Fig. 18.48) or intra-cardiac ECG may help to establish the diagnosis. When there is doubt, it is safer to manage the problem as VT.

Patients recovering from MI sometimes have periods of idioventricular rhythm ('slow' VT) at a rate only slightly above the preceding sinus rate and below $120/\text{min}$. These episodes often reflect reperfusion of the infarct territory and may be a good sign. They are usually self-limiting and asymptomatic, and do not require treatment. Other forms of VT, if they last for more than a few beats, will require treatment, often as an emergency.

VT occasionally occurs in patients with otherwise healthy hearts ('normal heart VT'), usually because of abnormal automaticity in the right ventricular outflow tract or one of the fascicles of the left bundle branch. The prognosis is good and catheter ablation can be curative.

Management

Prompt action to restore sinus rhythm is required and should usually be followed by prophylactic therapy. Synchronised DC cardioversion is the treatment of choice if systolic BP is $< 90\text{ mmHg}$. If the arrhythmia is well tolerated, intravenous amiodarone may be given as a bolus followed by a continuous infusion (p. 573).

Fig. 18.47 Ventricular tachycardia: fusion beat (arrow). In ventricular tachycardia there is independent atrial and ventricular activity. Occasionally a P wave is conducted to the ventricles through the AV node, producing a normal sinus beat in the middle of the tachycardia (a capture beat); however, more commonly the conducted impulse fuses with an impulse from the tachycardia (a fusion beat). This can only occur when there is AV dissociation and is therefore diagnostic of ventricular tachycardia.

18.34 Features in favour of ventricular tachycardia in the differential diagnosis of broad-complex tachycardia

- History of MI
- AV dissociation (pathognomonic)
- Capture/fusion beats (pathognomonic, see Fig. 18.47)
- Extreme left axis deviation
- Very broad QRS complexes ($> 140\text{ ms}$)
- No response to carotid sinus massage or i.v. adenosine

Fig. 18.48 Ventricular tachycardia: 12-lead ECG. There are typically very broad QRS complexes and marked left axis deviation. There is also AV dissociation; some P waves are visible and others are buried in the QRS complexes (arrows).

Intravenous lidocaine can be used but may depress left ventricular function, causing hypotension or acute heart failure. Hypokalaemia, hypomagnesaemia, acidosis and hypoxaemia should be corrected.

Beta-blockers are effective at preventing VT by reducing automaticity and by blocking conduction in scar re-entry circuits. Amiodarone can be added if additional control is needed. Class Ic anti-arrhythmic drugs should not be used for prevention of VT in patients with ischaemic heart disease or heart failure because they depress myocardial function and can be pro-arrhythmic (increase the likelihood of a dangerous arrhythmia). In patients at high risk of arrhythmic death (e.g. those with poor left ventricular function, or where VT is associated with haemodynamic compromise), the use of an implantable cardiac defibrillator is recommended (p. 576). Rarely, surgery or catheter ablation can be used to interrupt the arrhythmia focus or circuit.

Torsades de pointes (ventricular tachycardia)

This form of polymorphic VT is a complication of prolonged ventricular repolarisation (prolonged QT interval).

Fig. 18.49 Torsades de pointes. A bradycardia with a long QT interval is followed by polymorphic VT that is triggered by an R on T ectopic.

18.35 Causes of long QT interval and torsades de pointes

Bradycardia

- Bradycardia compounds other factors that cause torsades de pointes

Electrolyte disturbance

- Hypokalaemia
- Hypomagnesaemia
- Hypocalcaemia

Drugs

- Disopyramide (and other class Ia anti-arrhythmic drugs, p. 573)
- Sotalol, amiodarone (and other class III anti-arrhythmic drugs)
- Amitriptyline (and other tricyclic antidepressants)
- Chlorpromazine (and other phenothiazines)
- Erythromycin (and other macrolides)

... and many more

Congenital syndromes

- LQT1: gene affected *KCNQ1*: K^+ channel, 30–35%
- LQT2: gene affected *HERG*: K^+ channel, 25–30%
- LQT3: gene affected *SCNSA*: Na^+ channel, 5–10%
- LQT4–12: rare

The ECG shows rapid irregular complexes that oscillate from an upright to an inverted position and seem to twist around the baseline as the mean QRS axis changes (Fig. 18.49). The arrhythmia is usually non-sustained and repetitive but may degenerate into ventricular fibrillation. During periods of sinus rhythm, the ECG will usually show a prolonged QT interval (> 0.42 s at a rate of 60/min).

Some of the common causes are listed in Box 18.35. The arrhythmia is more common in women and is often triggered by a combination of aetiological factors (e.g. QT-prolonging medications and hypokalaemia). The congenital long QT syndromes are a family of genetic disorders that are characterised by mutations in genes that code for cardiac sodium or potassium channels. Long QT syndrome subtypes have different triggers which are important when counselling patients. Adrenergic stimulation (e.g. exercise) is a common trigger in long QT type 1, and a sudden noise (e.g. an alarm clock) may trigger arrhythmias in long QT type 2. Arrhythmias are more common during sleep in type 3.

Treatment should be directed at the underlying cause. Intravenous magnesium (8 mmol over 15 minutes, then 72 mmol over 24 hours) should be given in all cases. Atrial pacing will usually suppress the arrhythmia through rate-dependent shortening of the QT interval. Intravenous isoprenaline is a reasonable alternative to pacing but should be avoided in patients with the congenital long QT syndromes.

Long-term therapy may not be necessary if the underlying cause can be removed. Beta-blockers are effective at preventing syncope in patients with congenital long

QT syndrome. Some patients, particularly those with extreme QT interval prolongation (> 500 ms) or certain high-risk genotypes should be considered for implantation of a defibrillator. Left stellate ganglion block may be of value in patients with resistant arrhythmias.

The Brugada syndrome is a related genetic disorder that may present with polymorphic VT or sudden death. It is characterised by a defect in sodium channel function and an abnormal ECG (right bundle branch block and ST elevation in V_1 and V_2 but not usually prolongation of the QT interval).

Sinoatrial disease (sick sinus syndrome)

Sinoatrial disease can occur at any age but is most common in older people. The underlying pathology involves fibrosis, degenerative changes or ischaemia of the SA (sinus) node. The condition is characterised by a variety of arrhythmias (Box 18.36) and may present with palpitation, dizzy spells or syncope, due to intermittent tachycardia, bradycardia, or pauses with no atrial or ventricular activity (SA block or sinus arrest) (Fig. 18.50).

A permanent pacemaker may benefit patients with troublesome symptoms due to spontaneous bradycardias, or those with symptomatic bradycardias induced by drugs required to prevent tachyarrhythmias. Atrial pacing may help to prevent episodes of atrial fibrillation. Permanent pacing improves symptoms but not prognosis, and is not indicated in patients who are asymptomatic.

18.36 Common features of sinoatrial disease

- Sinus bradycardia
- SA block (sinus arrest)
- Paroxysmal atrial tachycardia
- Paroxysmal atrial fibrillation
- AV block

Atrioventricular and bundle branch block

AV block

AV conduction is influenced by autonomic activity. AV block can therefore be intermittent and may only be evident when the conducting tissue is stressed by a rapid atrial rate. Accordingly, atrial tachyarrhythmias are often associated with AV block (see Fig. 18.43, p. 562).

First-degree AV block

In this condition, AV conduction is delayed so the PR interval is prolonged (> 0.20 s; Fig. 18.51). It rarely causes symptoms.

Fig. 18.50 Sinoatrial disease (sick sinus syndrome). A continuous rhythm strip from a 24-hour ECG tape recording illustrating periods of sinus rhythm, atrial ectopics, junctional beats, sinus bradycardia, sinus arrest and paroxysmal atrial fibrillation.

18

Fig. 18.51 First-degree AV block. The PR interval is prolonged and measures 0.26 s.

Second-degree AV block

In this condition dropped beats occur because some impulses from the atria fail to conduct to the ventricles.

In Mobitz type I second-degree AV block (Fig. 18.52) there is progressive lengthening of successive PR inter-

vals, culminating in a dropped beat. The cycle then repeats itself. This is known as Wenckebach's phenomenon and is usually due to impaired conduction in the AV node itself. The phenomenon may be physiological and is sometimes observed at rest or during sleep in athletic young adults with high vagal tone.

In Mobitz type II second-degree AV block (Fig. 18.53) the PR interval of the conducted impulses remains constant but some P waves are not conducted. This is usually caused by disease of the His–Purkinje system and carries a risk of asystole.

In 2:1 AV block (Fig. 18.54) alternate P waves are conducted, so it is impossible to distinguish between Mobitz type I and type II block.

Third-degree (complete) AV block

When AV conduction fails completely, the atria and ventricles beat independently (AV dissociation, Fig. 18.55).

Fig. 18.52 Second-degree AV block (Mobitz type I—Wenckebach's phenomenon). The PR interval progressively increases until a P wave is not conducted. The cycle then repeats itself. In this example, conduction is at a ratio of 4:3, leading to groupings of three ventricular complexes in a row.

Fig. 18.53 Second-degree AV block (Mobitz type II). The PR interval of conducted beats is normal but some P waves are not conducted. The constant PR interval distinguishes this from Wenckebach's phenomenon.

Fig. 18.54 Second-degree AV block with fixed 2:1 block. Alternate P waves are not conducted. This may be due to Mobitz type I or II block.

Ventricular activity is maintained by an escape rhythm arising in the AV node or bundle of His (narrow QRS complexes) or the distal Purkinje tissues (broad QRS complexes). Distal escape rhythms tend to be slower and less reliable.

Complete AV block (Box 18.37) produces a slow (25–50/min), regular pulse that, except in the case of congenital complete AV block, does not vary with exercise. There is usually a compensatory increase in stroke volume producing a large-volume pulse. Cannon waves may be visible in the neck and the intensity of the first heart sound varies due to the loss of AV synchrony.

Stokes–Adams attacks

Episodes of ventricular asystole may complicate complete heart block or Mobitz type II second-degree AV block, or occur in patients with sinoatrial disease (see Fig. 18.50). This may cause recurrent syncope or ‘Stokes–Adams’ attacks.

A typical episode is characterised by sudden loss of consciousness that occurs without warning and results in collapse. A brief anoxic seizure (due to cerebral ischaemia) may occur if there is prolonged asystole. There is pallor and a death-like appearance during the attack, but when the heart starts beating again there is a characteristic flush. Unlike epilepsy, recovery is rapid. Sinoatrial disease and neurocardiogenic syncope (p. 552) may cause similar symptoms.

Management

AV block complicating acute MI

Acute inferior MI is often complicated by transient AV block because the RCA supplies the AV node. There is usually a reliable escape rhythm and, if the patient remains well, no treatment is required. Symptomatic second- or third-degree AV block may respond to atropine (0.6 mg i.v., repeated as necessary) or, if this fails, a temporary pacemaker. In most cases the AV block will resolve within 7–10 days.

Second- or third-degree AV heart block complicating acute anterior MI indicates extensive ventricular damage involving both bundle branches and carries a poor prognosis. Asystole may ensue and a temporary pacemaker

18.37 Aetiology of complete AV block

Congenital

Acquired

- Idiopathic fibrosis
- MI/ischaemia
- Inflammation
 - Acute (e.g. aortic root abscess in infective endocarditis)
 - Chronic (e.g. sarcoidosis, p. 708; Chagas disease, p. 354)
- Trauma (e.g. cardiac surgery)
- Drugs (e.g. digoxin, β -blocker)

should be inserted promptly. If the patient presents with asystole, i.v. atropine (3 mg) or i.v. isoprenaline (2 mg in 500 ml 5% dextrose, infused at 10–60 mL/hour) may help to maintain the circulation until a temporary pacing electrode can be inserted. External (transcutaneous) pacing can provide effective temporary rhythm support.

Chronic AV block

Patients with symptomatic bradyarrhythmias associated with AV block should receive a permanent pacemaker (see below). Asymptomatic first-degree or Mobitz type I second-degree AV block (Wenckebach phenomenon) does not require treatment but may be an indication of serious underlying heart disease. A permanent pacemaker is usually indicated in patients with asymptomatic Mobitz type II second- or third-degree AV block because of the risk of asystole and sudden death. Pacing improves prognosis.

Bundle branch block and hemiblock

Conduction block in the right or left bundle branch can occur as a result of many pathologies, including ischaemic or hypertensive heart disease or cardiomyopathies (Box 18.38). Depolarisation proceeds

18.38 Common causes of bundle branch block

Right bundle branch block

- Normal variant
- Right ventricular hypertrophy or strain, e.g. pulmonary embolism
- Congenital heart disease, e.g. atrial septal defect
- Coronary artery disease

Left bundle branch block

- Coronary artery disease
- Hypertension
- Aortic valve disease
- Cardiomyopathy

Fig. 18.55 Complete (third-degree) AV block. There is complete dissociation of atrial and ventricular complexes. The atrial rate is 80/min and the ventricular rate is 38/min.

through a slow myocardial route in the affected ventricle rather than through the rapidly conducting Purkinje tissues that constitute the bundle branches. This causes delayed conduction into the LV or RV, broadens the QRS complex (≥ 0.12 s) and produces the characteristic alterations in QRS morphology (Figs 18.56 and 18.57). Right bundle branch block (RBBB)

Fig. 18.56 Right bundle branch block. Note the wide QRS complexes with 'M'-shaped configuration in leads V_1 and V_2 and a wide S wave in lead I.

Fig. 18.57 Left bundle branch block. Note the wide QRS complexes with the loss of the Q wave or septal vector in lead I and 'M'-shaped QRS complexes in V_5 and V_6 .

can occur in healthy people but left bundle branch block (LBBB) often signifies important underlying heart disease.

The left bundle branch divides into an anterior and a posterior fascicle. Damage to the conducting tissue at this point (hemiblock) does not broaden the QRS complex but alters the mean direction of ventricular depolarisation (mean QRS axis), causing left axis deviation in left anterior hemiblock and right axis deviation in left posterior hemiblock (see Fig. 18.8, p. 530). The combination of right bundle branch and left anterior or posterior hemiblock is known as bifascicular block.

Anti-arrhythmic drug therapy

The classification of anti-arrhythmic drugs

These agents may be classified according to their mode or site of action (Box 18.39 and Fig. 18.58). Identification of ion channel subtypes has led to refinement of drug classifications according to the specific mechanisms targeted. The Vaughn Williams classification is a crude system, but is convenient for describing the main mode of action of anti-arrhythmic drugs (Box 18.40) that should be used following guiding principles (Box 18.41). Anti-arrhythmic drugs can also be more accurately categorised by referring to the cardiac ion channels and receptors on which they act.

Class I drugs

Class I drugs act principally by suppressing excitability and slowing conduction in atrial or ventricular muscle. They act by blocking sodium channels, of which there are several types in cardiac tissue. These drugs should generally be avoided in patients with heart failure because they depress myocardial function, and class Ia and Ic drugs are often pro-arrhythmic.

Class Ia drugs

These prolong cardiac action potential duration and increase the tissue refractory period. They are used to prevent both atrial and ventricular arrhythmias.

18.39 Classification of anti-arrhythmic drugs according to effect on the intracellular action potential

Class I: membrane-stabilising agents (sodium channel blockers)

- (a) Block Na^+ channel and prolong action potential
 - Quinidine, disopyramide
- (b) Block Na^+ channel and shorten action potential
 - Lidocaine, mexiletine
- (c) Block Na^+ channel with no effect on action potential
 - Flecainide, propafenone

Class II: β -adrenoceptor antagonists (β -blockers)

- Atenolol, bisoprolol, metoprolol, l-sotalol

Class III: drugs whose main effect is to prolong the action potential

- Amiodarone, d-sotalol

Class IV: slow calcium channel blockers

- Verapamil, diltiazem

N.B. Some drugs (e.g. digoxin and adenosine) have no place in this classification, while others have properties in more than one class: e.g. amiodarone, which has actions in all four classes.

Fig. 18.58 Classification of anti-arrhythmic drugs by site of action.

Disopyramide. An effective drug but causes anticholinergic side-effects, such as urinary retention, and can precipitate glaucoma. It can depress myocardial function and should be avoided in cardiac failure.

Quinidine. Now rarely used, as it increases mortality and causes gastrointestinal upset.

Class Ib drugs

These shorten the action potential and tissue refractory period. They act on channels found predominantly in ventricular myocardium so are used to treat or prevent VT and VF.

Lidocaine. Must be given intravenously and has a very short plasma half-life.

Mexiletine. Can be given intravenously or orally, but has many side-effects (see Box 18.40).

Class Ic drugs

These affect the slope of the action potential without altering its duration or refractory period. They are used mainly for prophylaxis of AF but are effective in prophylaxis and treatment of supraventricular or ventricular arrhythmias. They are useful for WPW syndrome because they block conduction in accessory pathways. They should not be used as oral prophylaxis in patients with previous MI because of pro-arrhythmia.

Flecainide. Effective for prevention of atrial fibrillation, and an intravenous infusion may be used for pharmacological cardioversion of atrial fibrillation of less than 24 hours' duration. It should be prescribed along with an AV node-blocking drug, such as a β -blocker, to prevent pro-arrhythmia.

Propafenone. Also has some β -blocker (class II) properties. Important interactions with digoxin, warfarin and cimetidine have been described.

Class II drugs

This group comprises the β -adrenoceptor antagonists (β -blockers). These agents reduce the rate of SA node

depolarisation and cause relative block in the AV node, making them useful for rate control in atrial flutter and AF. They can be used to prevent supraventricular and ventricular tachycardia. They reduce myocardial excitability and reduce risk of arrhythmic death in patients with coronary heart disease and heart failure.

'Non-selective' β -blockers. Act on both β_1 and β_2 receptors. β_2 blockade causes side-effects such as bronchospasm and peripheral vasoconstriction. *Propranolol* is non-selective and is subject to extensive first-pass metabolism in the liver. The effective oral dose is therefore unpredictable and must be titrated after treatment is started with a small dose. Other non-selective drugs include *nadolol* and *carvedilol*.

'Cardioselective' β -blockers. Act mainly on myocardial β_1 receptors and are relatively well tolerated. *Atenolol*, *bisoprolol* and *metoprolol* are all cardioselective β -blockers.

Sotalol. A racemic mixture of two isomers with non-selective β -blocker (mainly l-sotalol) and class III (mainly d-sotalol) activity. It may cause torsades de pointes.

Class III drugs

Class III drugs act by prolonging the plateau phase of the action potential, thus lengthening the refractory period. These drugs are very effective at preventing atrial and ventricular tachyarrhythmias. They cause QT interval prolongation and can predispose to torsades de pointes and VT (p. 566), especially in patients with other predisposing risk factors (see Box 18.35, p. 568).

Amiodarone. The principal drug in this class, although both disopyramide and sotalol have class III activity. Amiodarone is a complex drug that also has class I, II and IV activity. It is probably the most effective drug currently available for controlling paroxysmal AF. It is also used to prevent episodes of recurrent VT, particularly in patients with poor left ventricular function or those with implantable defibrillators (to prevent unnecessary DC shocks). Amiodarone has a very long tissue half-life (25–110 days). An intravenous or oral loading regime is often used to achieve therapeutic tissue concentrations rapidly. The drug's effects may last for weeks or months after treatment has been stopped. Side-effects are common (up to one-third of patients), numerous and potentially serious. Drug interactions are also common (see Box 18.40).

Dronedarone. A related drug that has a short tissue half-life and fewer side effects. It has recently been shown to be effective at preventing episodes of atrial flutter and fibrillation.

Class IV drugs

These block the 'slow calcium channel' which is important for impulse generation and conduction in atrial and nodal tissue, although it is also present in ventricular muscle. Their main indications are prevention of SVT (by blocking the AV node) and rate control in patients with AF.

Verapamil. The most widely used drug in this class. Intravenous verapamil may cause profound bradycardia or hypotension, and should not be used in conjunction with β -blockers.

Diltiazem. Has similar properties.

18.40 The main uses, dosages and side-effects of the most widely used anti-arrhythmic drugs

Drug	Main uses	Route	Dose (adult)	Important side-effects
Class I				
Disopyramide	Prevention and treatment of atrial and ventricular tachyarrhythmias	I.v.	2 mg/kg at 30 mg/min, then 0.4 mg/kg/hr (max 800 mg/day)	Myocardial depression, hypotension, dry mouth, urinary retention
		Oral	300–800 mg daily in divided dosage	
Lidocaine	Treatment and short-term prevention of VT and VF	I.v.	Bolus 50–100 mg, 4 mg/min for 30 mins, then 2 mg/min for 2 hrs, then 1 mg/min for 24 hrs	Myocardial depression, confusion, convulsions
Mexiletine	Prevention and treatment of ventricular tachyarrhythmias	I.v.	Loading dose: 100–250 mg at 25 mg/min, then 250 mg in 1 hr, then 250 mg in 2 hrs	Myocardial depression, GI irritation, confusion, dizziness, tremor, nystagmus, ataxia
		Oral	Maintenance therapy: 0.5 mg/min	
Flecainide	Prevention and treatment of atrial and ventricular tachyarrhythmias	I.v.	2 mg/kg over 10 mins, then 1.5 mg/kg/hr for 1 hr, then 0.1 mg/kg/hr	Myocardial depression, dizziness
		Oral	50–100 mg 12-hourly	
Propafenone	Prevention and treatment of atrial and ventricular tachyarrhythmias	Oral	150 mg 8-hourly for 1 wk, then 300 mg 12-hourly	Myocardial depression, dizziness
Class II				
Atenolol	Treatment and prevention of SVT and AF Prevention of VEs and exercise-induced VT	I.v.	2.5 mg at 1 mg/min repeated at 5-min intervals (max 10 mg)	Myocardial depression, bradycardia, bronchospasm, fatigue, depression, nightmares, cold peripheries
Bisoprolol		Oral	25–100 mg daily	
		Oral	2.5–10 mg daily	
Metoprolol		I.v.	5 mg over 2 mins to a maximum of 15 mg	
		Oral	50–100 mg 8- or 12-hourly	Sotalol can cause torsades de pointes
Sotalol		I.v.	10–20 mg slowly	
		Oral	40–160 mg 12-hourly	
Class III				
Amiodarone	Serious or resistant atrial and ventricular tachyarrhythmias	I.v.	5 mg/kg over 20–120 mins, then up to 15 mg/kg/24 hrs	Photosensitivity, skin discoloration, corneal deposits, thyroid dysfunction, alveolitis, nausea and vomiting, hepatotoxicity, peripheral neuropathy, torsades de pointes; potentiates digoxin and warfarin
		Oral	Initially 600–1200 mg/day, then 100–400 mg daily	
Class IV				
Verapamil	Treatment of SVT, control of AF	I.v.	5–10 mg over 30 secs	Myocardial depression, hypotension, bradycardia, constipation
		Oral	40–120 mg 8-hourly or 240 mg SR daily	
Other				
Atropine	Treatment of bradycardia and/or hypotension due to vagal overactivity	I.v.	0.6–3 mg	Dry mouth, thirst, blurred vision, atrial and ventricular extrasystoles
Adenosine	Treatment of SVT, aid to diagnosis in unidentified tachycardia	I.v.	3 mg over 2 secs, followed if necessary by 6 mg, then 12 mg at intervals of 1–2 mins	Flushing, dyspnoea, chest pain Avoid in asthma
Digoxin	Treatment and prevention of SVT, rate control of AF	I.v.	Loading dose: 0.5–1 mg (total), 0.5 mg over 30 mins, then 0.25–0.5 mg 4- to 8-hourly to maximum total of 1 mg, assessing response before each additional dose	GI disturbance, xanthopsia, arrhythmias (see Box 18.43)
		Oral	0.5 mg 6-hourly for 2 doses, then 0.125–0.25 mg daily	
(AF = atrial fibrillation; SR = sustained-release formulation; SVT = supraventricular tachycardia; VE = ventricular ectopic; VF = ventricular fibrillation; VT = ventricular tachycardia)				

(AF = atrial fibrillation; SR = sustained-release formulation; SVT = supraventricular tachycardia; VE = ventricular ectopic; VF = ventricular fibrillation; VT = ventricular tachycardia)

18.41 Anti-arrhythmic drugs: principles of use

Anti-arrhythmic drugs are potentially toxic and should be used carefully according to the following principles:

- Many arrhythmias are benign and do not require specific treatment
- Precipitating or causal factors should be corrected if possible, e.g. excess alcohol or caffeine consumption, myocardial ischaemia, hyperthyroidism, acidosis, hypokalaemia and hypomagnesaemia
- If drug therapy is required, it is best to use as few drugs as possible
- In difficult cases, programmed electrical stimulation (electrophysiological study) may help to identify the optimum therapy
- When managing life-threatening arrhythmias, it is essential to ensure that prophylactic treatment is effective. Ambulatory monitoring and exercise testing may be of value
- Patients on long-term anti-arrhythmic drugs should be reviewed regularly and attempts made to withdraw therapy if the factors which precipitated the arrhythmias are no longer operative
- For patients with recurrent SVT, radiofrequency ablation is often preferable to long-term drug therapy

Other anti-arrhythmic drugs

Atropine sulphate (0.6 mg i.v., repeated if necessary to a maximum of 3 mg). Increases the sinus rate and SA and AV conduction, and is the treatment of choice for severe bradycardia or hypotension due to vagal over-activity. It is used for initial management of symptomatic bradyarrhythmias complicating inferior MI, and in cardiac arrest due to asystole. Repeat dosing may be necessary because the drug disappears rapidly from the circulation after parenteral administration. Side-effects are listed in Box 18.40.

Adenosine. Must be given intravenously. It produces transient AV block lasting a few seconds. Accordingly, it may be used to terminate SVTs when the AV node is part of the re-entry circuit, or to help establish the diagnosis in difficult arrhythmias such as atrial flutter with 2:1 AV block (see Fig. 18.40, p. 561) or broad-complex tachycardia (Boxes 18.40 and 18.42). Adenosine is given as an intravenous bolus, initially 3 mg over 2 seconds (see Box 18.40). If there is no response after 1–2 minutes, 6 mg should be given; if necessary, after another 1–2 minutes, the maximum dose of 12 mg may be given. Patients should be warned that they may experience short-lived and sometimes distressing flushing, breathlessness and chest pain. Adenosine can cause bronchospasm and should be avoided in asthmatics; its effects are greatly potentiated by dipyridamole and inhibited by theophylline and other xanthines.

Digoxin. A purified glycoside from the European foxglove, *Digitalis lanata*, which slows conduction and

18.42 Response to intravenous adenosine

Arrhythmia	Response
Supraventricular tachycardia	Termination
Atrial fibrillation, atrial flutter	Transient AV block
Ventricular tachycardia	No effect

18.43 Digoxin toxicity

Extracardiac manifestations

- Anorexia, nausea, vomiting
- Diarrhoea
- Altered colour vision (xanthopsia)

Cardiac manifestations

- Bradycardia
- Multiple ventricular ectopics
- Ventricular bigeminy (alternate ventricular ectopics)
- Atrial tachycardia (with variable block)
- VT
- VF

prolongs the refractory period in the AV node. This effect helps to control the ventricular rate in AF and may interrupt SVTs involving the AV node. On the other hand, digoxin tends to shorten refractory periods and enhance excitability and conduction in other parts of the heart (including accessory conduction pathways). It may therefore increase atrial and ventricular ectopic activity and can lead to more complex atrial and ventricular tachyarrhythmias. Digoxin is largely excreted by the kidneys, and the maintenance dose (see Box 18.40) should be reduced in children, older people and those with renal impairment. It is widely distributed and has a long tissue half-life (36 hours), so that effects may persist for several days after the last dose. Measurements of plasma digoxin concentration are useful in demonstrating whether the dose is inadequate or excessive (Box 18.43).

Therapeutic procedures

External defibrillation and cardioversion

The heart can be completely depolarised by passing a sufficiently large electrical current through it from an external source. This will interrupt any arrhythmia and produce a brief period of asystole that is usually followed by the resumption of sinus rhythm. Defibrillators deliver a DC, high-energy, short-duration shock via two metal paddles coated with conducting jelly or a gel pad, positioned over the upper right sternal edge and the apex. Modern units deliver a biphasic shock, during which the shock polarity is reversed mid-shock. This reduces the total shock energy required to depolarise the heart.

Electrical cardioversion

This is the termination of an organised rhythm such as AF or VT with a synchronised shock, usually under general anaesthesia. The shock is delivered immediately after detection of the R wave, because if it is applied during ventricular repolarisation (on the T wave) it may provoke VF. High-energy shocks may cause chest wall pain post-procedure, so if there is no urgency it is appropriate to begin with a lower-amplitude shock (e.g. 50 joules), going on to larger shocks if necessary. Patients with atrial fibrillation or flutter of > 48 hours' duration are at risk of systemic embolism after cardio-

version, so it should be ensured that the patient is adequately anticoagulated for at least 4 weeks before and after the procedure.

Defibrillation

This is the delivery of an unsynchronised shock during a cardiac arrest caused by VF. The precise timing of the discharge is not important in this situation. In VF and other emergencies, the energy of the first and second shocks should be 150 joules and thereafter up to 200 joules; there is no need for an anaesthetic as the patient is unconscious.

Catheter ablation

Catheter ablation therapy has become the treatment of choice for many patients with recurrent arrhythmias (see Fig. 18.15, p. 536). A series of catheter electrodes are inserted into the heart via the venous system and are used to record the activation sequence of the heart in sinus rhythm, during tachycardia and after pacing manoeuvres. Once the arrhythmia focus or circuit is identified, a steerable catheter is placed into this critical zone (e.g. over an accessory pathway in WPW syndrome) and the culprit tissue is selectively ablated using heat (via radiofrequency current) or sometimes by freezing (cryoablation). The procedure takes approximately 1–3 hours and does not require a general anaesthetic. The patient may experience some discomfort during the ablation itself. Serious complications are rare (<1%) but include inadvertent complete heart block requiring pacemaker implantation, and cardiac tamponade. For many arrhythmias, radiofrequency ablation is very attractive because it offers the prospect of a lifetime cure, thereby eliminating the need for long-term drug therapy.

The technique has revolutionised the management of many arrhythmias and is now the treatment of choice for AVNRT and AV re-entrant (accessory pathway) tachycardias, when it is curative in >90% of cases. Focal atrial tachycardias and atrial flutter can also be eliminated by radiofrequency ablation, although some patients subsequently experience episodes of AF. The applications of the technique are expanding and it can now be used to treat some forms of VT. Recently, catheter ablation techniques have been developed to prevent AF. This involves ablation at two sites: the ostia of the pulmonary veins, from which ectopic beats may trigger paroxysms of arrhythmia, and in the LA itself, where re-entry circuits maintain AF once established. This is effective at reducing episodes of AF in around 70–80% of younger patients with structurally normal hearts, and tends to be reserved for patients with drug-resistant AF.

Exceptionally troublesome AF and other refractory atrial tachyarrhythmias can be treated by using radiofrequency ablation to induce complete heart block deliberately; a permanent pacemaker must be implanted as well to achieve proper rate control.

Temporary pacemakers

Temporary pacing involves delivery of an electrical impulse into the heart to initiate tissue depolarisation and to trigger cardiac contraction. This is usually done by inserting a bipolar pacing electrode via the internal jugular, subclavian or femoral vein and positioning it at the apex of the RV, using fluoroscopic imaging. The electrode is connected to an external pacemaker with an adjustable energy output and pacing rate. The threshold is the lowest output that will reliably pace the heart and should be <1 volt (for pulse width 0.5 ms) at implantation. The generator should be set to deliver an output that is at least twice this figure, and adjusted daily because the threshold tends to rise over time. The ECG of right ventricular pacing is characterised by regular broad QRS complexes with a left bundle branch block pattern. Each complex is immediately preceded by a 'pacing spike' (Fig. 18.59). Nearly all pulse generators are used in the 'demand' mode so that the pacemaker will only operate if the heart rate falls below a preset level. Occasionally temporary atrial or dual-chamber pacing (see below) is used.

Temporary pacing may be indicated in the management of transient AV block and other arrhythmias complicating acute MI or cardiac surgery, to maintain the rhythm in other situations of reversible bradycardia (i.e. due to metabolic disturbance or drug overdose), or as a bridge to permanent pacing. Complications include pneumothorax, brachial plexus or subclavian artery injury, local infection or septicaemia (usually *Staphylococcus aureus*), and pericarditis. Failure of the system may be due to lead displacement or a progressive increase in the threshold (exit block) caused by tissue oedema. Complication rates increase with time and so a temporary pacing system should not be used for more than 7 days.

Transcutaneous pacing is administered by delivering an electrical stimulus through two large adhesive gel pad electrodes placed over the apex and upper right sternal edge, or over the anterior and posterior chest. It is easy and quick to set up, but causes discomfort because it induces forceful pectoral and intercostal muscle contraction. Modern external cardiac defibrillators often incorporate a transcutaneous pacing system that can be used during an emergency until transvenous pacing is established.

Fig. 18.59 Dual-chamber pacing. The first three beats show atrial and ventricular pacing with narrow pacing spikes in front of each P wave and QRS complex. The last four beats show spontaneous P waves with a different morphology and no pacing spike; the pacemaker senses or tracks these P waves and maintains AV synchrony by pacing the ventricle after an appropriate interval.

Permanent pacemakers

Permanent pacemakers are small, flat, metal devices that are implanted under the skin, usually in the pectoral area. They contain a battery, a pulse generator, and programmable electronics that allow adjustment of pacing and memory functions. Pacing electrodes (leads) can be placed via the subclavian or cephalic veins into the RV (usually at the apex), the right atrial appendage or, for AV sequential (dual chamber) pacing, both (see Fig. 18.15, p. 536).

Permanent pacemakers are programmed using an external programmer via a wireless telemetry system. Pacing rate, output, timing and other parameters can be adjusted. This allows the device to be set to the optimum settings to suit the patient's needs. For example, programming can be used to increase output in the face of an unexpected increase in threshold, or to increase the lower rate of the pacemaker in a patient with cardiac failure. Pacemakers store useful diagnostic data about the patient's heart rate trends and the occurrence of tachyarrhythmias, such as VT.

Atrial pacing is appropriate for patients with sinoatrial disease without AV block (the pacemaker acts as an external sinus node). Ventricular pacing is suitable for patients with continuous AF and bradycardia. In dual-chamber pacing, the atrial electrode can be used to detect spontaneous atrial activity and trigger ventricular pacing (see Fig. 18.59), thereby preserving AV synchrony and allowing the ventricular rate to increase together with the sinus node rate during exercise and other forms of stress. Dual-chamber pacing has many advantages over ventricular pacing; these include superior haemodynamics leading to a better effort tolerance, a lower prevalence of atrial arrhythmias in patients with sinoatrial disease, and avoidance of 'pacemaker syndrome' (a fall in BP and dizziness precipitated by loss of AV synchrony).

A code is used to signify the pacing mode (Box 18.44). For example, a system that paces the atrium, senses the atrium and is inhibited if it senses spontaneous activity is designated AAI. Most dual-chamber pacemakers are programmed to a mode termed DDD; here, ventricular pacing is triggered by a sensed sinus P wave and inhibited by a sensed spontaneous QRS complex. A fourth letter, 'R', is added if the pacemaker has a rate response function (e.g. AAIR = atrial demand pacemaker with rate response function). Rate-responsive pacemakers are used in patients who are unable to mount an increase in heart rate during exercise. These devices have a sensor that triggers a rise in heart rate in response to movement or increased respiratory rate. The sensitivity of the sensor is programmable, as is the maximum paced heart rate.

18.44 International generic pacemaker code		
Chamber paced	Chamber sensed	Response to sensing
O = none	O = none	O = none
A = atrium	A = atrium	T = triggered
V = ventricle	V = ventricle	I = inhibited
D = both	D = both	D = both

Early complications of permanent pacing include pneumothorax, cardiac tamponade, infection and lead displacement. Late complications include infection (which usually necessitates removing the pacing system), erosion of the generator or lead, chronic pain related to the implant site, and lead fracture due to mechanical fatigue.

Implantable cardiac defibrillators (ICDs)

These devices have all the functions of a permanent pacemaker but can also detect and terminate life-threatening ventricular tachyarrhythmias. ICDs are larger than pacemakers mainly because of the need for a large battery and capacitor to enable cardioversion or defibrillation. ICD leads are similar to pacing leads but have one or two shock coils along the length of the lead, used for delivering defibrillation. ICDs treat ventricular tachyarrhythmias using overdrive pacing, cardioversion or defibrillation. ICD implant procedures have similar complications to pacemaker implants. In addition, patients can be prone to psychological problems and anxiety, particularly if they have experienced repeated shocks from their device.

The evidence-based indications for ICD implantation are shown in Box 18.45. These can be divided into 'secondary prevention' indications, when patients have already had a potentially life-threatening ventricular arrhythmia, and 'primary prevention' indications, when patients are considered to be at significant future risk of arrhythmic death. ICDs may be used prophylactically in selected patients with inherited conditions associated with high risk of sudden cardiac death, such as long QT syndrome (p. 567), hypertrophic cardiomyopathy and arrhythmogenic right ventricular dysplasia (pp. 635–637). ICD treatment is expensive so the indications for which the devices are routinely implanted depend on the health-care resources available.

18.45 Key indications for ICD therapy	
Primary prevention	
<ul style="list-style-type: none"> After MI, if LV ejection fraction < 30% Mild to moderate symptomatic heart failure on optimal drug therapy, with LV ejection fraction < 35% 	
Secondary prevention	
<ul style="list-style-type: none"> Survivors of VF or VT cardiac arrest not due to transient or reversible cause VT with haemodynamic compromise or significant LV impairment (LV ejection fraction < 35%) 	

Cardiac resynchronisation therapy (CRT)

This is a treatment for selected patients with heart failure who are in sinus rhythm and have left bundle branch block. This conduction defect is associated with left ventricular dys-synchrony (poorly coordinated left ventricular contraction) and can aggravate heart failure in susceptible patients. CRT systems have an additional lead that is placed via the coronary sinus into one of the veins

EBM 18.46 Cardiac resynchronisation therapy (CRT) for heart failure

'CRT improves symptoms and quality of life, and reduces mortality in patients with moderate to severe symptomatic heart failure who are in sinus rhythm, with left bundle branch block and LV ejection fraction $\leq 35\%$.'

- Cardiac Resynchronisation-Heart Failure (CARE-HF) Study. Cleland J, et al. *N Engl J Med* 2005; 352:1539–1549.
- COMPANION Study. Bristow MR, et al. *N Engl J Med* 2004; 350:2140–2150.

on the epicardial surface of the LV (see Fig. 18.28, p. 550). Simultaneous septal and left ventricular epicardial pacing resynchronises left ventricular contraction. These devices can improve effort tolerance and reduce heart failure symptoms (Box 18.46). Most CRT devices are also defibrillators (CRT-D) because many patients with heart failure are predisposed to ventricular arrhythmias. CRT-pacemakers (CRT-P) are used in patients considered to be at relatively low risk of these arrhythmias.

ATHEROSCLEROSIS

Atherosclerosis can affect any artery in the body. When it occurs in the heart, it may cause angina, MI and sudden death; in the brain, stroke and transient ischaemic attack; and in the limbs, claudication and critical limb ischaemia. Occult coronary artery disease is common in those who present with other forms of atherosclerotic vascular disease, such as intermittent claudication or stroke, and is an important cause of morbidity and mortality in these patients.

Pathophysiology

Atherosclerosis is a progressive inflammatory disorder of the arterial wall that is characterised by focal lipid-rich deposits of atheroma that remain clinically silent until they become large enough to impair tissue perfusion, or until ulceration and disruption of the lesion result in thrombotic occlusion or distal embolisation of the vessel. These mechanisms are common to the entire vascular tree, and the clinical manifestations of atherosclerosis depend upon the site of the lesion and the vulnerability of the organ supplied.

Atherosclerosis begins early in life. Abnormalities of arterial function have been detected among high-risk children and adolescents, such as cigarette smokers and those with familial hyperlipidaemia or hypertension. Early atherosclerotic lesions have been found in the arteries of victims of accidental death in the second and third decades of life. Nevertheless, clinical manifestations often do not appear until the sixth, seventh or eighth decade.

Early atherosclerosis

Fatty streaks tend to occur at sites of altered arterial shear stress, such as bifurcations, and are associated with abnormal endothelial function. They develop when inflammatory cells, predominantly monocytes, bind to receptors expressed by endothelial cells, migrate into the intima, take up oxidised low-density lipoprotein (LDL) particles and become lipid-laden macrophages or foam cells. Extracellular lipid pools appear in the intimal space when these foam cells die and release their contents (Fig. 18.60).

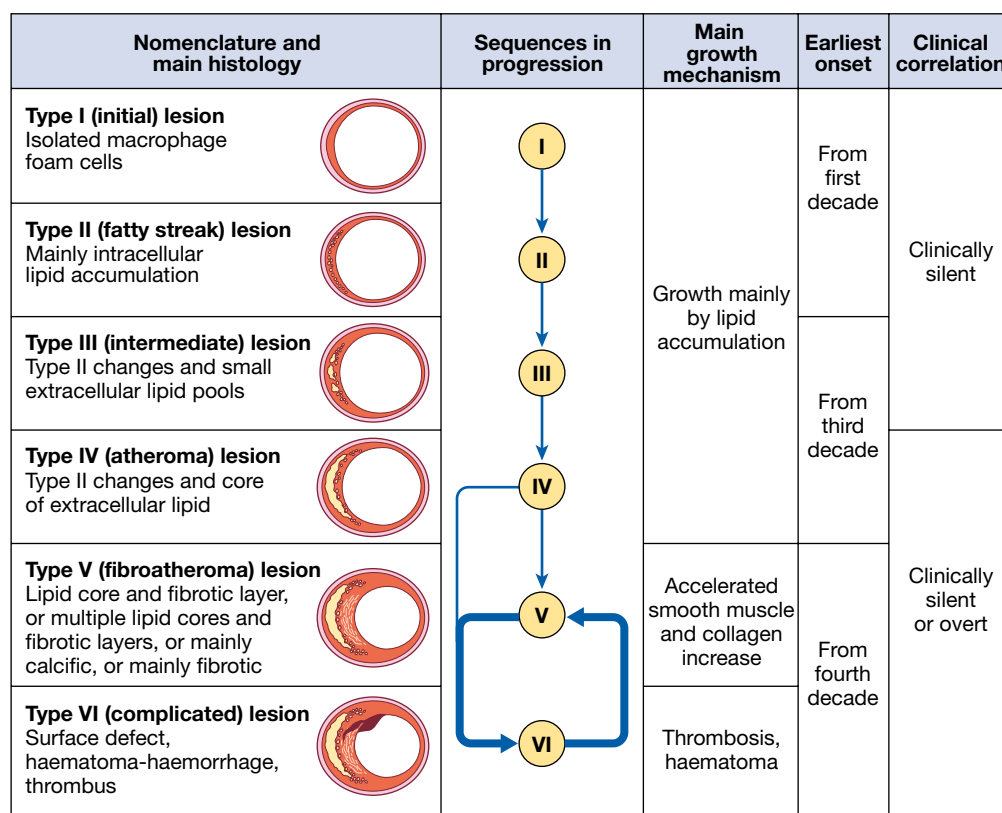

Fig. 18.60 The six stages of atherosclerosis. American Heart Association classification.

In response to cytokines and growth factors produced by the activated macrophages, smooth muscle cells migrate from the media of the arterial wall into the intima, and change from a contractile to a repair phenotype in an attempt to stabilise the atherosclerotic lesion. If they are successful, the lipid core will be covered by smooth muscle cells and matrix, producing a stable atherosclerotic plaque that will remain asymptomatic until it becomes large enough to obstruct arterial flow.

Advanced atherosclerosis

In an established atherosclerotic plaque, macrophages mediate inflammation and smooth muscle cells promote repair. If inflammation predominates, the plaque becomes active or unstable and may be complicated by ulceration and thrombosis. Cytokines, such as interleukin-1, tumour necrosis factor- α , interferon- γ , platelet-derived growth factors, and matrix metalloproteinases are released by activated macrophages; they cause the intimal smooth muscle cells overlying the plaque to become senescent and collagen cross-struts within the plaque to degrade. This results in thinning of the protective fibrous cap, making the lesion vulnerable to mechanical stress that ultimately causes erosion, fissuring or rupture of the plaque surface (see Fig. 18.60). Any breach in the integrity of the plaque will expose its contents to blood, and trigger platelet aggregation and thrombosis that extend into the atheromatous plaque and the arterial lumen. This type of plaque event may cause partial or complete obstruction at the site of the lesion or distal embolisation resulting in infarction or ischaemia of the affected organ. This common mechanism underlies many of the acute manifestations of atherosclerotic vascular disease, such as acute lower limb ischaemia, MI and stroke.

The number and complexity of arterial plaques increase with age and with risk factors (see below) but the rate of progression of individual plaques is variable. There is a complex and dynamic interaction between mechanical wall stress and atherosclerotic lesions. 'Vulnerable' plaques are characterised by a lipid-rich core, a thin fibrocellular cap and an increase in inflammatory cells that release specific enzymes to degrade matrix proteins. In contrast, stable plaques are typified by a small lipid pool, a thick fibrous cap, calcification and plentiful collagenous cross-struts. Fissuring or rupture tends to occur at sites of maximal mechanical stress, particularly the margins of an eccentric plaque, and may be triggered by a surge in BP, such as during exercise or emotional stress. Surprisingly, plaque events are often subclinical and heal spontaneously, although this may allow thrombus to be incorporated into the lesion, producing plaque growth and further obstruction to flow in the arterial lumen.

Atherosclerosis may induce complex changes in the media that lead to arterial remodelling. Some arterial segments may slowly constrict (negative remodelling) whilst others may gradually enlarge (positive remodelling). These changes are important because they may amplify or minimise the degree to which atheroma encroaches into the arterial lumen.

Risk factors

The role and relative importance of many risk factors for the development of coronary, peripheral and cerebrovascular disease have been defined in experimental animal

studies, epidemiological studies and clinical interventional trials. Key factors have emerged but do not explain all the risk, and unknown factors may account for up to 40% of the variation in risk from one person to the next.

The impact of genetic risk is illustrated by twin studies; a monozygotic twin of an affected individual has an eightfold increased risk, and a dizygotic twin a fourfold increased risk of dying from coronary heart disease compared to the general population.

The effect of risk factors is multiplicative rather than additive. People with a combination of risk factors are at greatest risk and so assessment should take account of all identifiable risk factors. It is important to distinguish between relative risk (the proportional increase in risk) and absolute risk (the actual chance of an event). Thus, a man of 35 years with a plasma cholesterol of 7 mmol/L (approximately 170 mg/dL) who smokes 40 cigarettes a day is relatively much more likely to die from coronary disease within the next decade than a non-smoking woman of the same age with a normal cholesterol, but the absolute likelihood of his dying during this time is still small (high relative risk, low absolute risk).

- *Age and sex.* Age is the most powerful independent risk factor for atherosclerosis. Premenopausal women have lower rates of disease than men, although this sex difference disappears after the menopause. However, hormone replacement therapy has no role in the primary or secondary prevention of coronary heart disease, and isolated oestrogen therapy may cause an increased cardiovascular event rate.
- *Family history.* Atherosclerotic vascular disease often runs in families, due to a combination of shared genetic, environmental and lifestyle factors. The most common inherited risk characteristics (hypertension, hyperlipidaemia, diabetes mellitus) are polygenic. A 'positive' family history is present when clinical problems in first-degree relatives occur at relatively young age, such as < 50 years for men and < 55 years for women.
- *Smoking.* This is probably the most important avoidable cause of atherosclerotic vascular disease. There is a strong consistent and dose-linked relationship between cigarette smoking and ischaemic heart disease, especially in younger (< 70 years) individuals.
- *Hypertension* (see below). The incidence of atherosclerosis increases as BP rises, and this excess risk is related to both systolic and diastolic BP as well as pulse pressure. Antihypertensive therapy reduces cardiovascular mortality, stroke and heart failure.
- *Hypercholesterolaemia* (pp. 451–454). Risk rises with increasing serum cholesterol concentrations. Lowering serum total and LDL cholesterol concentrations reduces the risk of cardiovascular events, including death, MI, stroke and coronary revascularisation.
- *Diabetes mellitus.* This is a potent risk factor for all forms of atherosclerosis and is often associated with diffuse disease that is difficult to treat. Insulin resistance (normal glucose homeostasis with high levels of insulin) is associated with obesity and physical inactivity, and is a risk factor for coronary heart disease (p. 802). Glucose intolerance accounts

for a major part of the high incidence of ischaemic heart disease in certain ethnic groups, e.g. South Asians.

- *Haemostatic factors.* Platelet activation and high levels of fibrinogen are associated with an increased risk of coronary thrombosis. Antiphospholipid antibodies are associated with recurrent arterial thromboses (p. 1050).
- *Physical activity.* Physical inactivity roughly doubles the risk of coronary heart disease and is a major risk factor for stroke. Regular exercise (brisk walking, cycling or swimming for 20 minutes two or three times a week) has a protective effect which may be related to increased serum HDL cholesterol concentrations, lower BP, and collateral vessel development.
- *Obesity* (p. 116). Obesity, particularly if central or truncal, is an independent risk factor, although it is often associated with other adverse factors such as hypertension, diabetes mellitus and physical inactivity.
- *Alcohol.* Alcohol consumption is associated with reduced rates of coronary artery disease. Excess alcohol consumption is associated with hypertension and cerebrovascular disease.
- *Other dietary factors.* Diets deficient in fresh fruit, vegetables and polyunsaturated fatty acids are associated with an increased risk of cardiovascular disease. The introduction of a Mediterranean-style diet reduces cardiovascular events. However, dietary supplements, such as vitamin C and E, beta-carotene, folate and fish oils, do not reduce cardiovascular events and, in some cases, have been associated with harm.
- *Personality.* Certain personality traits are associated with an increased risk of coronary disease. Nevertheless, there is little or no evidence to support the popular belief that stress is a major cause of coronary artery disease.
- *Social deprivation.* Health inequalities have a major influence on cardiovascular disease. The impact of established risk factors is amplified in patients who are socially deprived and current guidelines recommend that treatment thresholds should be lowered for them.

Primary prevention

Two complementary strategies can be used to prevent atherosclerosis in apparently healthy but at-risk individuals: population and targeted strategies.

The population strategy aims to modify the risk factors of the whole population through diet and lifestyle advice, on the basis that even a small reduction in smoking or average cholesterol, or modification of exercise and diet will produce worthwhile benefits (Box 18.47). Some risk factors for atheroma, such as obesity and smoking, are also associated with a high risk of other diseases and should be actively discouraged through public health measures. Legislation restricting smoking in public places is associated with reductions in rates of MI.

The targeted strategy aims to identify and treat high-risk individuals who usually have a combination of risk factors and can be identified by using composite scoring systems (Fig. 18.61). It is important to consider the

18.47 Population advice to prevent coronary disease

- Do not smoke
- Take regular exercise (minimum of 20 mins, three times a week)
- Maintain 'ideal' body weight
- Eat a mixed diet rich in fresh fruit and vegetables
- Aim to get no more than 10% of energy intake from saturated fat

absolute risk of atheromatous cardiovascular disease that an individual is facing before contemplating specific antihypertensive or lipid-lowering therapy because this will help to determine whether the possible benefits of intervention are likely to outweigh the expense, inconvenience and possible side-effects of treatment. For example, a 65-year-old man with an average BP of 150/90 mmHg, who smokes and has diabetes mellitus, a total:HDL cholesterol ratio of 8 and left ventricular hypertrophy on ECG, will have a 10-year risk of CHD of 68% and a 10-year risk of any cardiovascular event of 90%. Lowering his cholesterol will reduce these risks by 30% and lowering his BP will produce a further 20% reduction; both would obviously be worthwhile. Conversely, a 55-year-old woman who has an identical BP, is a non-smoker, does not have diabetes mellitus and has a normal ECG and a total:HDL cholesterol ratio of 6 has a much better outlook, with a predicted CHD risk of 14% and cardiovascular risk of 19% over the next 10 years. Although lowering her cholesterol and BP would also reduce risk by 30% and 20% respectively, the value of either or both treatments would clearly be borderline.

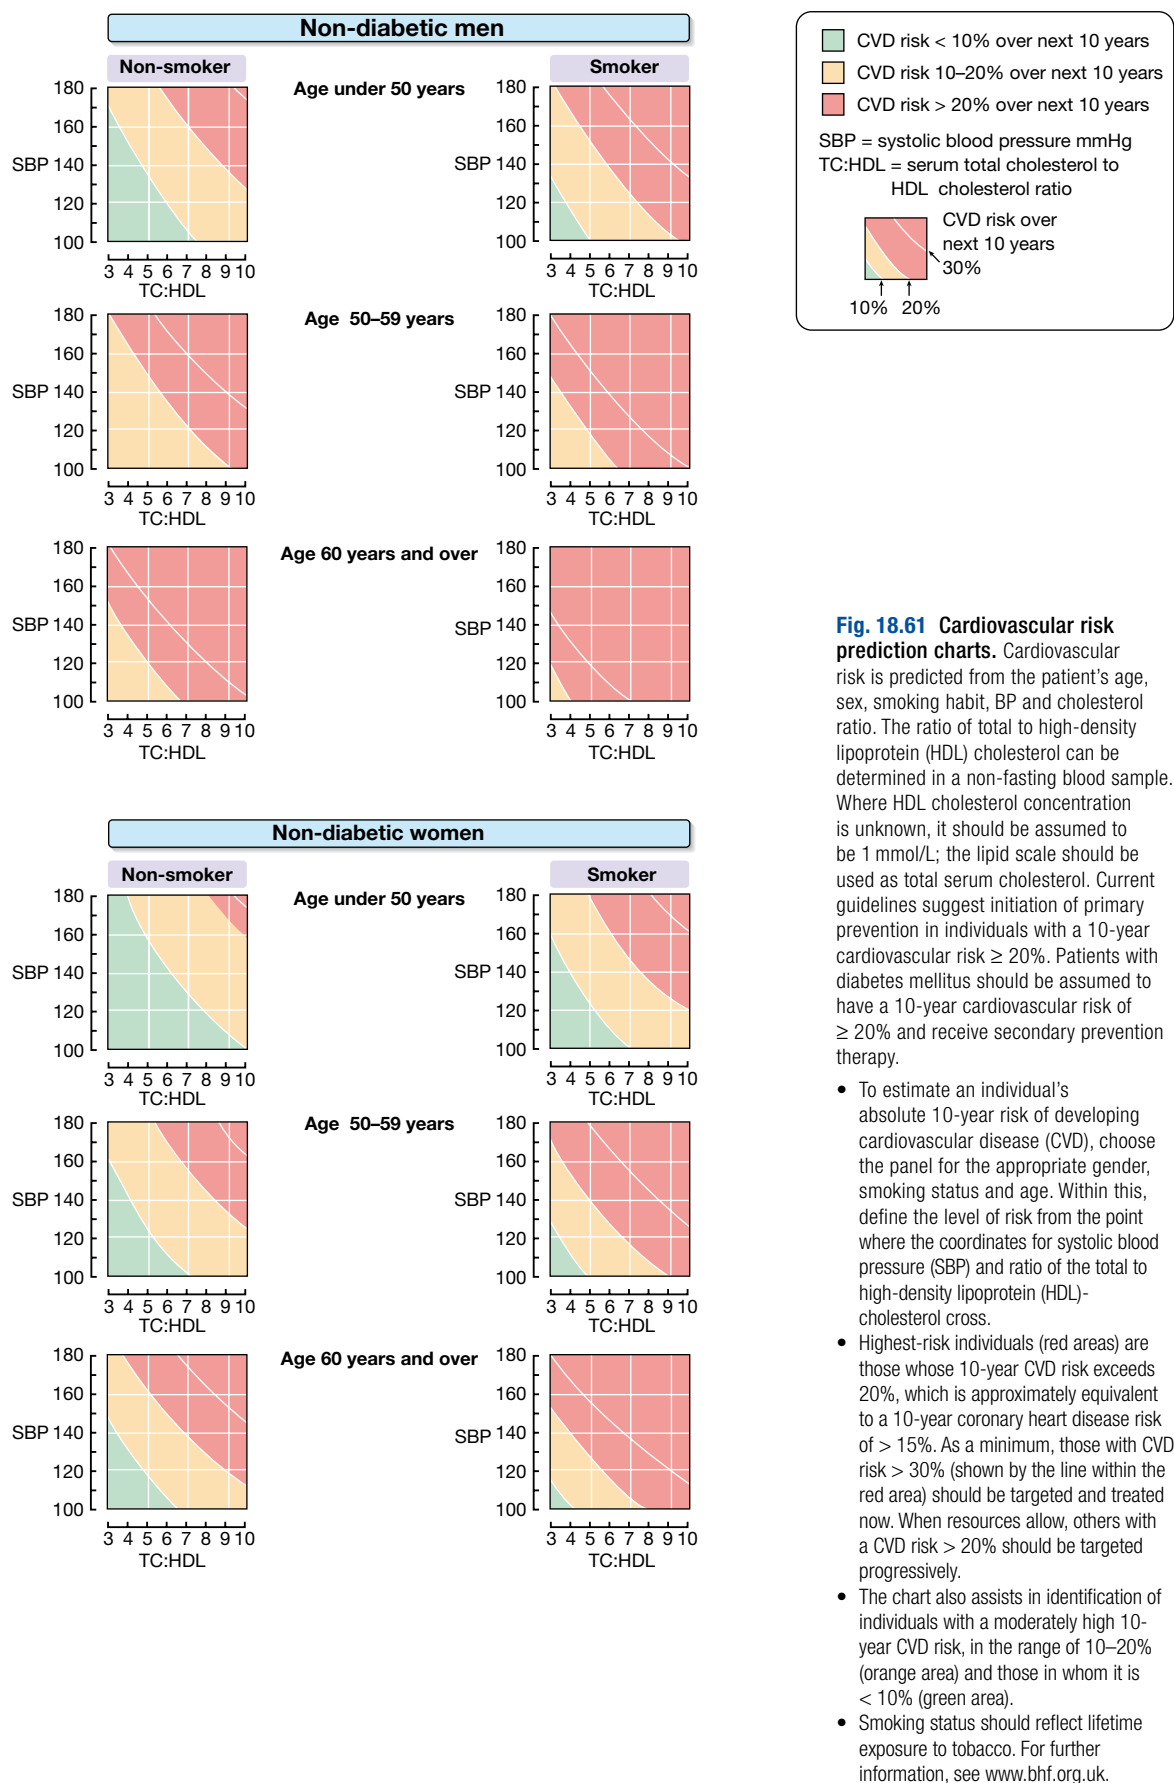

Secondary prevention

Patients who already have evidence of atheromatous vascular disease are at high risk of future cardiovascular events and should be offered treatments and measures to improve their outlook. The energetic correction of modifiable risk factors, particularly smoking, hypertension and hypercholesterolaemia, is particularly important because the absolute risk of further vascular events is high. All patients with coronary heart disease should be given statin therapy irrespective of their serum cholesterol concentration (Box 18.48). BP should be treated to a target of $\leq 140/85$ mmHg (p. 609). Aspirin and ACE inhibitors are of benefit in patients with evidence of vascular disease (Boxes 18.49 and 18.50). Beta-blockers benefit patients with a history of MI (see below) or heart failure.

Many clinical events offer an unrivalled opportunity to introduce effective secondary preventive measures; patients who have just survived an MI or undergone bypass surgery are usually keen to help themselves and may be particularly receptive to lifestyle advice, such as dietary modification and smoking cessation.

CORONARY HEART DISEASE

Coronary heart disease (CHD) is the most common form of heart disease and the single most important cause of premature death in Europe, the Baltic states, Russia, North and South America, Australia and New Zealand.

EBM 18.48 Use of statins in prevention of atherosclerotic disease**Primary prevention**

'In patients *without evidence of coronary disease* but with high serum cholesterol concentrations, cholesterol-lowering with statins does not lower mortality but does prevent coronary events (angina and MI).'

Secondary prevention

'In patients *with established coronary disease* (MI or angina), statin therapy can safely reduce the 5-year incidence of all-cause death as well as major coronary events, coronary revascularisation and stroke. Benefit depends on the overall risk of the study population but the NNT₅ for 5 years to prevent one death ranges from 10 to 90.'

- Cholesterol Treatment Trialists' Collaborators. Lancet 2005; 366:1267–1277.

For further information:  www.sign.ac.uk

EBM 18.49 ACE inhibitors and secondary prevention of atherosclerotic disease

'ACE inhibitor therapy reduces the risk of death, MI and stroke in patients with atherosclerotic vascular disease without apparent left ventricular systolic dysfunction or heart failure. NNT₅ to avoid one event over 4 years ranges from 6 to 50, depending upon the level of cardiovascular risk.'

- HOPE trial. N Engl J Med 2000; 342:145–153.
- EUROPA trial. Lancet 2003; 362:782–788.

EBM 18.50 Aspirin and secondary prevention in atherosclerotic vascular disease

'In patients with established coronary heart disease, peripheral vascular disease or thrombotic stroke, aspirin is effective in reducing morbidity and mortality (non-fatal MI, stroke and cardiovascular death). In patients at high risk of future vascular events, the overall risk reduction is 22%.'

- Antithrombotic Trialist Collaboration. BMJ 2002; 324:71–86.

For further information:  www.clinicalevidence.org

By 2020 it is estimated that it will be the major cause of death in all regions of the world.

In the UK, 1 in 3 men and 1 in 4 women die from CHD, an estimated 330 000 people have a myocardial infarct each year, and approximately 1.3 million people have angina. The death rates from CHD in the UK are amongst the highest in Western Europe (more than 140 000 people) but are falling, particularly in younger age groups; in the last 10 years CHD mortality has fallen by 42% among UK men and women aged 16–64. However, in Eastern Europe and much of Asia, the rates of CHD are rapidly rising.

Disease of the coronary arteries is almost always due to atheroma and its complications, particularly thrombosis (Box 18.51). Occasionally, the coronary arteries are involved in other disorders such as aortitis, polyarteritis and other connective tissue disorders.

18.51 Coronary heart disease: clinical manifestations and pathology

Clinical problem	Pathology
Stable angina	Ischaemia due to fixed atheromatous stenosis of one or more coronary arteries
Unstable angina	Ischaemia caused by dynamic obstruction of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
Myocardial infarction	Myocardial necrosis caused by acute occlusion of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
Heart failure	Myocardial dysfunction due to infarction or ischaemia
Arrhythmia	Altered conduction due to ischaemia or infarction
Sudden death	Ventricular arrhythmia, asystole or massive MI

Stable angina

Angina pectoris is the symptom complex caused by transient myocardial ischaemia and constitutes a clinical syndrome rather than a disease. It may occur whenever there is an imbalance between myocardial oxygen supply and demand (Box 18.52). Coronary atheroma is by far the most common cause of angina, although the symptom may be a manifestation of other forms of heart disease, particularly aortic valve disease and hypertrophic cardiomyopathy.

Clinical features

The history is by far the most important factor in making the diagnosis (pp. 535–539). Stable angina is characterised by central chest pain, discomfort or breathlessness that is precipitated by exertion or other forms of stress (Box 18.53), and is promptly relieved by rest (see Figs 18.17 and 18.18, pp. 537–538). Some patients find that

18.52 Factors influencing myocardial oxygen supply and demand**Oxygen demand: cardiac work**

- Heart rate
- BP
- Myocardial contractility
- Left ventricular hypertrophy
- Valve disease, e.g. aortic stenosis

Oxygen supply: coronary blood flow

- Duration of diastole
- Coronary perfusion pressure (aortic diastolic minus coronary sinus or right atrial diastolic pressure)
- Coronary vasomotor tone
- Oxygenation
 - Haemoglobin
 - Oxygen saturation

N.B. Coronary blood flow occurs mainly in diastole.

18.53 Activities precipitating angina	
Common	
• Physical exertion	• Heavy meals
• Cold exposure	• Intense emotion
Uncommon	
• Lying flat (decubitus angina)	• Vivid dreams (nocturnal angina)

the discomfort comes when they start walking, and that later it does not return despite greater effort ('warm-up angina').

Physical examination is frequently unremarkable but should include a careful search for evidence of valve disease (particularly aortic), important risk factors (e.g. hypertension, diabetes mellitus), left ventricular dysfunction (cardiomegaly, gallop rhythm), other manifestations of arterial disease (carotid bruits, peripheral vascular disease) and unrelated conditions that may exacerbate angina (anaemia, thyrotoxicosis).

Investigations

Resting ECG

The ECG may show evidence of previous MI but is often normal, even in patients with severe coronary artery disease. Occasionally, there is T-wave flattening or inversion in some leads, providing non-specific evidence of myocardial ischaemia or damage. The most convincing ECG evidence of myocardial ischaemia is the demonstration of reversible ST segment depression or elevation, with or without T-wave inversion, at the time the patient is experiencing symptoms (whether spontaneous or induced by exercise testing).

Exercise ECG

An exercise tolerance test (ETT) is usually performed using a standard treadmill or bicycle ergometer protocol (p. 530) while monitoring the patient's ECG, BP and general condition. Planar or down-sloping ST segment depression of ≥ 1 mm is indicative of ischaemia (Fig. 18.62). Up-sloping ST depression is less specific and often occurs in normal individuals.

Exercise testing is also a useful means of assessing the severity of coronary disease and identifying high-risk individuals (Box 18.54). For example, the amount of exercise that can be tolerated and the extent and degree of any ST segment change (Fig. 18.63) provide a useful guide to the likely extent of coronary disease. Exercise testing is not infallible and may produce false positive results in the presence of digoxin therapy, left ventric-

Fig. 18.62 Forms of exercise-induced ST depression. **A** Planar ST depression is usually indicative of myocardial ischaemia. **B** Down-sloping depression also usually indicates myocardial ischaemia. **C** Up-sloping depression may be a normal finding.

18.54 Risk stratification in stable angina	
High risk	Low risk
Post-infarct angina	Predictable exertional angina
Poor effort tolerance	Good effort tolerance
Ischaemia at low workload	Ischaemia only at high workload
Left main or three-vessel disease	Single-vessel or two-vessel disease
Poor LV function	Good LV function
N.B. Patients may fall between these categories.	

ular hypertrophy, bundle branch block or WPW syndrome. The predictive accuracy of exercise testing is lower in women than men. The test should be classed as inconclusive (rather than negative) if the patient cannot achieve an adequate level of exercise because of locomotor or other non-cardiac problems.

Other forms of stress testing

- **Myocardial perfusion scanning.** This may be helpful in the evaluation of patients with an equivocal or uninterpretable exercise test and those who are unable to exercise (p. 535). It entails obtaining scintiscans of the myocardium at rest and during stress (either exercise testing or pharmacological stress, such as a controlled infusion of dobutamine) after the administration of an intravenous radioactive isotope, such as 99m technetium tetrofosmin. Thallium and tetrofosmin are taken up by viable perfused myocardium. A perfusion defect present during stress but not at rest provides evidence of reversible myocardial ischaemia (Fig. 18.64), whereas a persistent perfusion defect seen during both phases of the study is usually indicative of previous MI.
- **Stress echocardiography.** This is an alternative to myocardial perfusion scanning and can achieve similar predictive accuracy. It uses transthoracic echocardiography to identify ischaemic segments of myocardium and areas of infarction (p. 533). The former characteristically exhibit reversible defects in contractility during exercise or pharmacological stress, and the latter do not contract at rest or during stress.

Coronary arteriography

This provides detailed anatomical information about the extent and nature of coronary artery disease (see Fig. 18.14, p. 534), and is usually performed with a view to coronary artery bypass graft (CABG) surgery or percutaneous coronary intervention (PCI, pp. 585–586). In some patients, diagnostic coronary angiography may be indicated when non-invasive tests have failed to establish the cause of atypical chest pain. The procedure is performed under local anaesthesia and requires specialised radiological equipment, cardiac monitoring and an experienced operating team.

Management: general measures

The management of angina pectoris involves:

- a careful assessment of the likely extent and severity of arterial disease

Fig. 18.63 A positive exercise test. The resting 12-lead ECG shows some minor T-wave changes in the inferolateral leads but is otherwise normal. After 3 minutes' exercise on a treadmill there is marked planar ST depression in leads II, V₄ and V₅ (right offset). Subsequent coronary angiography revealed critical three-vessel coronary artery disease.

- the identification and control of risk factors such as smoking, hypertension and hyperlipidaemia
- the use of measures to control symptoms
- the identification of high-risk patients for treatment to improve life expectancy.

Symptoms alone are a poor guide to the extent of coronary artery disease. Stress testing is therefore advisable in all patients who are potential candidates for revascularisation. An algorithm for the investigation and treatment of patients with stable angina is shown in Figure 18.65.

Management should start with a careful explanation of the problem and a discussion of the potential lifestyle and medical interventions that may relieve symptoms and improve prognosis (Box 18.55). Anxiety and misconceptions often contribute to disability; for example, some patients avoid all forms of exertion because they believe that each attack of angina is a 'mini heart attack' that results in permanent damage. Effective management of these psychological factors can make a huge difference to the patient's quality of life.

i

18.55 Advice to patients with stable angina

- Do not smoke
- Aim for ideal body weight
- Take regular exercise (exercise up to, but not beyond, the point of chest discomfort is beneficial and may promote collateral vessels)
- Avoid severe unaccustomed exertion, and vigorous exercise after a heavy meal or in very cold weather
- Take sublingual nitrate before undertaking exertion that may induce angina

Antiplatelet therapy

Low-dose (75 mg) aspirin reduces the risk of adverse events such as MI and should be prescribed for all patients with coronary artery disease indefinitely (see Box 18.50). Clopidogrel (75 mg daily) is an equally effective antiplatelet agent that can be prescribed if aspirin causes troublesome dyspepsia or other side-effects.

Anti-anginal drug treatment

Five groups of drug are used to help relieve or prevent the symptoms of angina: nitrates, β -blockers, calcium antagonists, potassium channel activators and an I_f channel antagonist.

Nitrates

These drugs act directly on vascular smooth muscle to produce venous and arteriolar dilatation. Their beneficial effects are due to a reduction in myocardial oxygen demand (lower preload and afterload) and an increase in myocardial oxygen supply (coronary vasodilatation). Sublingual glyceryl trinitrate (GTN) administered from a metered-dose aerosol (400 μ g per spray) or as a tablet (300 or 500 μ g) will relieve an attack of angina in 2–3 minutes. Side-effects include headache, symptomatic hypotension and, rarely, syncope.

Patients should be encouraged to use the drug prophylactically before taking exercise that is liable to provoke symptoms. Sublingual GTN has a short duration of action (Box 18.56); however, a variety of alternative nitrate preparations can provide a more prolonged therapeutic effect. GTN can be given transcutaneously as a patch (5–10 mg daily), or as a slow-release buccal tablet (1–5 mg 6-hourly). GTN undergoes extensive first-pass metabolism in the liver and is ineffective when swallowed. Other nitrates such as isosorbide

Fig. 18.64 A myocardial perfusion scan showing reversible anterior myocardial ischaemia. The images are cross-sectional tomograms of the LV. The resting scans (left) show even uptake of the ^{99m}Tc -labelled tetrafosmin and look like doughnuts. During stress (e.g. a dobutamine infusion), there is reduced uptake of technetium, particularly along the anterior wall (arrows), and the scans look like crescents (right).

dinitrate (10–20 mg 8-hourly) and isosorbide mononitrate (20–60 mg once or twice a day) can be given by mouth. Headache is common but tends to diminish if the patient perseveres with the treatment. Continuous nitrate therapy can cause pharmacological tolerance. This can be avoided by a 6–8-hour nitrate-free period, best achieved at night when the patient is inactive. If nocturnal angina is a predominant symptom, long-acting nitrates can be given at the end of the day.

Beta-blockers

These lower myocardial oxygen demand by reducing heart rate, BP and myocardial contractility, but they may provoke bronchospasm in patients with asthma. The properties and side-effects of β -blockers are discussed on page 597.

In theory, non-selective β -blockers may aggravate coronary vasospasm by blocking the coronary artery β_2 -adrenoceptors and so a once-daily cardioselective preparation is used (e.g. slow-release metoprolol 50–200 mg daily, bisoprolol 5–15 mg daily). Beta-blockers should not be withdrawn abruptly because this may have a rebound effect and precipitate dangerous arrhythmias, worsening angina or MI: the β -blocker withdrawal syndrome.

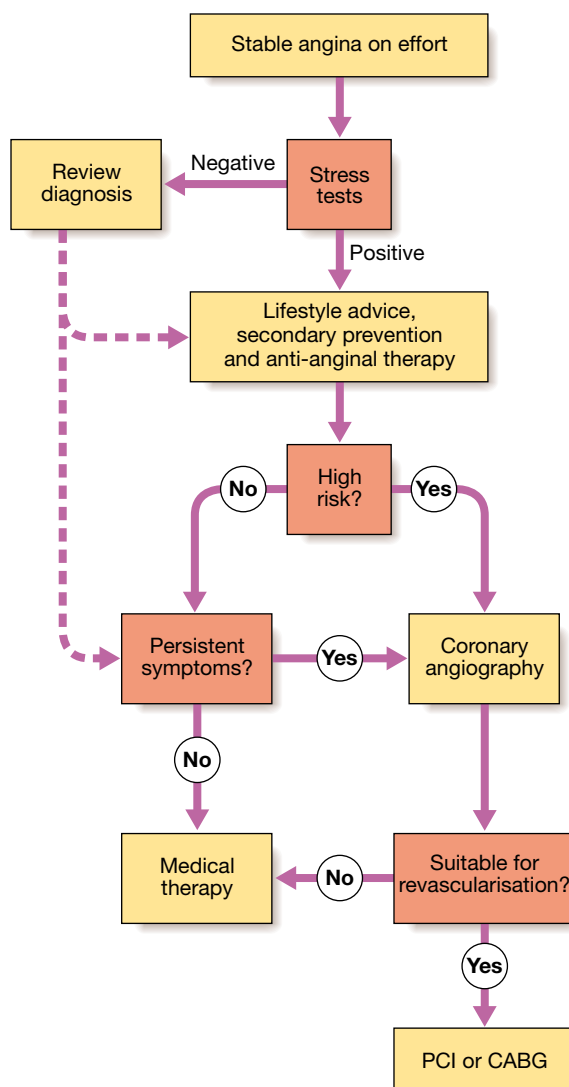

Fig. 18.65 A scheme for the investigation and treatment of stable angina on effort. The selection of percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG) depends upon patient choice, coronary artery anatomy and extent of coronary artery disease. In general, left main stem and three-vessel coronary artery disease should be treated by CABG surgery.

18.56 Duration of action of some nitrate preparations		
Preparation	Peak action	Duration of action
Sublingual GTN	4–8 mins	10–30 mins
Buccal GTN	4–10 mins	30–300 mins
Transdermal GTN	1–3 hrs	Up to 24 hrs
Oral isosorbide dinitrate	45–120 mins	2–6 hrs
Oral isosorbide mononitrate	45–120 mins	6–10 hrs

(GTN = glyceryl trinitrate)

Calcium channel antagonists

These drugs inhibit the slow inward current caused by the entry of extracellular calcium through the cell membrane of excitable cells, particularly cardiac and arteriolar smooth muscle, and lower myocardial oxygen demand by reducing BP and myocardial contractility.

Dihydropyridine calcium antagonists, such as nifedipine and nicardipine, often cause a reflex tachycardia. This may be counterproductive and it is best to use them in combination with a β -blocker. In contrast, verapamil and diltiazem are particularly suitable for patients who are not receiving a β -blocker (e.g. those with airways obstruction) because they slow SA node firing, inhibit conduction through the AV node and tend to cause a bradycardia. Calcium channel antagonists reduce myocardial contractility and can aggravate or precipitate heart failure. Other unwanted effects include peripheral oedema, flushing, headache and dizziness (Box 18.57).

Potassium channel activators

These have arterial and venous dilating properties but do not exhibit the tolerance seen with nitrates. Nicorandil (10–30 mg 12-hourly orally) is the only drug in this class currently available for clinical use.

I_f channel antagonist

Ivabradine is the first of this class of drug. It induces bradycardia by modulating ion channels in the sinus node. In contrast to β -blockers and rate-limiting calcium antagonists, it does not have other cardiovascular effects. It appears to be safe to use in patients with heart failure.

Although each of these anti-anginal drugs is superior to placebo in relieving the symptoms of angina, there is little evidence that one group is more effective than another. It is conventional to start therapy with low-dose aspirin, a statin, sublingual GTN and a β -blocker, and

18.57 Calcium channel antagonists used for the treatment of angina		
Drug	Dose	Feature
Nifedipine	5–20 mg 8-hourly*	May cause marked tachycardia
Nicardipine	20–40 mg 8-hourly	May cause less myocardial depression than the other calcium antagonists
Amlodipine	2.5–10 mg daily	Ultra long-acting
Verapamil	40–80 mg 8-hourly*	Commonly causes constipation; useful anti-arrhythmic properties (p. 572)
Diltiazem	60–120 mg 8-hourly*	Similar anti-arrhythmic properties to verapamil

*Once- or twice-daily slow-release preparations are available.

then add a calcium channel antagonist or a long-acting nitrate later if needed. The goal is the control of angina with minimum side-effects and the simplest possible drug regimen. There is little evidence that prescribing multiple anti-anginal drugs is of benefit, and revascularisation should be considered if an appropriate combination of two or more drugs fails to achieve an acceptable symptomatic response.

Invasive treatment

Percutaneous coronary intervention (PCI)

This is performed by passing a fine guidewire across a coronary stenosis under radiographic control and using it to position a balloon which is then inflated to dilate the stenosis (see Figs 18.15 (p. 536) and 18.66). A coronary stent is a piece of coated metallic 'scaffolding' that

Fig. 18.66 Percutaneous coronary intervention. A sequence of images from a 58-year-old woman with stable angina. **A** Severe stenosis of the circumflex artery (arrow). **B** A balloon has been advanced into the stenosis, over a guidewire, and has been inflated. (Note the waisting caused by the lesion). **C** Residual stenosis and dissection (tramline shadow—arrow) after balloon dilatation. **D** A stent is deployed on a balloon. **E** The stent is visible on plain fluoroscopy (arrow). **F** Angiogram after stenting.

EBM 18.58 Angioplasty and intracoronary stents in angina

'In comparison with simple balloon angioplasty, intracoronary stents afford superior acute and long-term clinical and angiographic results with lower rates of restenosis (e.g. 17% vs 40%) and recurrent angina (13% vs 30%). Restenosis rates are reduced even further (< 10%) with drug-eluting stents'

• Stettler C, et al. *BMJ* 2008; 337:a1331.

For further information:  www.nice.org.uk

can be deployed on a balloon and used to maximise and maintain dilatation of a stenosed vessel. The routine use of stents in appropriate vessels reduces both acute complications and the incidence of clinically important restenosis (Box 18.58).

PCI provides an effective symptomatic treatment but definitive evidence that it improves survival in patients with chronic stable angina is lacking. It is mainly used in single or two-vessel disease. Stenoses in bypass grafts can be dilated, as well as those in the native coronary arteries. The technique is often used to provide palliative therapy for patients with recurrent angina after CABG. Coronary surgery is usually the preferred option in patients with three-vessel or left main stem disease, although recent trials have demonstrated that PCI is also feasible in such patients.

The main acute complications of PCI are occlusion of the target vessel or a side branch by thrombus or a loose flap of intima (coronary artery dissection), and consequent myocardial damage. This occurs in about 2–5% of procedures and can often be corrected by deploying a stent; however, emergency CABG is sometimes required. Minor myocardial damage, as indicated by elevation of sensitive intracellular markers (troponins, p. 531), occurs in up to 10% of cases. The main long-term complication of PCI is restenosis (Box 18.59), which occurs in up to one-third of cases. This is due to a combination of elastic recoil and smooth muscle proliferation (neo-intimal hyperplasia) and tends to occur within 3 months. Stenting substantially reduces the risk of restenosis, probably because it allows the operator to achieve more complete dilatation in the first place. Drug-eluting stents can reduce this risk even further by allowing an antiproliferative drug such as sirolimus or paclitaxel to elute slowly from the coating and prevent neo-intimal hyperplasia and in-stent restenosis. There is an increased risk of late stent thrombosis with drug-eluting stents, although the absolute risk is small (< 0.5%). Recurrent angina (affecting up to 15–20% of patients receiving an intracoronary stent at 6 months) may require further PCI or bypass grafting.

EBM 18.59 Percutaneous coronary intervention vs medical therapy in stable angina

'PCI is more effective than medical therapy in alleviating angina pectoris and improving exercise tolerance but does not reduce mortality. It carries risks of procedure-related MI, emergency CABG and repeat procedures for restenosis.'

• Weintraub WS, et al. *N Engl J Med* 2008; 359(7):677–687.

For further information:  www.sign.ac.uk

The risk of complications and the likely success of the procedure are closely related to the morphology of the stenoses, the experience of the operator and the presence of important comorbidity, e.g. diabetes, peripheral arterial disease. A good outcome is less likely if the target lesion is complex, long, eccentric or calcified, lies on a bend or within a tortuous vessel, involves a branch or contains acute thrombus.

In combination with aspirin and heparin, adjunctive therapy with potent platelet inhibitors, such as clopidogrel or glycoprotein IIb/IIIa receptor antagonists, improves the outcome of PCI, with lower short- and long-term rates of death and MI.

Coronary artery bypass grafting (CABG)

The internal mammary arteries, radial arteries or reversed segments of the patient's own saphenous vein can be used to bypass coronary artery stenoses (Fig. 18.67). This usually involves major surgery under cardiopulmonary bypass, but in some cases, grafts can be applied to the beating heart: 'off-pump' surgery. The operative mortality is approximately 1.5% but risks are higher in elderly patients, those with poor left ventricular function and those with significant comorbidity, such as renal failure.

Approximately 90% of patients are free of angina 1 year after CABG surgery, but fewer than 60% of patients are asymptomatic after 5 or more years. Early post-operative angina is usually due to graft failure arising from technical problems during the operation, or poor 'run-off' due to disease in the distal native coronary vessels. Late recurrence of angina may be due to progressive disease in the native coronary arteries or graft degeneration. Less than 50% of vein grafts are patent 10 years after surgery. However, arterial grafts have a much better long-term patency rate, with more than 80% of internal mammary artery grafts patent at 10 years. This has led many surgeons to consider total arterial revascularisation during CABG surgery. Aspirin (75–150 mg daily) and clopidogrel (75 mg daily) have both been shown to improve graft patency, and one or other should be prescribed indefinitely if well tolerated. Intensive lipid-lowering therapy slows the progression of disease in the native coronary arteries and bypass grafts, and reduces clinical cardiovascular events. There is substantial excess cardiovascular morbidity and mortality in patients who continue to smoke after bypass grafting. Persistent smokers are twice as likely to die in the 10 years following surgery than those who give up at surgery.

CABG improves survival in symptomatic patients with left main stem stenosis or three-vessel coronary disease (i.e. involving LAD, CX and right coronary arteries, Box 18.60) or two-vessel disease involving the proximal LAD coronary artery. Improvement in survival is most marked in those with impaired left ventricular function or positive stress testing prior to surgery and those who have undergone left internal mammary artery grafting.

Neurological complications are common, with a 1–5% risk of perioperative stroke. Between 30% and 80% of patients develop short-term cognitive impairment that is often mild and typically resolves within 6 months. There are also reports of long-term cognitive decline that may be evident in more than 30% of patients at 5 years. PCI and CABG are compared in Boxes 18.61 and 18.62.

Fig. 18.67 Coronary artery bypass graft surgery. **A** Narrowed or stenosed arteries are bypassed using saphenous vein grafts connected to the aorta, or by utilising the internal mammary artery. **B** Three-dimensional reconstruction of multidetector CT of the heart. The image shows the patent saphenous vein grafts (SVG) to the right coronary artery (RCA), obtuse marginal branch (OM) and diagonal branch (LADD), and left internal mammary artery graft (LIMA) to the left anterior descending (LAD) coronary artery.

EBM 18.60 Coronary artery bypass grafting for stable angina

'CABG is superior to medical treatment for at least 10 years after surgery in terms of survival. Greatest benefit occurs in those with a significant stenosis in the left main coronary artery or those with three-vessel disease and impaired ventricular function.'

- Yusuf S, et al. *Lancet* 1994; 344:563–570.

18.61 Comparison of PCI and CABG

	PCI	CABG
Death	< 0.5%	< 1.5%
Myocardial infarction*	2%	10%
Hospital stay	12–36 hrs	5–8 days
Return to work	2–5 days	6–12 wks
Recurrent angina	15–20% at 6 mths	10% at 1 yr
Repeat revascularisation	10–20% at 2 yrs	2% at 2 yrs
Neurological complications	Rare	Common (see text)
Other complications	Emergency CABG Vascular damage related to access site	Diffuse myocardial damage Infection (chest, wound) Wound pain

*Defined as CK-MB > 2 × normal, pp. 589–591.

Prognosis

Symptoms are a poor guide to prognosis; nevertheless, the 5-year mortality of patients with severe angina (NYHA class III or IV, p. 535) is nearly double that of patients with mild symptoms. Exercise testing and other forms of stress testing are much more powerful predictors of mortality; for example, in one study, the 4-year mortality of patients with stable angina and a negative exercise test was 1%, compared to more than 20% in those with a strongly positive test.

In general, the prognosis of coronary artery disease is related to the number of diseased vessels and the degree of left ventricular dysfunction. A patient with single-vessel disease and good left ventricular function has an excellent outlook (5-year survival > 90%), whereas a patient with severe left ventricular dysfunction and extensive three-vessel disease has a poor prognosis (5-year survival < 30%) without revascularisation. Spontaneous symptomatic improvement due to the development of collateral vessels is common.

Angina with normal coronary arteries

Approximately 10% of patients who report stable angina on effort will have angiographically normal coronary

arteries. Many of these patients are women and the mechanism of their symptoms is often difficult to establish. It is important to review the original diagnosis and explore other potential causes.

Coronary artery spasm

Vasospasm in coronary arteries may coexist with atheroma, especially in unstable angina (see below); in < 1% of cases, vasospasm may occur without angiographically detectable atheroma. This form of angina is sometimes known as variant angina, and may be accompanied by spontaneous and transient ST elevation on the ECG (Prinzmetal's angina). Calcium channel antagonists, nitrates and other coronary vasodilators are the most useful therapeutic agents but may be ineffective.

Syndrome X

The constellation of typical angina on effort, objective evidence of myocardial ischaemia on stress testing, and angiographically normal coronary arteries is sometimes known as syndrome X. This disorder is poorly understood but carries a good prognosis and may respond to treatment with anti-anginal therapy.

Acute coronary syndrome

Acute coronary syndrome is a term that encompasses both unstable angina and MI. Unstable angina is characterised by new-onset or rapidly worsening angina (crescendo angina), angina on minimal exertion or angina at rest in the absence of myocardial damage. In contrast, MI occurs when symptoms occur at rest and there is evidence of myocardial necrosis, as demonstrated by an elevation in cardiac troponin or creatine kinase-MB isoenzyme (Box 18.63).

An acute coronary syndrome may present as a new phenomenon or against a background of chronic stable angina. The culprit lesion is usually a complex ulcerated or fissured atheromatous plaque with adherent platelet-rich thrombus and local coronary artery spasm (see Fig. 18.60, p. 577). This is a dynamic process whereby the degree of obstruction may either increase, leading to complete vessel occlusion, or regress due to the effects of platelet disaggregation and endogenous fibrinolysis. In acute MI, occlusive thrombus is almost always

18.63 Universal definition of myocardial infarction*

The term 'myocardial infarction' should be used when there is evidence of myocardial necrosis in a clinical setting consistent with myocardial ischaemia, in which case any one of the following meets the diagnosis for MI:

- Detection of rise and/or fall of cardiac biomarkers (preferably troponin), with at least one value above the 99th percentile of the upper reference limit, together with at least one of the following:
 - Symptoms of ischaemia
 - ECG changes indicative of new ischaemia (new ST-T changes or new left bundle branch block)
 - Development of pathological Q waves
 - Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
- Sudden unexpected cardiac death, involving cardiac arrest, often with symptoms suggestive of myocardial ischaemia, and accompanied by presumably new ST elevation or new left bundle branch block, and/or evidence of fresh thrombus by coronary angiography and/or at autopsy, but death occurring before blood samples could be obtained or before the appearance of cardiac biomarkers in the blood
- Pathological findings of an acute MI

*Further definitions exist for MI during PCI and CABG.

Adapted from Thygesen K, et al. Eur Heart J 2007; 28:2525–2538.

present at the site of rupture or erosion of an atheromatous plaque. The thrombus may undergo spontaneous lysis over the course of the next few days, although by this time irreversible myocardial damage has occurred. Without treatment, the infarct-related artery remains permanently occluded in 20–30% of patients. The process of infarction progresses over several hours (Fig. 18.68) and most patients present when it is still possible to salvage myocardium and improve outcome.

Clinical features

Pain is the cardinal symptom of an acute coronary syndrome but breathlessness, vomiting, and collapse are common features (Box 18.64). The pain occurs in the same sites as angina but is usually more severe and lasts longer; it is often described as a tightness, heaviness or

Fig. 18.68 The time course of MI. The relative proportion of ischaemic, infarcting and infarcted tissue slowly changes over a period of 12 hours. In the early stages of MI a significant proportion of the myocardium in jeopardy is potentially salvageable.

18.64 Clinical features of acute coronary syndromes

Symptoms

- Prolonged cardiac pain: chest, throat, arms, epigastrium or back
- Anxiety and fear of impending death
- Nausea and vomiting
- Breathlessness
- Collapse/syncope

Physical signs

- Signs of sympathetic activation: pallor, sweating, tachycardia
- Signs of vagal activation: vomiting, bradycardia
- Signs of impaired myocardial function
 - Hypotension, oliguria, cold peripheries
 - Narrow pulse pressure
 - Raised JVP
 - Third heart sound
 - Quiet first heart sound
 - Diffuse apical impulse
 - Lung crepitations
- Signs of tissue damage: fever
- Signs of complications: e.g. mitral regurgitation, pericarditis

constriction in the chest. In acute MI, the pain can be excruciating, and the patient's expression and pallor may vividly convey the seriousness of the situation.

Most patients are breathless and in some this is the only symptom. Indeed, MI may pass unrecognised. Painless or 'silent' MI is particularly common in older patients or those with diabetes mellitus. If syncope occurs, it is usually due to an arrhythmia or profound hypotension. Vomiting and sinus bradycardia are often due to vagal stimulation and are particularly common in patients with inferior MI. Nausea and vomiting may also be caused or aggravated by opiates given for pain relief. Sometimes infarction occurs in the absence of physical signs.

Sudden death, from VF or asystole, may occur immediately and often within the first hour. If the patient survives this most critical stage, the liability to dangerous arrhythmias remains, but diminishes as each hour goes by. It is vital that patients know not to delay calling for help if symptoms occur. The development of cardiac failure reflects the extent of myocardial ischaemia and is the major cause of death in those who survive the first few hours.

18

1. Find points for each predictive factor

Killip class	Points	SBP (mmHg)	Points	Heart rate (beats/min)	Points	Age (years)	Points	Serum creatinine level (μmol/L)	Points	Other risk factors	Points
I	0	≤ 80	58	≤ 50	0	≤ 30	0	0–34	1	Cardiac arrest at admission	39
II	29	80–99	53	50–69	3	30–39	8	35–70	4	ST-segment deviation	28
III	39	100–119	43	70–89	9	40–49	25	71–105	7	Elevated cardiac enzyme levels	14
IV	59	120–139	34	90–109	15	50–59	41	106–140	10		
		140–159	24	110–149	24	60–69	58	141–176	13		
		160–199	10	150–199	38	70–79	75	177–353	21		
		≥ 200	0	≥ 200	46	80–89	91	≥ 353	28		
						≥ 90	100				

2. Sum points for all predictive factors

Killip class	+	SBP	+	Heart rate	+	Age	+	Creatinine level	+	Cardiac arrest at admission	+	ST-segment deviation	+	Elevated cardiac enzyme levels	=	Total points
--------------	---	-----	---	------------	---	-----	---	------------------	---	-----------------------------	---	----------------------	---	--------------------------------	---	--------------

3. Look up risk corresponding to total points

Total points	≤ 60	70	80	90	100	110	120	130	140	150	160	170	180	190	200	210	220	230	240	≤ 250
Probability of in-hospital death (%)	≤ 0.2	0.3	0.4	0.6	0.8	1.1	1.6	2.1	2.9	3.9	5.4	7.3	9.8	13	18	23	29	36	44	≤ 52

Examples

A patient has Killip class II, SBP of 99 mmHg, heart rate of 100 beats/min, is 65 years of age, has serum creatinine level of 76 μmol/L, did not have a cardiac arrest at admission but did have ST-segment deviation and elevated enzyme levels. His score would be: 20 + 53 + 15 + 58 + 7 + 0 + 28 + 14 = 195. This gives about a 16% risk of having an in-hospital death.

Similarly, a patient with Killip class I, SPB of 80 mmHg, heart rate of 60 beats/min, is 55 years of age, has a serum creatinine level of 30 μmol/L, and no risk factors would have the following score: 0 + 58 + 3 + 41 + 1 = 103. This gives about a 0.9% risk of having an in-hospital death.

Fig 18.69 Risk stratification in the acute coronary syndrome: the GRACE score. Killip class refers to a categorisation of the severity of heart failure based on easily obtained clinical signs. The main clinical features are as follows: class I = no heart failure; class II = crackles audible halfway up the chest; class III = crackles heard in all the lung fields; class IV = cardiogenic shock. (SBP = systolic blood pressure)

Diagnosis and risk stratification

The differential diagnosis is wide and includes most causes of central chest pain or collapse (pp. 535 and 552). The assessment of acute chest pain depends heavily on an analysis of the character of the pain and its associated features, evaluation of the ECG, and serial measurements of biochemical markers of cardiac damage, such as troponin I and T. A 12-lead ECG is mandatory and defines the initial triage, management and treatment (see Fig. 18.19, p. 540). Patients with ST segment elevation or new bundle branch block require emergency reperfusion therapy (see below). In patients with acute coronary syndrome without ST segment elevation, the ECG may show transient or persistent ST/T wave changes including ST depression and T-wave inversion.

Approximately 12% of patients will die within 1 month and a fifth within 6 months of the index event. The risk markers that are indicative of an adverse prognosis include recurrent ischaemia, extensive ECG changes at rest or during pain, the release of biochemical markers (creatinine kinase or troponin), arrhythmias, recurrent ischaemia and haemodynamic complications (e.g. hypotension, mitral regurgitation) during episodes of ischaemia. Risk stratification is important because it guides the use of more complex pharmacological and interventional treatment (Figs 18.69 and 18.19 (p. 540)).

Investigations

Electrocardiography

The ECG is central to confirming the diagnosis but may be difficult to interpret if there is bundle branch block or previous MI. The initial ECG may be normal or non-diagnostic in one-third of cases. Repeated ECGs are important, especially where the diagnosis is uncertain or the patient has recurrent or persistent symptoms.

The earliest ECG change is usually ST-segment deviation. With proximal occlusion of a major coronary artery,

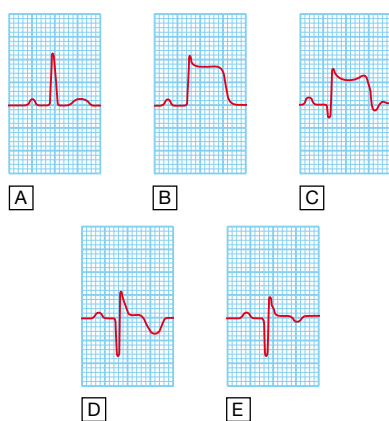

Fig. 18.70 The serial evolution of ECG changes in transmural MI.

A Normal ECG complex. **B** Acute ST elevation ('the current of injury'). **C** Progressive loss of the R wave, developing Q wave, resolution of the ST elevation and terminal T wave inversion. **D** Deep Q wave and T-wave inversion. **E** Old or established infarct pattern; the Q wave tends to persist but the T wave changes become less marked. The rate of evolution is very variable but, in general, stage B appears within minutes, stage C within hours, stage D within days and stage E after several weeks or months. This should be compared with the 12-lead ECGs in Figures 18.71–18.73.

Fig. 18.71 Recent anterior non-ST elevation (subendocardial) MI.

There is deep symmetrical T-wave inversion together with a reduction in the height of the R wave in leads V_1 , V_2 , V_3 and V_4 .

ST-segment elevation (or new bundle branch block) is seen initially with later diminution in the size of the R wave, and in transmural (full thickness) infarction, development of a Q wave. Subsequently, the T wave becomes inverted because of a change in ventricular repolarisation; this change persists after the ST segment has returned to normal. These sequential features (Fig. 18.70) are sufficiently reliable for the approximate age of the infarct to be deduced.

In non-ST segment elevation acute coronary syndrome, there is partial occlusion of a major vessel or complete occlusion of a minor vessel, causing unstable angina or partial-thickness (subendocardial) MI. This is usually associated with ST-segment depression and T-wave changes. In the presence of infarction, this may be accompanied by some loss of R waves in the absence of Q waves (Fig. 18.71).

The ECG changes are best seen in the leads that 'face' the ischaemic or infarcted area. When there has been anteroseptal infarction, abnormalities are found in one or more leads from V_1 to V_4 , while anterolateral infarction produces changes from V_4 to V_6 , in aVL and in lead I. Inferior infarction is best shown in leads II, III and aVF, while at the same time leads I, aVL and the anterior chest leads may show 'reciprocal' changes of ST depression (Figs 18.72–18.74). Infarction of the posterior wall of the LV does not cause ST elevation or Q waves in the standard leads, but can be diagnosed by the presence of reciprocal changes (ST depression and a tall R wave in leads V_1 – V_4). Some infarctions (especially inferior) also involve the RV. This may be identified by recording from additional leads placed over the right precordium.

Plasma cardiac markers

In unstable angina, there is no detectable rise in cardiac markers or enzymes, and the initial diagnosis is made

Fig. 18.72 Acute transmural anterior MI. This ECG was recorded from a patient who had developed severe chest pain 6 hours earlier. There is ST elevation in leads I, aVL, V₂, V₃, V₄, V₅ and V₆, and there are Q waves in leads V₂, V₃ and V₄. Anterior infarcts with prominent changes in leads V₂, V₃ and V₄ are sometimes called 'anteroseptal' infarcts, as opposed to 'anterolateral' infarcts in which the ECG changes are predominantly found in V₄, V₅ and V₆.

Fig. 18.73 Acute transmural inferolateral MI. This ECG was recorded from a patient who had developed severe chest pain 4 hours earlier. There is ST elevation in the inferior leads II, III and aVF and the lateral leads V₄, V₅ and V₆. There is also 'reciprocal' ST depression in leads aVL and V₂.

Fig. 18.74 Established anterior and inferior transmural MI. This ECG was recorded from a patient who had presented with an acute anterior infarct 2 days earlier and had been treated for an inferior myocardial infarction 11 months previously. There are Q waves in the inferior leads (II, III and aVF) and Q waves with some residual ST elevation in the anterior leads (I and V₂-V₄).

from the clinical history and ECG only. In contrast, MI causes a rise in the plasma concentration of enzymes and proteins that are normally concentrated within cardiac cells. These biochemical markers are creatine kinase (CK), a more sensitive and cardiospecific isoform of this enzyme (CK-MB), and the cardiospecific proteins, troponins T and I (p. 531). Admission and serial (usually daily) estimations are helpful because it is the change in plasma concentrations of these markers that confirms the diagnosis of MI (Fig. 18.75 and Box 18.63).

CK starts to rise at 4–6 hours, peaks at about 12 hours and falls to normal within 48–72 hours. CK is also present in skeletal muscle, and a modest rise in CK (but not CK-MB) may sometimes be due to an intramuscular injection, vigorous physical exercise or, particularly in older people, a fall. Defibrillation causes significant release of CK but not CK-MB or troponins. The most sensitive markers of myocardial cell damage are the cardiac troponins T and I, which are released within 4–6 hours and remain elevated for up to 2 weeks.

Other blood tests

A leucocytosis is usual, reaching a peak on the first day. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are also elevated.

Chest X-ray

This may demonstrate pulmonary oedema that is not evident on clinical examination (see Fig. 18.25, p. 547). The heart size is often normal but there may be cardiomegaly due to pre-existing myocardial damage.

Fig. 18.75 Changes in plasma cardiac marker concentrations after MI. Creatine kinase (CK) and troponin T (TnT) are the first to rise, followed by aspartate aminotransferase (AST) and then lactate (hydroxybutyrate) dehydrogenase (LDH). In patients treated with a thrombolytic agent, reperfusion is usually accompanied by a rapid rise in plasma creatine kinase (curve CK (R)) due to a washout effect; if there is no reperfusion, the rise is less rapid but the area under the curve is often greater (curve CK (N)).

Echocardiography

This is useful for assessing left and right ventricular function and for detecting important complications such as mural thrombus, cardiac rupture, ventricular septal defect, mitral regurgitation and pericardial effusion.

Immediate management: the first 12 hours

Patients should be admitted urgently to hospital because there is a significant risk of death or recurrent myocardial ischaemia during the early unstable phase, and appropriate medical therapy can reduce the incidence of these by at least 60%. The essentials of the immediate in-hospital management of acute coronary syndrome are shown in Figure 18.19 (p. 540).

Patients are usually managed in a dedicated cardiac unit where the necessary expertise, monitoring and resuscitation facilities can be concentrated. If there are no complications, the patient can be mobilised from the second day and discharged from hospital after 3–5 days.

Analgesia

Adequate analgesia is essential not only to relieve distress, but also to lower adrenergic drive and thereby reduce vascular resistance, BP, infarct size and susceptibility to ventricular arrhythmias. Intravenous opiates (initially morphine sulphate 5–10 mg or diamorphine 2.5–5 mg) and antiemetics (initially metoclopramide 10 mg) should be administered and titrated by giving repeated small aliquots until the patient is comfortable. Intramuscular injections should be avoided because the clinical effect may be delayed by poor skeletal muscle perfusion, and a painful haematoma may form following thrombolytic or anti-thrombotic therapy.

Antithrombotic therapy

Antiplatelet therapy

In patients with acute coronary syndrome, oral administration of 75–300 mg aspirin daily improves survival, with a 25% relative risk reduction in mortality. The first tablet (300 mg) should be given orally within the first 12 hours and therapy should be continued indefinitely if there are no side-effects. In combination with aspirin, the early (within 12 hours) use of clopidogrel 600 mg, followed by 150 mg daily for 1 week and 75 mg daily thereafter, confers a further reduction in ischaemic events (Box 18.65). In patients with an acute coronary syndrome with or without ST-segment elevation, ticagrelor (180 mg followed by 90 mg 12-hourly) is more effective than clopidogrel in reducing vascular death, MI or stroke, and all-cause death without affecting overall major bleeding risk.

Glycoprotein IIb/IIIa receptor antagonists, such as tirofiban and abciximab, block the final common pathway of platelet aggregation and are potent inhibitors of platelet-rich thrombus formation. They are of particular benefit in patients with acute coronary syndromes who undergo PCI (Box 18.66), those with recurrent ischaemia and those at particularly high risk, such as patients with diabetes mellitus or an elevated troponin concentration.

Anticoagulants

Anticoagulation reduces the risk of thromboembolic complications, and prevents reinfarction in the absence of reperfusion therapy or after successful thrombolysis (Box 18.67). Anticoagulation can be achieved using unfractionated heparin, fractionated (low molecular weight) heparin or a pentasaccharide. Comparative clinical trials suggest that the pentasaccharides (subcutaneous fondaparinux 2.5 mg daily) have the best safety and efficacy profile, with low molecular weight heparin (subcutaneous enoxaparin 1 mg/kg 12-hourly) being

EBM 18.65 Oral antiplatelet agents in acute coronary syndromes

'Aspirin alone (75–325 mg/day) reduces the risk of death, MI and stroke in acute coronary syndromes ($NNT_b = 20-25$). The addition of clopidogrel (75 mg daily) to aspirin causes a further modest reduction in these events ($NNT_b = 45-111$).'

a reasonable alternative. Anticoagulation should be continued for 8 days or until discharge from hospital or coronary revascularisation.

A period of treatment with warfarin should be considered if there is persistent atrial fibrillation or evidence of extensive anterior infarction, or if echocardiography shows mobile mural thrombus, because these patients are at increased risk of systemic thromboembolism.

Anti-anginal therapy

Sublingual glyceryl trinitrate (300–500 µg) is a valuable first-aid measure in unstable angina or threatened infarction, and intravenous nitrates (GTN 0.6–1.2 mg/hour or isosorbide dinitrate 1–2 mg/hour) are useful for the treatment of left ventricular failure and the relief of recurrent or persistent ischaemic pain.

Intravenous β -blockers (e.g. atenolol 5–10 mg or metoprolol 5–15 mg given over 5 mins) relieve pain, reduce arrhythmias and improve short-term mortality in patients who present within 12 hours of the onset of symptoms (see Fig. 18.19). However, they should be avoided if there is heart failure (pulmonary oedema), hypotension (systolic BP < 105 mmHg) or bradycardia (heart rate < 65/min).

**18.68 Angina in old age**

- **Incidence:** coronary artery disease increases and affects women almost as often as men.
- **Comorbid conditions:** anaemia and thyroid disease are common and may worsen angina.
- **Calcific aortic stenosis:** common and should be sought in all old people with angina.
- **Atypical presentations:** when myocardial ischaemia occurs, age-related changes in myocardial compliance and diastolic relaxation can cause the presentation to be with symptoms of heart failure such as breathlessness, rather than with chest discomfort.
- **Angioplasty and coronary artery bypass surgery:** provide symptomatic relief, although with an increased procedure-related morbidity and mortality. Outcome is determined by the number of diseased vessels, severity of cardiac dysfunction and the number of concomitant diseases, as much as age itself.

A dihydropyridine calcium channel antagonist (e.g. nifedipine or amlodipine) can be added to the β -blocker if there is persistent chest discomfort but may cause an unwanted tachycardia if used alone. Because of their rate-limiting action, verapamil and diltiazem are the calcium channel antagonists of choice if a β -blocker is contraindicated.

Reperfusion therapy*Non-ST segment elevation acute coronary syndrome*

Immediate emergency reperfusion therapy has no demonstrable benefit in patients with non-ST segment elevation MI and thrombolytic therapy may be harmful. Selected medium- to high-risk patients do benefit from in-hospital coronary angiography and coronary revascularisation but this does not need to take place in the first 12 hours.

ST segment elevation acute coronary syndrome

Immediate reperfusion therapy restores coronary artery patency, preserves left ventricular function and improves survival. Successful therapy is associated with pain relief, resolution of acute ST elevation and sometimes transient arrhythmias (e.g. idioventricular rhythm).

Primary percutaneous coronary intervention (PCI).

This is the treatment of choice for ST segment elevation MI (Figs 18.19 and 18.76). Outcomes are best when it is used in combination with glycoprotein IIb/IIIa receptor antagonists and intracoronary stent implantation. In comparison to thrombolytic therapy, it is associated with a greater reduction in the risk of death, recurrent MI or stroke (Box 18.69). The universal use of primary PCI has been limited by availability of the necessary resources to provide this highly specialised emergency service. Thus, intravenous thrombolytic therapy remains the first-line reperfusion treatment in many hospitals, especially those in rural or remote areas. When primary PCI cannot be achieved within 2 hours of diagnosis, thrombolytic therapy should be administered.

Thrombolysis. The appropriate use of thrombolytic therapy can reduce hospital mortality by 25–50% and this survival advantage is maintained for at least 10 years (Box 18.70). The benefit is greatest in those patients who receive treatment within the first few hours: 'minutes mean muscle'.

Alteplase (human tissue plasminogen activator or tPA) is a genetically engineered drug that is given over 90 minutes (bolus dose of 15 mg, followed by 0.75 mg/kg body weight, but not exceeding 50 mg, over 30 mins and then 0.5 mg/kg body weight, but not exceeding 35 mg, over 60 mins). Its use is associated with better survival rates than other thrombolytic agents, such as streptokinase, but carries a slightly higher risk of intracerebral

EBM 18.69 Primary PCI in acute ST segment elevation MI

'Primary PCI is more effective than thrombolysis for the treatment of acute MI. Death, non-fatal reinfarction and stroke are reduced from 14% with thrombolytic therapy to 8% with primary PCI (NNT_d = 33 for death and 9 for recurrent ischaemia).'

- Keeley EC, et al. *Lancet* 2003; 361:13–20.

Fig. 18.76 Primary PCI. **A** Acute right coronary artery occlusion. **B** Initial angioplasty demonstrates a large thrombus filling defect (arrows). **C** Complete restoration of normal flow following intracoronary stent insertion.

bleeding (10 per 1000 increased survival, but 1 per 1000 more non-fatal stroke).

Analogues of tPA, such as tenecteplase and reteplase, have a longer plasma half-life than alteplase and can be given as an intravenous bolus. Tenecteplase (TNK) is as effective as alteplase at reducing death and MI whilst conferring similar intracerebral bleeding risks. However, other major bleeding and transfusion risks are lower and the practical advantages of bolus administration may provide opportunities for prompt treatment in the emergency department or in the pre-hospital setting. Reteplase (rPA) is administered as a double bolus and also produces a similar outcome to that achieved with alteplase, although some of the bleeding risks appear slightly higher.

An overview of all the large randomised trials confirms that thrombolytic therapy reduces short-term mortality in patients with MI if it is given within 12 hours of the onset of symptoms and the ECG shows bundle branch block or characteristic ST segment elevation > 1 mm in the limb leads or 2 mm in the chest leads (see Box 18.70). Thrombolysis appears to be of little net benefit and may be harmful in those who present more than 12 hours after the onset of symptoms and in those with a normal ECG or ST depression. In patients with ST elevation or bundle branch block, the absolute benefit of thrombolysis plus aspirin is approximately 50 lives saved per 1000 patients treated within 6 hours and 40 lives saved per 1000 patients treated between 7 and 12 hours after the onset of symptoms. The benefit is greatest for patients treated within the first 2 hours.

The major hazard of thrombolytic therapy is bleeding. Cerebral haemorrhage causes 4 extra strokes per 1000 patients treated and the incidence of other major bleeds is between 0.5% and 1%. Accordingly, the treatment should be withheld if there is a significant risk of serious bleeding (Box 18.71).

EBM 18.70 Thrombolytic treatment in acute ST segment elevation MI

'Prompt thrombolytic treatment (within 12 hours, and particularly within 6 hours, of the onset of symptoms) reduces mortality in patients with acute MI and ECG changes of ST elevation or new bundle branch block ($NNT_b = 56$). Intracranial haemorrhage is more common in people given thrombolysis with one additional stroke for every 250 people treated.'

For further information:  www.escardio.org

18.71 Relative contraindications to thrombolytic therapy: potential candidates for primary angioplasty

- Active internal bleeding
- Previous subarachnoid or intracerebral haemorrhage
- Uncontrolled hypertension
- Recent surgery (within 1 mth)
- Recent trauma (including traumatic resuscitation)
- High probability of active peptic ulcer
- Pregnancy

For some patients, thrombolytic therapy is contraindicated or fails to achieve coronary arterial reperfusion (see Fig. 18.19, p. 540). Early emergency PCI may then be considered, particularly where there is evidence of cardiogenic shock.

Complications of acute coronary syndrome

Complications are seen in all forms of acute coronary syndrome, although the frequency and extent vary with the severity of ischaemia and infarction. Major mechanical and structural complications are only seen with significant, often transmural, MI.

Arrhythmias

Many patients with acute coronary syndrome have some form of arrhythmia (Box 18.72). In the majority of cases this is transient and of no haemodynamic or prognostic importance. Pain relief, rest and the correction of hypokalaemia may help prevent them. Diagnosis and management of arrhythmias are discussed in detail on pages 559–577.

18.72 Common arrhythmias in acute coronary syndrome

- Ventricular fibrillation
- Ventricular tachycardia
- Accelerated idioventricular rhythm
- Ventricular ectopics
- Atrial fibrillation
- Atrial tachycardia
- Sinus bradycardia (particularly after inferior MI)
- Atrioventricular block

Ventricular fibrillation

This occurs in about 5–10% of patients who reach hospital and is thought to be the major cause of death in those who die before receiving medical attention. Prompt defibrillation will usually restore sinus rhythm and is life-saving. The prognosis of patients with early ventricular fibrillation (within the first 48 hours) who are successfully and promptly resuscitated is identical to that of patients who do not suffer ventricular fibrillation.

Atrial fibrillation

This is common but frequently transient, and usually does not require emergency treatment. However, if the arrhythmia causes a rapid ventricular rate with hypotension or circulatory collapse, prompt cardioversion by immediate synchronised DC shock is essential. In other situations, digoxin or a β -blocker is usually the treatment of choice. Atrial fibrillation (due to acute atrial stretch) is often a feature of impending or overt left ventricular failure, and therapy may be ineffective if heart failure is not recognised and treated appropriately. Anticoagulation is required if atrial fibrillation persists.

Bradycardia

This does not usually require treatment, but if there is hypotension or haemodynamic deterioration, atropine (0.6–1.2mg i.v.) may be given. AV block complicating inferior infarction is usually temporary and often resolves following reperfusion therapy. If there is clinical deterioration due to second-degree or complete AV block, a temporary pacemaker should be considered. AV block complicating anterior infarction is more serious because asystole may suddenly supervene; a prophylactic temporary pacemaker should be inserted (p. 575).

Ischaemia

Patients who develop recurrent angina at rest or on minimal exertion following an acute coronary syndrome are at high risk and should be considered for prompt coronary angiography with a view to revascularisation. Patients with dynamic ECG changes and ongoing pain should be treated with intravenous glycoprotein IIb/IIIa receptor antagonists. Patients with resistant pain or marked haemodynamic changes should be considered for intra-aortic balloon counterpulsation and emergency coronary revascularisation.

Post-infarct angina occurs in up to 50% of patients treated with thrombolysis. Most patients have a residual stenosis in the infarct-related vessel despite successful thrombolysis, and this may cause angina if there is still viable myocardium downstream. For this reason, all patients who have received successful thrombolysis should be considered for early (within the first 6–24 hours) coronary angiography with a view to coronary revascularisation.

Acute circulatory failure

Acute circulatory failure usually reflects extensive myocardial damage and indicates a bad prognosis. All the other complications of MI are more likely to occur when acute heart failure is present. The assessment and management of heart failure complicating acute MI are discussed in detail on page 542.

Pericarditis

This only occurs following infarction and is particularly common on the second and third days. The patient may recognise that a different pain has developed, even though it is at the same site, and that it is positional and tends to be worse or sometimes only present on inspiration. A pericardial rub may be audible. Opiate-based analgesia should be used. Non-steroidal and steroidal anti-inflammatory drugs may increase the risk of aneurysm formation and myocardial rupture in the early recovery period, and so should be avoided.

The post-MI syndrome (Dressler's syndrome) is characterised by persistent fever, pericarditis and pleurisy, and is probably due to autoimmunity. The symptoms tend to occur a few weeks or even months after the infarct and often subside after a few days; prolonged or severe symptoms may require treatment with high-dose aspirin, NSAIDs or even corticosteroids.

Mechanical complications

Part of the necrotic muscle in a fresh infarct may tear or rupture, with devastating consequences:

- *Rupture of the papillary muscle* can cause acute pulmonary oedema and shock due to the sudden onset of severe mitral regurgitation, which presents with a pansystolic murmur and third heart sound. In the presence of severe valvular regurgitation, the murmur may be quiet or absent. The diagnosis is confirmed by echocardiography and emergency mitral valve replacement may be necessary. Lesser degrees of mitral regurgitation due to papillary muscle dysfunction are common and may be transient.
- *Rupture of the interventricular septum* causes left-to-right shunting through a ventricular septal defect. This usually presents with sudden haemodynamic

deterioration accompanied by a new loud pansystolic murmur radiating to the right sternal border, but may be difficult to distinguish from acute mitral regurgitation. However, patients with an acquired ventricular septal defect tend to develop right heart failure rather than pulmonary oedema. Doppler echocardiography and right heart catheterisation will confirm the diagnosis. Without prompt surgery, the condition is usually fatal.

- *Rupture of the ventricle* may lead to cardiac tamponade and is usually fatal (p. 542), although it may rarely be possible to support a patient with an incomplete rupture until emergency surgery is performed.

Embolism

Thrombus often forms on the endocardial surface of freshly infarcted myocardium. This can lead to systemic embolism and occasionally causes a stroke or ischaemic limb.

Venous thrombosis and pulmonary embolism may occur but have become less common with the use of prophylactic anticoagulants and early mobilisation.

Impaired ventricular function, remodelling and ventricular aneurysm

Acute transmural MI is often followed by thinning and stretching of the infarcted segment (infarct expansion). This leads to an increase in wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling, Fig. 18.77). As the ventricle dilates, it becomes less efficient and heart failure may supervene. Infarct expansion occurs over a few days and weeks but ventricular remodelling can take years. ACE

Fig. 18.77 Infarct expansion and ventricular remodelling. Full-thickness MI causes thinning and stretching of the infarcted segment (infarct expansion), which leads to increased wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling).

inhibitor therapy reduces late ventricular remodelling and can prevent the onset of heart failure (p. 548).

A left ventricular aneurysm develops in approximately 10% of patients with MI and is particularly common when there is persistent occlusion of the infarct-related vessel. Heart failure, ventricular arrhythmias, mural thrombus and systemic embolism are all recognised complications of aneurysm formation. Other clinical features include a paradoxical impulse on the chest wall, persistent ST elevation on the ECG, and sometimes an unusual bulge from the cardiac silhouette on the chest X-ray. Echocardiography is usually diagnostic. Surgical removal of a left ventricular aneurysm carries a high morbidity and mortality but is sometimes necessary.

Later in-hospital management (Box 18.73)

Risk stratification and further investigation

Simple clinical tools can be used to identify medium- to high-risk patients. The GRACE score (see Fig. 18.69, p. 589) is a simple method of calculating early mortality that can help guide which patients should be selected for intensive therapy, and specifically early inpatient coronary angiography.

The prognosis of patients who have survived an acute coronary syndrome is related to the extent of residual myocardial ischaemia, the degree of myocardial damage and the presence of ventricular arrhythmias.

Left ventricular function

The degree of left ventricular dysfunction can be crudely assessed from physical findings (tachycardia, third heart sound, crackles at the lung bases, elevated venous pressure and so on), ECG changes and chest X-ray (size of the heart and presence of pulmonary oedema). However, formal assessment with echocardiography should be undertaken in the early recovery phase.

Ischaemia

Patients with early ischaemia following an acute coronary syndrome should undergo coronary angiography with a view to revascularisation. Low-risk patients without spontaneous ischaemia should undergo an exercise

18.73 Late management of MI

Risk stratification and further investigation (see text)

Lifestyle modification

- Cessation of smoking
- Regular exercise
- Diet (weight control, lipid-lowering)

Secondary prevention drug therapy

- Antiplatelet therapy (aspirin and/or clopidogrel)
- β -blocker
- ACE inhibitor/ARB
- Statin
- Additional therapy for control of diabetes and hypertension
- Aldosterone receptor antagonist

Rehabilitation

Devices

- Implantable cardiac defibrillator (high-risk patients)

tolerance test approximately 4 weeks after the acute coronary syndrome. This will help to identify those individuals with residual myocardial ischaemia who require further investigation and may help to boost the confidence of the remainder.

If the exercise test is negative and the patient has a good effort tolerance, the outlook is good, with a 1–4% chance of an adverse event in the next 12 months. In contrast, patients with residual ischaemia in the form of chest pain or ECG changes at low exercise levels are at high risk, with a 15–25% chance of suffering a further ischaemic event in the next 12 months.

Arrhythmias

The presence of ventricular arrhythmias during the convalescent phase of acute coronary syndrome may be a marker of poor ventricular function and may herald sudden death. Although empirical anti-arrhythmic treatment is of no value and even hazardous, selected patients may benefit from electrophysiological testing and specific anti-arrhythmic therapy (including implantable cardiac defibrillators, p. 576).

Recurrent ventricular arrhythmias are sometimes manifestations of myocardial ischaemia or impaired left ventricular function and may respond to appropriate treatment directed at the underlying problem.

Lifestyle and risk factor modification

Smoking

The 5-year mortality of patients who continue to smoke cigarettes is double that of those who quit smoking at the time of their acute coronary syndrome. Giving up smoking is the single most effective contribution a patient can make to his or her future. The success of smoking cessation can be increased by supportive advice and pharmacological therapy (p. 99).

Hyperlipidaemia

The importance of lowering serum cholesterol following acute coronary syndrome has been demonstrated in large-scale randomised clinical trials. Lipids should be measured within 24 hours of presentation because there is often a transient fall in blood cholesterol in the 3 months following infarction. HMG CoA reductase enzyme inhibitors ('statins', p. 455) can produce marked reductions in total (and LDL) cholesterol and reduce the subsequent risk of death, reinfarction, stroke and the need for revascularisation (see Box 18.48, p. 581). Irrespective of serum cholesterol concentrations, all patients should receive statin therapy after acute coronary syndrome, but those with serum LDL cholesterol concentrations > 3.2 mmol/L (~120 mg/dL) benefit from more intensive lipid-lowering, such as atorvastatin 80 mg daily.

Other risk factors

Maintaining an ideal body weight, eating a Mediterranean-style diet, taking regular exercise, and achieving good control of hypertension and diabetes mellitus may all improve the long-term outlook.

Mobilisation and rehabilitation

The necrotic muscle of an acute myocardial infarct takes 4–6 weeks to be replaced with fibrous tissue and it is conventional to restrict physical activities during this period. When there are no complications, the patient can

mobilise on the second day, return home in 3–5 days and gradually increase activity with the aim of returning to work in 4–6 weeks. The majority of patients may resume driving after 4–6 weeks, although in most countries vocational driving licence holders (e.g. heavy goods and public service vehicles) require special assessment.

Emotional problems, such as denial, anxiety and depression, are common and must be addressed. Many patients are severely and even permanently incapacitated as a result of the psychological rather than the physical effects of acute coronary syndrome, and all benefit from thoughtful explanation, counselling and reassurance at every stage of the illness. Many patients mistakenly believe that 'stress' was the cause of their heart attack and may restrict their activity inappropriately. The patient's spouse or partner will also require emotional support, information and counselling. Formal rehabilitation programmes based on graded exercise protocols with individual and group counselling are often very successful, and in some cases have been shown to improve the long-term outcome.

Secondary prevention drug therapy

Aspirin and clopidogrel

Low-dose aspirin therapy reduces the risk of further infarction and other vascular events by approximately 25% and should be continued indefinitely if there are no unwanted effects. Clopidogrel should be given in combination with aspirin for at least 3 months. If patients are intolerant of long-term aspirin, clopidogrel is a suitable alternative.

Beta-blockers

Continuous treatment with an oral β -blocker reduces long-term mortality by approximately 25% among the survivors of acute MI (Box 18.74). Unfortunately, a minority of patients do not tolerate β -blockers because of bradycardia, AV block, hypotension or asthma. Patients with heart failure, irreversible chronic obstructive pulmonary disease or peripheral vascular disease derive similar, if not greater secondary preventative benefits from β -blocker therapy if they can tolerate it, so it should be tried. The secondary preventative role of β -blockers in patients with unstable angina is unknown.

ACE inhibitors

Several clinical trials have shown that long-term treatment with an ACE inhibitor (e.g. enalapril 10 mg 12-hourly or ramipril 2.5–5 mg 12-hourly) can counteract ventricular remodelling, prevent the onset of heart failure, improve survival, reduce recurrent MI and avoid rehospitalisation. The benefits are greatest in those with overt heart failure (clinical or radiological) but extend to

EBM 18.74 Beta-blockers in secondary prevention after MI

'Beta-blockers reduce the risk of overall mortality ($\text{NNT}_b = 48$), sudden death ($\text{NNT}_b = 63$) and non-fatal reinfarction ($\text{NNT}_b = 56$) in patients after MI. The greatest benefit is seen in those at highest risk and about one-quarter of patients suffer adverse events.'

• Freemantle N, et al. Br Med J 1999; 318: 1730–1737.

For further information:  www.sign.ac.uk

patients with asymptomatic left ventricular dysfunction and those with preserved left ventricular function. They should therefore be considered in all patients with acute coronary syndrome. Caution must be exercised in hypovolaemic or hypotensive patients because the introduction of an ACE inhibitor may exacerbate hypotension and impair coronary perfusion. In patients intolerant of ACE inhibitor therapy, angiotensin receptor blockers (e.g. valsartan 40–160 mg 12-hourly or candesartan 4–16 mg daily) are suitable alternatives and are better tolerated.

Patients with acute MI and left ventricular dysfunction (ejection fraction < 35%) and either pulmonary oedema or diabetes mellitus further benefit from additional aldosterone receptor antagonism (e.g. eplerenone 25–50 mg daily).

Coronary revascularisation

Most low-risk patients stabilise with aspirin, clopidogrel, anticoagulation and anti-anginal therapy, and can be rapidly mobilised. In the absence of recurrent symptoms, low-risk patients do not benefit from routine coronary angiography. Coronary angiography should be considered with a view to revascularisation in all patients at moderate or high risk, including those who fail to settle on medical therapy, those with extensive ECG changes, those with an elevated plasma troponin and those with severe pre-existing stable angina. This often reveals disease that is amenable to PCI or urgent CABG. In these cases coronary revascularisation is associated with short- and long-term benefits, including reductions in MI and death.

Device therapy

Implantable cardiac defibrillators are of benefit in preventing sudden cardiac death in patients who have severe left ventricular impairment (ejection fraction ≤ 30%) after MI (p. 576).

Prognosis

In almost one-quarter of all cases of MI, death occurs within a few minutes without medical care. Half the

deaths occur within 24 hours of the onset of symptoms and about 40% of all affected patients die within the first month. The prognosis of those who survive to reach hospital is much better, with a 28-day survival of more than 85%. Patients with unstable angina have a mortality approximately half those with MI.

Early death is usually due to an arrhythmia and is independent of the extent of MI. However, late outcomes are determined by the extent of myocardial damage and unfavourable features include poor left ventricular function, AV block and persistent ventricular arrhythmias. The prognosis is worse for anterior than for inferior infarcts. Bundle branch block and high cardiac marker levels both indicate extensive myocardial damage. Old age, depression and social isolation are also associated with a higher mortality.

Of those who survive an acute attack, more than 80% live for a further year, about 75% for 5 years, 50% for 10 years and 25% for 20 years.

Cardiac risk of non-cardiac surgery

Non-cardiac surgery, particularly major vascular, abdominal or thoracic surgery, can precipitate serious perioperative cardiac complication such as MI and death in patients with coronary artery and other forms of heart disease. Careful pre-operative cardiac assessment may help to determine the balance of benefit versus risk on an individual basis, and identify measures that minimise the operative risk (Box 18.76).

A hypercoagulable state is part of the normal physiological response to surgery, and may promote coronary thrombosis leading to an acute coronary syndrome in the early post-operative period. Patients with a history of recent PCI or acute coronary syndrome are at greatest risk and, whenever possible, elective non-cardiac surgery should be avoided for 3 months after such an event. Antiplatelet agents, statins and β -blockers reduce the risk of perioperative MI in patients with coronary artery disease and, where possible, should be prescribed throughout the perioperative period.

Careful attention to fluid balance during and after surgery is particularly important in patients with impaired left ventricular function and valvular heart disease because antidiuretic hormone is released as part of the normal physiological response to surgery, and in these circumstances the overzealous administration of intravenous fluids can easily precipitate heart failure. Patients with severe valvular heart disease, particularly aortic stenosis and mitral stenosis, are also at increased risk because they may not be able to increase their cardiac output in response to the stress of surgery.

18.75 Myocardial infarction in old age

- **Atypical presentation:** often with anorexia, fatigue or weakness rather than chest pain.
- **Case fatality:** rises steeply. Hospital mortality exceeds 25% in those > 75 yrs old, which is five times greater than that seen in those aged < 55 yrs.
- **Survival benefit of treatments:** not influenced by age. The absolute benefit of evidence-based treatments may therefore be greatest in older people.
- **Hazards of treatments:** rise with age (e.g. increased risk of intracerebral bleeding after thrombolysis) and are due partly to increased comorbidity.
- **Quality of evidence:** older patients, particularly those with significant comorbidity, were under-represented in many of the randomised controlled clinical trials that helped to establish the treatment of MI. The balance of risk and benefit for many treatments (e.g. thrombolysis, primary percutaneous transluminal coronary angiography) in frail older people is therefore uncertain.

18.76 Major risk factors for cardiac complications of non-cardiac surgery

- Recent (< 6 mths) MI or unstable angina
- Severe coronary artery disease: left main stem or three-vessel disease
- Severe stable angina on effort
- Severe left ventricular dysfunction
- Severe valvular heart disease (especially aortic stenosis)

Atrial fibrillation may be triggered by hypoxia, myocardial ischaemia or heart failure, and is a common post-operative complication in patients with pre-existing heart disease. It usually terminates spontaneously when the precipitating factors have been eliminated, but digoxin or β -blockers can be prescribed to control the heart rate.

VASCULAR DISEASE

Peripheral arterial disease

In developed countries, almost all peripheral arterial disease (PAD) is due to atherosclerosis (pp. 577–579) and so shares common risk factors with coronary artery disease (CAD): namely, smoking, diabetes mellitus, hyperlipidaemia and hypertension. As with CAD, plaque rupture is responsible for the most serious manifestations of PAD, and not infrequently occurs in a plaque that hitherto has been asymptomatic.

Approximately 20% of middle-aged (55–75 years) people in the UK have PAD but only one-quarter of them will have symptoms. The clinical manifestations depend upon the anatomical site, the presence or absence of a collateral supply, the speed of onset and the mechanism of injury (Box 18.77).

Chronic lower limb arterial disease

PAD affects the leg eight times more often than the arm. The lower limb arterial tree comprises the aorto-iliac ('inflow'), femoro-popliteal and infra-popliteal ('out-flow') segments. One or more segments may be affected in a variable and asymmetric manner. Lower limb ischaemia presents as two distinct clinical entities: intermittent claudication (IC) and critical limb ischaemia (CLI). The presence and severity of ischaemia can be determined by clinical examination (Box 18.78) and measurement of the ankle-brachial pressure index (ABPI), which is the ratio between the (highest systolic) ankle and brachial blood pressures. In health the ABPI is > 1.0 , in IC typically 0.5–0.9 and in CLI usually < 0.5 .

Intermittent claudication (IC)

This term describes ischaemic pain affecting the muscles of the leg upon walking. The pain is usually felt in the calf because the disease most commonly affects the superficial femoral artery. However, the pain may be felt in the thigh or buttock if the iliac arteries are involved. Typically, the pain comes on after a reasonably constant 'claudication distance', and rapidly subsides on stopping walking. Resumption of walking leads to a return of the pain. Most patients describe a cyclical pattern of exacerbation and resolution due to the progression of disease and the subsequent development of collaterals.

Approximately 5% of middle-aged men report IC. Provided patients comply with 'best medical therapy' (BMT) (Box 18.79), only 1–2% per year will deteriorate to a point where amputation and/or revascularisation is required. However, the annual mortality rate exceeds 5%, 2–3 times higher than in an equivalent non-claudicant population. This is because IC is nearly always found in association with widespread atherosclerosis, so that most claudicants succumb to MI or stroke. The mainstay of treatment is BMT, including (preferably

18.77 Factors influencing the clinical manifestations of peripheral arterial disease

Anatomical site

Cerebral circulation

- TIA, amaurosis fugax, vertebrobasilar insufficiency

Renal arteries

- Hypertension and renal failure

Mesenteric arteries

- Mesenteric angina, acute intestinal ischaemia

Limbs (legs >> arms)

- Intermittent claudication, critical limb ischaemia, acute limb ischaemia

Collateral supply

- In a patient with a complete circle of Willis, occlusion of one carotid artery may be asymptomatic
- In a patient without cross-circulation, stroke is likely

Speed of onset

- Where PAD develops slowly, a collateral supply will develop
- Sudden occlusion of a previously normal artery is likely to cause severe distal ischaemia

Mechanism of injury

Haemodynamic

- Plaque must reduce arterial diameter by 70% ('critical stenosis') to reduce flow and pressure at rest. On exertion (e.g. walking), a much lesser stenosis may become 'critical'. This mechanism tends to have a relatively benign course due to collateralisation

Thrombotic

- Occlusion of a long-standing critical stenosis may be asymptomatic due to collateralisation. However, acute rupture and thrombosis of a non-haemodynamically significant plaque usually has severe consequences

Atheroembolic

- Symptoms depend upon embolic load and size
- Carotid (TIA, amaurosis fugax or stroke) and peripheral arterial (blue toe/finger syndrome) plaque are common examples

Thromboembolic

- Usually secondary to atrial fibrillation
- The clinical consequences are usually dramatic, as the thrombus load is often large and tends to occlude a major, previously healthy, non-collateralised artery suddenly and completely

18.78 Clinical features of chronic lower limb ischaemia

- Pulses: diminished or absent
- Bruits: denote turbulent flow but bear no relationship to the severity of the underlying disease
- Reduced skin temperature
- Pallor on elevation and rubor on dependency (Buerger's sign)
- Superficial veins that fill sluggishly and empty ('gutter') upon minimal elevation
- Muscle-wasting
- Skin and nails: dry, thin and brittle
- Loss of hair

18.79 Best medical therapy for peripheral arterial disease*

- Smoking cessation
- Regular exercise (30 mins of walking, three times per week)
- Antiplatelet agent (aspirin 75 mg daily or clopidogrel 75 mg daily)
- Reduction of cholesterol (diet + statin therapy)
- Diagnosis and treatment of diabetes mellitus (all should have fasting glucose measured)
- Diagnosis and treatment of frequently associated conditions (e.g. hypertension, anaemia, heart failure)

*All patients with any manifestation of PAD should be considered candidates for BMT.

supervised) exercise therapy. The peripheral vasodilator, cilostazol, has been shown to improve walking distance. Intervention with angioplasty, stenting, endarterectomy or bypass is usually only considered after BMT has been given at least 6 months to effect symptomatic improvement, and then only in patients who are severely disabled or whose livelihood is threatened by their disability.

Critical limb ischaemia (CLI)

This is defined as rest (night) pain, requiring opiate analgesia, and/or tissue loss (ulceration or gangrene), present for more than 2 weeks, in the presence of an ankle BP of < 50 mmHg (Fig. 18.78). Rest pain only, with ankle pressures > 50 mmHg, is known as subcritical limb ischaemia (SCLI). The term severe limb ischaemia (SLI) is used to describe both CLI and SCLI. Whereas IC is usually due to single-segment plaque, SLI is always due to multilevel disease.

Many patients with SLI have not previously sought medical advice for IC, principally because they have other comorbidity that prevents them from walking to a point where claudication pain might develop. In contrast to IC, patients with SLI are at high risk of losing their limb, and sometimes their life, in a matter of weeks or months without surgical bypass or endovascular revascularisation by angioplasty or stenting. However, treatment is difficult because patients have extensive and severe (often bilateral) end-stage disease, are usually elderly and nearly always have significant multisystem comorbidity. Imaging is performed using duplex ultrasonography, MRI or CT with intravenous injection of contrast agents. Intra-arterial digital subtraction angiography (IA-DSA) is usually reserved for those undergoing endovascular revascularisation.

Diabetic vascular disease

Approximately 5–10% of patients with PAD have diabetes but this proportion increases to 30–40% in those with SLI. Diabetes does not cause obstructive microangiopathy at the capillary level, as previously thought, and so is not a contraindication to lower limb revascularisation. Nevertheless, the 'diabetic foot' does pose a number of particular problems (Box 18.80 and p. 833). If the blood supply is adequate, then dead tissue can be excised in the expectation that healing will occur, provided infection is controlled and the foot is protected from pressure. However, if significant ischaemia is also present, the priority is to revascularise the foot if possible. Sadly, many diabetic patients present late with extensive tissue loss, which accounts for the high amputation rate.

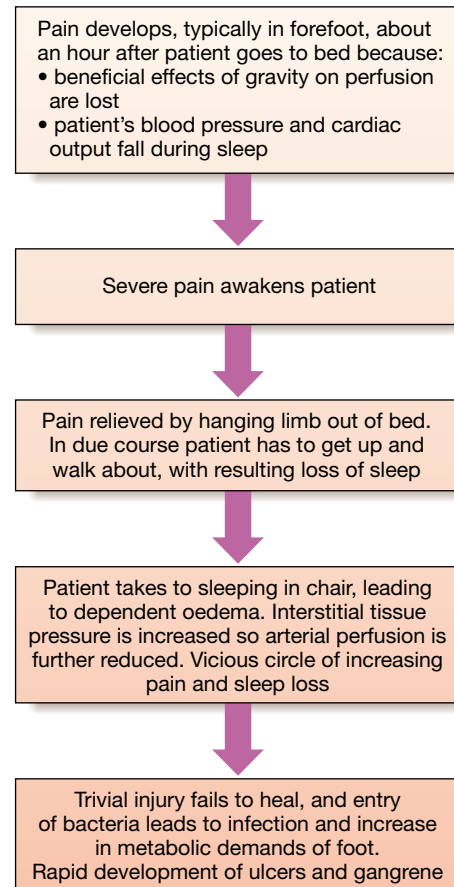

Fig. 18.78 Progressive night pain and the development of tissue loss.

Buerger's disease (thromboangiitis obliterans)

This is an inflammatory obliterative arterial disease that is distinct from atherosclerosis and usually presents in young (20–30 years) male smokers. It is most common in those from the Mediterranean and North Africa. It characteristically affects distal arteries, giving rise to claudication in the feet or rest pain in the fingers or toes. Wrist and ankle pulses are absent but brachial and popliteal are present. Disease also affects the veins, giving rise to superficial thrombophlebitis. It often remits if the patient stops smoking; sympathectomy and prostaglandin infusions may be helpful. Major limb amputation is the most frequent outcome if patients continue to smoke.

Chronic upper limb arterial disease

In the arm, the subclavian artery is the most common site of disease, which may manifest as:

- Arm claudication (rare).
- Atheroembolism (blue finger syndrome). Small emboli lodge in digital arteries and may be confused with Raynaud's phenomenon (see below), but in this case the symptoms are unilateral. Failure to make the diagnosis may eventually lead to amputation.
- Subclavian steal. When the arm is used, blood is 'stolen' from the brain via the vertebral artery.

18.80 Diabetic vascular disease: the 'diabetic foot'

Feature	Difficulty
Arterial calcification	Spuriously high ABPI due to incompressible ankle vessels Inability to clamp arteries for the purposes of bypass surgery Resistant to angioplasty
Immunocompromise	Prone to rapidly spreading cellulitis, gangrene and osteomyelitis
Multisystem arterial disease	Coronary and cerebral arterial disease increase the risks of intervention
Distal disease	Diabetic vascular disease has a predilection for the calf vessels. Although vessels in the foot are often spared, performing a satisfactory bypass or angioplasty to these small vessels is a technical challenge
Sensory neuropathy	Even severe ischaemia and/or tissue loss may be completely painless. Diabetic patients often present late with extensive destruction of the foot. Loss of proprioception leads to abnormal pressure loads and exacerbates joint destruction (Charcot joints)
Motor neuropathy	Weakness of the long and short flexors and extensors leads to abnormal foot architecture, abnormal pressure loads, callus formation and ulceration
Autonomic neuropathy	This leads to a dry foot deficient in sweat that normally lubricates the skin and contains antibacterial substances. Scaling and fissuring create a portal of entry for bacteria. Abnormal blood flow in the bones of the ankle and foot may also contribute to osteopenia and bony collapse

This leads to vertebro-basilar ischaemia, which is characterised by dizziness, cortical blindness and/or collapse. Where possible, subclavian artery disease is treated by means of angioplasty and stenting, as surgery (e.g. carotid-subclavian bypass) can be difficult.

Raynaud's phenomenon and Raynaud's disease

Cold (and emotional) stimuli may trigger vasospasm, leading to the characteristic sequence of digital pallor due to vasospasm, cyanosis due to deoxygenated blood, and rubor due to reactive hyperaemia.

Primary Raynaud's phenomenon (or disease)

This affects 5–10% of young women aged 15–30 years in temperate climates and may be familial. It does not progress to ulceration or infarction, and significant pain is unusual. The underlying cause is unclear. No investigation is necessary. The patient should be reassured and advised to avoid exposure to cold. Long-acting nifedipine may be helpful but sympathectomy is not indicated.

18.81 Atherosclerotic vascular disease in old age

- **Prevalence:** related almost exponentially to age in developed countries, although atherosclerosis is not considered part of the normal ageing process.
- **Statin therapy:** no role in the primary prevention of atherosclerotic disease in those > 75 yrs but reduces cardiovascular events in those with established vascular disease, albeit with no reduction in overall mortality.
- **Presentation in the frail:** frequently with advanced multisystem arterial disease, along with a host of other comorbidities.
- **Intervention in the frail:** in those with extensive disease and limited life expectancy, the risks of surgery may outweigh the benefits, and symptomatic care is all that should be offered.

Secondary Raynaud's phenomenon (or syndrome)

This tends to occur in older people in association with connective tissue disease (most commonly systemic sclerosis or the CREST syndrome, p. 1109), vibration-induced injury (from the use of power tools) and thoracic outlet obstruction (e.g. cervical rib). Unlike primary disease, it is often associated with fixed obstruction of the digital arteries, fingertip ulceration, and necrosis and pain. The fingers must be protected from cold and trauma, infection requires treatment with antibiotics, and surgery should be avoided if possible. Vasoactive drugs have no clear benefit. Sympathectomy helps for a year or two. Prostacyclin infusions are sometimes beneficial.

Acute limb ischaemia

This is most frequently caused by acute thrombotic occlusion of a pre-existing stenotic arterial segment, thromboembolism, and trauma which may be iatrogenic. Apart from paralysis (inability to wiggle toes/fingers) and paraesthesia (loss of light touch over the dorsum of the foot/hand), the so-called 'Ps of acute ischaemia' (Box 18.82) are non-specific for ischaemia and/or inconsistently related to its severity. Pain on squeezing the calf indicates muscle infarction and impending irreversible ischaemia.

All patients with suspected acutely ischaemic limbs must be discussed immediately with a vascular surgeon; a few hours can make the difference between death/amputation and complete recovery of limb function.

18.82 Symptoms and signs of acute limb ischaemia

Symptoms/signs	Comment
Pain	May be absent in complete acute ischaemia, and can be present in chronic ischaemia
Pallor	
Pulselessness	
Perishing cold	Unreliable, as the ischaemic limb takes on the ambient temperature
Paraesthesia	Important features of impending irreversible ischaemia
Paralysis	

18.83 Acute limb ischaemia: distinguishing features of embolism and thrombosis in situ		
Clinical features	Embolism	Thrombosis in situ
Severity	Complete (no collaterals)	Incomplete (collaterals)
Onset	Seconds or minutes	Hours or days
Limb	Leg 3:1 arm	Leg 10:1 arm
Multiple sites	Up to 15%	Rare
Embolic source	Present (usually AF)	Absent
Previous claudication	Absent	Present
Palpation of artery	Soft, tender	Hard, calcified
Bruits	Absent	Present
Contralateral leg pulses	Present	Absent
Diagnosis	Clinical	Angiography
Treatment	Embolectomy, warfarin	Medical, bypass, thrombolysis
Prognosis	Loss of life > loss of limb	Loss of limb > loss of life

If there are no contraindications (for example, acute aortic dissection or trauma, particularly head injury), an intravenous bolus of heparin (3000–5000 U) should be administered to limit propagation of thrombus and protect the collateral circulation. Distinguishing thrombosis from embolism is frequently difficult but is important because treatment and prognosis are different (Box 18.83). Acute limb ischaemia due to thrombosis in situ can usually be treated medically in the first instance with intravenous heparin (target activated partial thromboplastin time (APTT) 2.0–3.0), antiplatelet agents, high-dose statins, intravenous fluids to avoid dehydration, correction of anaemia, oxygen and sometimes prostaglandins such as iloprost. Careful monitoring is required. Embolism will normally result in extensive tissue necrosis within 6 hours unless the limb is revascularised. The indications for thrombolysis, if any, remain controversial. Irreversible ischaemia mandates early amputation or palliative care.

Cerebrovascular disease, renovascular disease and ischaemic gut injury

See pages 1180–1191, 496–499 and 906–907.

Diseases of the aorta

Aneurysm, dissection and aortitis are the main pathologies (Fig. 18.79).

Aortic aneurysm

This is an abnormal dilatation of the aortic lumen; a true aneurysm involves all the layers of the wall, whereas a false aneurysm does not.

Aetiology and types of aneurysm

Non-specific aneurysms

Why some patients develop occlusive vascular disease, some aneurysmal vascular disease and some both in response to atherosclerosis risk factors remains unclear. Unlike occlusive disease, aneurysmal disease tends to run in families and genetic factors are undoubtedly important. The most common site for 'non-specific' aneurysm formation is the infrarenal abdominal aorta. The suprarenal abdominal aorta and a variable length of the descending thoracic aorta may be affected in 10–20% of patients but the ascending aorta is usually spared.

Marfan's syndrome

This disorder of connective tissue is inherited as an autosomal dominant trait and is caused by mutations in the *fibrillin* gene on chromosome 15. Affected systems include the skeleton (arachnodactyly, joint hypermobility, scoliosis, chest deformity and high arched palate), the eyes (dislocation of the lens) and the cardiovascular system (aortic disease and mitral regurgitation). Weakening of the aortic media leads to aortic root dilatation, aortic regurgitation and aortic dissection (see below). Pregnancy is particularly hazardous. Chest X-ray, echocardiography, MRI or CT may detect aortic dilatation at an early stage and can be used to monitor the disease.

Treatment with β -blockers reduces the rate of aortic dilatation and the risk of rupture. Elective replacement of the ascending aorta may be considered in patients with evidence of progressive aortic dilatation but carries a mortality of 5–10%.

Aortitis

Syphilis is a rare cause of aortitis that characteristically produces saccular aneurysms of the ascending aorta containing calcification. Other rare conditions associated with aortitis include Takayasu's disease (p. 1113), Reiter's syndrome (p. 1115), giant cell arteritis and ankylosing spondylitis (pp. 1093–1094).

Thoracic aortic aneurysms

These may produce chest pain, aortic regurgitation, compressive symptoms such as stridor (trachea, bronchus) and hoarseness (recurrent laryngeal nerve), and superior vena cava syndrome (see Fig. 18.79A). If they erode into adjacent structures e.g. aorto-oesophageal fistula, massive bleeding occurs.

Abdominal aortic aneurysms (AAAs)

AAAs are present in 5% of men aged over 60 years and 80% are confined to the infrarenal segment. Men are affected three times more commonly than women. AAA can present in a number of ways (Box 18.84). The usual age at presentation is 65–75 years for elective presentations and 75–85 years for emergency presentations. Ultrasound is the best way of establishing the diagnosis, and of following up patients with asymptomatic aneurysms that are not yet large enough to warrant surgical repair. CT provides more accurate information about the size and extent of the aneurysm, the surrounding structures and whether there is any other intra-abdominal pathology. It is the standard pre-operative investigation but is not suitable for surveillance because of cost and radiation dose.

Fig. 18.79 Types of aortic disease and their complications. **A** Types of aortic aneurysm. **B** Types of aortic dissection.

Management. Until an asymptomatic AAA has reached a maximum of 5.5 cm in diameter, the risks of surgery generally outweigh the risks of rupture (Box 18.85). All symptomatic AAAs should be considered for repair, not only to rid the patient of symptoms but also because pain often predates rupture. Distal embolisation is a strong indication for repair, regardless of size, because otherwise limb loss is common. Most patients with a ruptured AAA do not survive to reach hospital, but if they do and surgery is thought to be appropriate, there must be no delay in getting them to the operating theatre to clamp the aorta.

Open AAA repair has been the treatment of choice in both the elective and the emergency settings, and entails replacing the aneurysmal segment with a prosthetic (usually Dacron) graft. The 30-day mortality for this procedure is approximately 5–8% for elective asymptomatic AAA, 10–20% for emergency symptomatic AAA and 50% for ruptured AAA. However, patients who survive the operation to leave hospital have a long-term survival which approaches that of the normal population.

Increasingly, endovascular aneurysm repair (EVAR), using a stent-graft introduced via the femoral arteries in the groin, is replacing open surgery. It is cost-effective and likely to become the treatment of choice for infrarenal AAA. It is possible to treat many suprarenal and thoraco-abdominal aneurysms by EVAR too.

Aortic dissection

A breach in the integrity of the aortic wall allows arterial blood to enter the media, which is then split into two layers, creating a 'false lumen' alongside the existing or 'true lumen' (see Fig. 18.79B). The aortic valve may be damaged and the branches of the aorta may be compromised. Typically, the false lumen eventually re-enters the true lumen, creating a double-barrelled aorta, but it may also rupture into the left pleural space or pericardium with fatal consequences.

The primary event is often a spontaneous or iatrogenic tear in the intima of the aorta; multiple tears or entry points are common. Other dissections appear to be triggered by primary haemorrhage in the media of the

18.84 Abdominal aortic aneurysm: common presentations
Incidental
<ul style="list-style-type: none"> On physical examination, plain X-ray or, most commonly, abdominal ultrasound Even large AAAs can be difficult to feel, so many remain undetected until they rupture Studies are currently underway to determine whether screening will reduce the number of deaths from rupture (see Box 18.85)

aorta that then ruptures through the intima into the true lumen. This form of spontaneous bleeding from the vasa vasorum is sometimes confined to the aortic wall, when it may present as a painful intramural haematoma.

Disease of the aorta and hypertension are the most important aetiological factors but a variety of other conditions may be implicated (Box 18.86). Chronic dissections may lead to aneurysmal dilatation of the aorta, and thoracic aneurysms may be complicated by dissection. It is therefore sometimes difficult to identify the primary pathology.

The peak incidence is in the sixth and seventh decades of life but dissection can occur in younger patients, most commonly in association with Marfan's syndrome, pregnancy or trauma; men are twice as frequently affected as women.

Aortic dissection is classified anatomically and for management purposes into type A and type B (see Fig. 18.79B), involving or sparing the ascending aorta respectively. Type A dissections account for two-thirds of cases and frequently also extend into the descending aorta.

18.86 Factors that may predispose to aortic dissection
<ul style="list-style-type: none"> Hypertension (80% of cases) Aortic atherosclerosis Non-specific aortic aneurysm Aortic coarctation (p. 631) Collagen disorders (e.g. Marfan's syndrome, Ehlers–Danlos syndrome) Fibromuscular dysplasia Previous aortic surgery (e.g. CABG, aortic valve replacement) Pregnancy (usually third trimester) Trauma Iatrogenic (e.g. cardiac catheterisation, intra-aortic balloon pumping)

Clinical features

Involvement of the ascending aorta typically gives rise to anterior chest pain, and involvement of the descending aorta to intrascapular pain. The pain is typically described as 'tearing' and very abrupt in onset; collapse is common. Unless there is major haemorrhage, the patient is invariably hypertensive. There may be asymmetry of the brachial, carotid or femoral pulses and signs of aortic regurgitation. Occlusion of aortic branches may cause MI (coronary), stroke (carotid) paraplegia (spinal), mesenteric infarction with an acute abdomen (coeliac and superior mesenteric), renal failure (renal) and acute limb (usually leg) ischaemia.

Investigations

The chest X-ray characteristically shows broadening of the upper mediastinum and distortion of the aortic 'knuckle', but these findings are variable and are absent in 10% of cases. A left-sided pleural effusion is common. The ECG may show left ventricular hypertrophy in patients with hypertension, or rarely changes of acute MI (usually inferior). Doppler echocardiography may show aortic regurgitation, a dilated aortic root and, occasionally, the flap of the dissection. Transoesophageal echocardiography is particularly helpful because transthoracic echocardiography can only image the first 3–4 cm of the ascending aorta (Fig. 18.80). CT and MRI angiography (Figs 18.81 and 18.82) are both highly specific and sensitive.

Management

The early mortality of acute dissection is approximately 1–5% per hour so treatment is urgently required. Initial management comprises pain control and antihypertensive treatment. Type A dissections require emergency surgery to replace the ascending aorta. Type B aneurysms are treated medically unless there is actual or impending external rupture, or vital organ (gut, kidneys) or limb ischaemia, as the morbidity and mortality associated with surgery is very high. The aim of medical management is to maintain a mean arterial pressure (MAP) of 60–75 mmHg to reduce the force of the ejection of blood from the LV. First-line therapy is with β -blockers; the additional α -blocking properties of labetalol make it especially useful. Rate-limiting calcium channel blockers, such as verapamil or diltiazem, are used if β -blockers are contraindicated. Sodium nitroprusside may be considered if these fail to control BP adequately.

Fig. 18.80 Echocardiograms from a patient with a chronic aortic dissection. **A** Transoesophageal echocardiogram (FL = false lumen; TL = true lumen). **B** Colour-flow Doppler shows flow from the larger false lumen into the true lumen, characteristic of chronic disease.

Fig. 18.81 Sagittal view of an MRI scan from a patient with long-standing aortic dissection illustrating a biluminal aorta. There is sluggish flow in the false lumen (FL), accounting for its grey appearance. (TL = true lumen)

Percutaneous or minimal access endoluminal repair is sometimes possible and involves either ‘fenestrating’ (perforating) the intimal flap so that blood can return from the false to the true lumen (so decompressing the former), or implanting a stent graft placed from the femoral artery (see Fig. 18.82).

Fig. 18.82 Images from a patient with an acute type B aortic dissection that had ruptured into the left pleural space and was repaired by deploying an endoluminal stent graft. **A** CT scan illustrating an intimal flap (arrow) in the descending aorta and a large pleural effusion. **B** Aortogram illustrating aneurysmal dilatation; a stent graft has been introduced from the right femoral artery and is about to be deployed. **C** CT scan after endoluminal repair. The pleural effusion has been drained but there is a haematoma around the descending aorta. **D** Aortogram illustrating the stent graft. **E** Three-dimensional reconstruction of aortic stent graft.

Hypertension

Hypertension is a condition in which arterial BP is chronically elevated. BP occurs within a continuous range, so cutoff levels are defined according to their effect on patients' risk. The British Hypertension Society has defined ranges of BP which are normal and those that indicate hypertension (Box 18.87).

Aetiology

In more than 95% of cases, a specific underlying cause of hypertension cannot be found. Such patients are said to have essential hypertension. The pathogenesis of this is not clearly understood. Many factors may contribute to its development, including renal dysfunction, peripheral resistance vessel tone, endothelial dysfunction, autonomic tone, insulin resistance and neurohumoral factors. Hypertension is more common in some ethnic groups, particularly Black Americans and Japanese, and approximately 40–60% is explained by genetic factors. Important environmental factors include a high salt intake, heavy consumption of alcohol, obesity, lack of exercise and impaired intrauterine growth. There is little evidence that 'stress' causes hypertension.

In about 5% of cases, hypertension can be shown to be a consequence of a specific disease or abnormality leading to sodium retention and/or peripheral vasoconstriction (secondary hypertension, Box 18.88).

Measurement of blood pressure

A decision to embark upon antihypertensive therapy effectively commits the patient to life-long treatment, so BP readings must be as accurate as possible.

Measurements should be made to the nearest 2 mmHg, in the sitting position with the arm supported, and repeated after 5 minutes' rest if the first recording is high (Box 18.89). To avoid spuriously high recordings in obese subjects, the cuff should contain a bladder that encompasses at least two-thirds of the circumference of the arm.

Home and ambulatory BP recordings

Exercise, anxiety, discomfort and unfamiliar surroundings can all lead to a transient rise in BP. Sphygmomanometry,

18.87 Definition of hypertension

Category	Systolic BP (mmHg)	Diastolic BP (mmHg)
BP		
Optimal	< 120	< 80
Normal	< 130	85
High normal	130–139	85–89
Hypertension		
Grade 1 (mild)	140–159	90–99
Grade 2 (moderate)	160–179	100–109
Grade 3 (severe)	≥ 180	≥ 110

Drugs

- e.g. Oral contraceptives containing oestrogens, anabolic steroids, corticosteroids, NSAIDs, carbenoxolone, sympathomimetic agents

Coarctation of the aorta (p. 631)

18.89 How to measure blood pressure

- Use a machine that has been validated, well maintained and properly calibrated
- Measure sitting BP routinely, with additional standing BP in elderly and diabetic patients and those with possible postural hypotension
- Remove tight clothing from the arm
- Support the arm at the level of the heart
- Use a cuff of appropriate size (the bladder must encompass > two-thirds of the arm)
- Lower the pressure slowly (2 mmHg per second)
- Read the BP to the nearest 2 mmHg
- Use phase V (disappearance of sounds) to measure diastolic BP
- Take two measurements at each visit

particularly when performed by a doctor, can cause an unrepresentative surge in BP which has been termed 'white coat' hypertension, and as many as 20% of patients with apparent hypertension in the clinic may have a normal BP when it is recorded by automated devices used at home. The risk of cardiovascular disease in these patients is less than that in patients with sustained hypertension but greater than that in normotensive subjects.

A series of automated ambulatory BP measurements obtained over 24 hours or longer provides a better profile than a limited number of clinic readings and correlates

more closely with evidence of target organ damage than casual BP measurements. However, treatment thresholds and targets (see Box 18.95, p. 609) must be adjusted downwards because ambulatory BP readings are systematically lower (approximately 12/7 mmHg) than clinic measurements. The average ambulatory daytime (not 24-hour or night-time) BP should be used to guide management decisions.

Patients can measure their own BP at home using a range of commercially available semi-automatic devices. The value of such measurements is less well established and is dependent on the environment and timing of the readings measured. Home or ambulatory BP measurements are particularly helpful in patients with unusually labile BP, those with refractory hypertension, those who may have symptomatic hypotension, and those in whom white coat hypertension is suspected.

History

Family history, lifestyle (exercise, salt intake, smoking habit) and other risk factors should be recorded. A careful history will identify those patients with drug- or alcohol-induced hypertension and may elicit the symptoms of other causes of secondary hypertension such as pheochromocytoma (paroxysmal headache, palpitation and sweating, p. 779) or complications such as coronary artery disease (e.g. angina, breathlessness).

Examination

Radio-femoral delay (coarctation of the aorta, see Fig. 18.97 (p. 632)), enlarged kidneys (polycystic kidney disease), abdominal bruits (renal artery stenosis) and the characteristic facies and habitus of Cushing's syndrome are all examples of physical signs that may help to identify causes of secondary hypertension (see Box 18.88). Examination may also reveal features of important risk factors such as central obesity and hyperlipidaemia (tendon xanthomas etc.). Most abnormal signs are due to the complications of hypertension.

Non-specific findings may include left ventricular hypertrophy (apical heave), accentuation of the aortic component of the second heart sound, and a fourth heart sound. The optic fundi are often abnormal (see Fig. 18.83 below) and there may be evidence of generalised atheroma or specific complications such as aortic aneurysm or peripheral vascular disease.

Target organ damage

The adverse effects of hypertension on the organs can often be detected clinically.

Blood vessels

In larger arteries (> 1 mm in diameter), the internal elastic lamina is thickened, smooth muscle is hypertrophied and fibrous tissue is deposited. The vessels dilate and become tortuous, and their walls become less compliant. In smaller arteries (< 1 mm), hyaline arteriosclerosis occurs in the wall, the lumen narrows and aneurysms may develop. Widespread atheroma develops and may lead to coronary and cerebrovascular disease, particularly if other risk factors (e.g. smoking, hyperlipidaemia, diabetes) are present.

These structural changes in the vasculature often perpetuate and aggravate hypertension by increasing peripheral

vascular resistance and reducing renal blood flow, thereby activating the renin-angiotensin-aldosterone axis (p. 544).

Hypertension is a major risk factor in the pathogenesis of aortic aneurysm and aortic dissection.

Central nervous system

Stroke is a common complication of hypertension and may be due to cerebral haemorrhage or infarction. Carotid atheroma and transient ischaemic attacks are more common in hypertensive patients. Subarachnoid haemorrhage is also associated with hypertension.

Hypertensive encephalopathy is a rare condition characterised by high BP and neurological symptoms, including transient disturbances of speech or vision, paraesthesiae, disorientation, fits and loss of consciousness. Papilloedema is common. A CT scan of the brain often shows haemorrhage in and around the basal ganglia; however, the neurological deficit is usually reversible if the hypertension is properly controlled.

Retina

The optic fundi reveal a gradation of changes linked to the severity of hypertension; fundoscopy can, therefore, provide an indication of the arteriolar damage occurring elsewhere (Box 18.90).

'Cotton wool' exudates are associated with retinal ischaemia or infarction, and fade in a few weeks (Fig. 18.83A). 'Hard' exudates (small, white, dense deposits of lipid) and microaneurysms ('dot' haemorrhages) are more characteristic of diabetic retinopathy (see Fig. 21.16, p. 827). Hypertension is also associated with central retinal vein thrombosis (Fig. 18.83B).

Heart

The excess cardiac mortality and morbidity associated with hypertension are largely due to a higher incidence of coronary artery disease. High BP places a pressure load on the heart and may lead to left ventricular hypertrophy with a forceful apex beat and fourth heart sound. ECG or echocardiographic evidence of left ventricular hypertrophy is highly predictive of cardiovascular complications and therefore particularly useful in risk assessment.

Atrial fibrillation is common and may be due to diastolic dysfunction caused by left ventricular hypertrophy or the effects of coronary artery disease.

Severe hypertension can cause left ventricular failure in the absence of coronary artery disease, particularly when renal function, and therefore sodium excretion, is impaired.

18.90 Hypertensive retinopathy

- | | |
|------------------|---|
| • Grade 1 | Arteriolar thickening, tortuosity and increased reflectiveness ('silver wiring') |
| • Grade 2 | Grade 1 plus constriction of veins at arterial crossings ('arteriovenous nipping') |
| • Grade 3 | Grade 2 plus evidence of retinal ischaemia (flame-shaped or blot haemorrhages and 'cotton wool' exudates) |
| • Grade 4 | Grade 3 plus papilloedema |

Fig. 18.83 Retinal changes in hypertension. **A** Grade 4 hypertensive retinopathy showing swollen optic disc, retinal haemorrhages and multiple cotton wool spots (infarcts). **B** Central retinal vein thrombosis showing swollen optic disc and widespread fundal haemorrhage, commonly associated with systemic hypertension.

Kidneys

Long-standing hypertension may cause proteinuria and progressive renal failure (p. 482) by damaging the renal vasculature.

'Malignant' or 'accelerated' phase hypertension

This rare condition may complicate hypertension of any aetiology and is characterised by accelerated microvascular damage with necrosis in the walls of small arteries and arterioles ('fibrinoid necrosis') and by intravascular thrombosis. The diagnosis is based on evidence of high BP and rapidly progressive end organ damage, such as retinopathy (grade 3 or 4), renal dysfunction (especially proteinuria) and/or hypertensive encephalopathy (see above). Left ventricular failure may occur and, if this is untreated, death occurs within months.

Investigations

All hypertensive patients should undergo a limited number of investigations (Box 18.91). Additional investigations are appropriate in selected patients (Box 18.92).

Management

Quantification of cardiovascular risk

The sole objective of antihypertensive therapy is to reduce the incidence of adverse cardiovascular events, particularly coronary heart disease, stroke and heart failure. The relative benefit of antihypertensive therapy (approximately 30% reduction in risk of stroke and 20% reduction in risk of coronary heart disease, Box 18.93) is similar in all patient groups, so the absolute benefit of treatment (total number of events prevented) is greatest in those at highest risk. For example, to extrapolate from the Medical Research Council (MRC) Mild Hypertension Trial (1985), 566 young patients would have to be treated with bendroflumethiazide for 1 year to prevent 1 stroke, while in the MRC trial of antihypertensive treatment in the elderly (1992), 1 stroke was prevented for every 286 patients treated for 1 year.

A formal estimate of absolute cardiovascular risk which takes account of all the relevant risk factors may help to determine whether the likely benefits of

18.91 Hypertension: investigation of all patients

- Urinalysis for blood, protein and glucose
- Blood urea, electrolytes and creatinine
 - N.B.** Hypokalaemic alkalosis may indicate primary hyperaldosteronism but is usually due to diuretic therapy
- Blood glucose
- Serum total and HDL cholesterol
- 12-lead ECG (left ventricular hypertrophy, coronary artery disease)

18.92 Hypertension: investigation of selected patients

- Chest X-ray: to detect cardiomegaly, heart failure, coarctation of the aorta
- Ambulatory BP recording: to assess borderline or 'white coat' hypertension
- Echocardiogram: to detect or quantify left ventricular hypertrophy
- Renal ultrasound: to detect possible renal disease
- Renal angiography: to detect or confirm presence of renal artery stenosis
- Urinary catecholamines: to detect possible phaeochromocytoma (p. 779)
- Urinary cortisol and dexamethasone suppression test: to detect possible Cushing's syndrome (p. 770)
- Plasma renin activity and aldosterone: to detect possible primary aldosteronism (p. 777)

EBM 18.93 Benefit of antihypertensive drug therapy

'Diuretics or β -blockers have been shown to reduce the risk of coronary heart disease by 16%, stroke by 38%, cardiovascular death by 21% and all causes of mortality by 13%. The effects of ACE inhibitors and calcium antagonists are similar. NNT_b varies greatly according to the absolute baseline risk of cardiovascular disease.'

- Blood Pressure Lowering Treatment Trialists' Collaboration. *Lancet* 2003; 362:1527–1535.

therapy will outweigh its costs and hazards. A variety of risk algorithms are available for this purpose (see Fig. 18.61, p. 580). Most of the excess morbidity and mortality associated with hypertension is attributable to coronary heart disease and many treatment guidelines are therefore based on estimates of the 10-year coronary heart disease risk. Total cardiovascular risk can be estimated by multiplying coronary heart disease risk by 4/3 (i.e. if coronary heart disease risk is 30%, cardiovascular risk is 40%). The value of this approach can be illustrated by comparing the two hypothetical cases on page 579.

Threshold for intervention

Systolic BP and diastolic BP are both powerful predictors of cardiovascular risk. The British Hypertension Society management guidelines therefore utilise both readings, and treatment should be initiated if they exceed the given threshold (Fig. 18.84).

Patients with diabetes or cardiovascular disease are at particularly high risk and the threshold for initiating antihypertensive therapy is therefore lower ($\geq 140/90$ mmHg) in these patient groups. The thresholds for treatment in the elderly are the same as for younger patients (Box 18.94).

Treatment targets

The optimum BP for reduction of major cardiovascular events has been found to be 139/83 mmHg, and even lower in patients with diabetes mellitus. Moreover, reducing BP below this level causes no harm. The targets suggested by the British Hypertension Society (Box 18.95) are ambitious. Primary care strategies have been devised to improve screening and detection of hypertension that, in the past, remained undetected in up to half of affected individuals. Application of new treatment guidelines should help establish patients on appropriate treatment, and allow step-up of treatment if lifestyle modification and first-line drug therapy fail to control patients' BP.

Patients taking antihypertensive therapy require follow-up at 3-monthly intervals to monitor BP, minimise side-effects and reinforce lifestyle advice.

Non-drug therapy

Appropriate lifestyle measures may obviate the need for drug therapy in patients with borderline hypertension, reduce the dose and/or the number of drugs required in patients with established hypertension, and directly reduce cardiovascular risk.

Correcting obesity, reducing alcohol intake, restricting salt intake, taking regular physical exercise and increasing consumption of fruit and vegetables can all lower BP. Moreover, quitting smoking, eating oily fish and adopting a diet that is low in saturated fat may produce further reductions in cardiovascular risk.

Antihypertensive drugs

- **Thiazide and other diuretics.** The mechanism of action of these drugs is incompletely understood and it may take up to a month for the maximum effect to be observed. An appropriate daily dose is 2.5 mg bendroflumethiazide or 0.5 mg cyclopenthiazide. More potent loop diuretics, such as furosemide 40 mg daily or bumetanide 1 mg daily, have few

advantages over thiazides in the treatment of hypertension unless there is substantial renal impairment or they are used in conjunction with an ACE inhibitor.

- **ACE inhibitors** (e.g. enalapril 20 mg daily, ramipril 5–10 mg daily or lisinopril 10–40 mg daily). These inhibit the conversion of angiotensin I to angiotensin II and are usually well tolerated. They should be used with particular care in patients with impaired renal function or renal artery stenosis because they can reduce the filtration pressure in the glomeruli and precipitate renal failure. Electrolytes and creatinine should be checked before and 1–2 weeks after commencing therapy. Side-effects include first-dose hypotension, cough, rash, hyperkalaemia and renal dysfunction.
- **Angiotensin receptor blockers** (e.g. irbesartan 150–300 mg daily, valsartan 40–160 mg daily). These block the angiotensin II type I receptor and have similar effects to ACE inhibitors; however, they do not cause cough and are better tolerated.
- **Calcium channel antagonists.** The dihydropyridines (e.g. amlodipine 5–10 mg daily, nifedipine 30–90 mg daily) are effective and usually well-tolerated antihypertensive drugs that are particularly useful in older people. Side-effects include flushing, palpitations and fluid retention. The rate-limiting calcium channel antagonists (e.g. diltiazem 200–300 mg daily, verapamil 240 mg daily) can be useful when hypertension coexists with angina but they may cause bradycardia. The main side-effect of verapamil is constipation.
- **Beta-blockers.** These are no longer used as first-line antihypertensive therapy, except in patients with another indication for the drug (e.g. angina).

18.94 Hypertension in old age

- **Prevalence:** affects more than half of all people over the age of 60 (including isolated systolic hypertension).
- **Risks:** hypertension is the most important risk factor for MI, heart failure and stroke in older people.
- **Benefit of treatment:** absolute benefit from antihypertensives is greatest in older people (at least up to age 80 years).
- **Target BP:** similar to that for younger patients.
- **Tolerance of treatment:** antihypertensives are tolerated as well as in younger patients.
- **Drug of choice:** low-dose thiazides, but in the presence of coexistent disease (e.g. gout, diabetes) other agents may be more appropriate.

18.95 Optimal target blood pressures during antihypertensive treatment: BHS guidelines

	No diabetes	Diabetes
Clinic measurements	< 140/85	< 130/80
Mean day-time ambulatory or home measurement	< 130/80	< 130/75
N.B. Both systolic and diastolic values should be attained.		

Fig. 18.84 Management of hypertension: British Hypertension Society guidelines. *Assessed with risk chart for cardiovascular disease; see Fig. 18.61. (CVD = cardiovascular disease)

Metoprolol (100–200 mg daily), atenolol (50–100 mg daily) and bisoprolol (5–10 mg daily) preferentially block cardiac β_1 -adrenoceptors, as opposed to the β_2 -adrenoceptors that mediate vasodilatation and bronchodilatation.

- **Labetalol and carvedilol.** Labetalol (200 mg–2.4 g daily in divided doses) and carvedilol (6.25–25 mg 12-hourly) are combined β - and α -adrenoceptor antagonists which are sometimes more effective than pure β -blockers. Labetalol can be used as an infusion in malignant phase hypertension (see below).

- **Other drugs.** A variety of vasodilators may be used. These include the α_1 -adrenoceptor antagonists (α -blockers), such as prazosin (0.5–20 mg daily in divided doses), indoramin (25–100 mg 12-hourly) and doxazosin (1–16 mg daily), and drugs that act directly on vascular smooth muscle, such as hydralazine (25–100 mg 12-hourly) and minoxidil (10–50 mg daily). Side-effects include first-dose and postural hypotension, headache, tachycardia and fluid retention. Minoxidil also causes increased facial hair and is therefore unsuitable for female patients.

Choice of antihypertensive drug

Trials that have compared thiazides, calcium antagonists, ACE inhibitors and angiotensin receptor blockers have not shown consistent differences in outcome, efficacy, side-effects or quality of life. Beta-blockers, which previously featured as first-line therapy in guidelines, have a weaker evidence base (see Box 18.93). The choice of antihypertensive therapy is initially dictated by the patient's age and ethnic background, although cost and convenience will affect the exact drug and preparation used. Response to initial therapy and side-effects dictate subsequent treatment. Comorbid conditions also have an influence on initial drug selection (Box 18.96); for example, a β -blocker might be the most appropriate treatment for a patient with angina. Thiazide diuretics and dihydropyridine calcium channel antagonists are the most suitable drugs for the treatment of high BP in older people.

Although some patients can be satisfactorily treated with a single antihypertensive drug, a combination

of drugs is often required to achieve optimal BP control (Fig. 18.85). Combination therapy may be desirable for other reasons; for example, low-dose therapy with two drugs may produce fewer unwanted effects than treatment with the maximum dose of a single drug. Some drug combinations have complementary or synergistic actions; for example, thiazides increase activity of the renin-angiotensin system while ACE inhibitors block it.

Emergency treatment of accelerated phase or malignant hypertension

In accelerated phase hypertension, lowering BP too quickly may compromise tissue perfusion (due to altered autoregulation) and can cause cerebral damage, including occipital blindness, and precipitate coronary or renal insufficiency. Even in the presence of cardiac failure or hypertensive encephalopathy, a controlled reduction to a level of about 150/90 mmHg over a period of 24–48 hours is ideal.

18.96 The influence of comorbidity on the choice of antihypertensive drug therapy				
Class of drug	Compelling indications	Possible indications	Caution	Compelling contraindications
α-blockers	Benign prostatic hypertrophy	–	Postural hypotension, heart failure ¹	Urinary incontinence
ACE inhibitors	Heart failure Left ventricular dysfunction, post-MI or established coronary heart disease Type 1 diabetic nephropathy Secondary stroke prevention ⁴	Chronic renal disease ² Type 2 diabetic nephropathy	Renal impairment ² Peripheral vascular disease ³	Pregnancy Renovascular disease ²
Angiotensin II receptor blockers	ACE inhibitor intolerance Type 2 diabetic nephropathy Hypertension with left ventricular hypertrophy Heart failure in ACE-intolerant patients, after MI	Left ventricular dysfunction after MI Intolerance of other antihypertensive drugs Proteinuric renal disease, chronic renal disease ² Heart failure	Renal impairment ² Peripheral vascular disease ³	Pregnancy
β-blockers	MI, angina Heart failure ⁵		Heart failure ⁵ Peripheral vascular disease Diabetes (except with coronary heart disease)	Asthma or chronic obstructive pulmonary disease Heart block
Calcium channel blockers (dihydropyridine)	Older patients, isolated systolic hypertension	Angina	–	–
Calcium channel blockers (rate-limiting)	Angina	Older patients	Combination with β -blockade	Atrioventricular block, heart failure
Thiazides or thiazide-like diuretics	Older patients, isolated systolic hypertension, heart failure, secondary stroke prevention	–	–	Gout ⁶

¹In heart failure when used as monotherapy.
²ACE inhibitors or angiotensin II receptor blockers may be beneficial in chronic renal failure and those with renovascular disease but should be used with caution, close supervision and specialist advice when there is established and significant renal impairment.
³Caution with ACE inhibitors and angiotensin II receptor blockers in peripheral vascular disease because of association with renovascular disease.
⁴In combination with a thiazide or thiazide-like diuretic.
⁵Beta-blockers are used increasingly to treat stable heart failure but may worsen acute heart failure.
⁶Thiazides or thiazide-like diuretics may sometimes be necessary to control BP in people with a history of gout, ideally used in combination with allopurinol.

Fig. 18.85 Antihypertensive drug combinations. Black patients are those of African or Caribbean descent, and not mixed-race, Asian or Chinese patients. (A = ACE inhibitor (consider angiotensin II receptor antagonist if ACE-intolerant); C = calcium channel blocker; D = thiazide-type diuretic)

In most patients, it is possible to avoid parenteral therapy and bring BP under control with bed rest and oral drug therapy. Intravenous or intramuscular labetalol (2mg/min to a maximum of 200mg), intravenous glyceryl trinitrate (0.6–1.2mg/hour), intramuscular hydralazine (5 or 10mg aliquots repeated at half-hourly intervals) and intravenous sodium nitroprusside (0.3–1.0 µg/kg body weight/min) are all effective but require careful supervision, preferably in a high-dependency unit.

Refractory hypertension

The common causes of treatment failure in hypertension are non-adherence to drug therapy, inadequate therapy, and failure to recognise an underlying cause such as renal artery stenosis or pheochromocytoma; of these, the first is by far the most prevalent. There is no easy solution to compliance problems but simple treatment regimens, attempts to improve rapport with the patient and careful supervision may all help.

Adjuvant drug therapy

- **Aspirin.** Antiplatelet therapy is a powerful means of reducing cardiovascular risk but may cause bleeding, particularly intracerebral haemorrhage, in a small number of patients. The benefits are thought to outweigh the risks in hypertensive patients aged 50 or over who have well-controlled BP and either target organ damage, diabetes or a 10-year coronary heart disease risk of $\geq 15\%$ (or 10-year cardiovascular disease risk of $\geq 20\%$).
- **Statins.** Treating hyperlipidaemia can produce a substantial reduction in cardiovascular risk. These drugs are strongly indicated in patients who have

established vascular disease, or hypertension with a high ($\geq 20\%$ in 10 years) risk of developing cardiovascular disease (p. 579).

DISEASES OF THE HEART VALVES

A diseased valve may be narrowed (stenosed) or may fail to close adequately, and thus permit regurgitation of blood. 'Incompetence' is a less precise term for regurgitation or reflux, and should be avoided. Box 18.97 gives the principal causes of valve disease.

18.97 Principal causes of valve disease

Valve regurgitation

- Congenital
- Acute rheumatic carditis
- Chronic rheumatic carditis
- Infective endocarditis
- Valve ring dilatation (e.g. dilated cardiomyopathy)
- Syphilitic aortitis
- Traumatic valve rupture
- Senile degeneration
- Damage to chordae and papillary muscles (e.g. MI)

Valve stenosis

- Congenital
- Rheumatic carditis
- Senile degeneration

Doppler echocardiography is the most useful technique for assessing valvular heart disease (p. 532) but may also detect minor and even 'physiological' abnormalities, such as trivial mitral regurgitation. Disease of the heart valves may progress with time and selected patients require regular review every 1 or 2 years, to ensure that deterioration is detected before complications such as heart failure ensue. Patients with valvular heart disease are susceptible to bacterial endocarditis, which can be prevented by good dental hygiene. The routine use of antibiotic prophylaxis at times of bacteraemia, such as dental extraction, is no longer recommended.

Rheumatic heart disease

Acute rheumatic fever

Incidence and pathogenesis

Acute rheumatic fever usually affects children (most commonly between 5 and 15 years) or young adults, and has become very rare in Western Europe and North America. However, it remains endemic in parts of Asia, Africa and South America, with an annual incidence in some countries of > 100 per 100 000, and is the most common cause of acquired heart disease in childhood and adolescence.

The condition is triggered by an immune-mediated delayed response to infection with specific strains of group A streptococci, which have antigens that may cross-react with cardiac myosin and sarcolemmal membrane protein. Antibodies produced against the streptococcal antigens cause inflammation in the endocardium, myocardium and pericardium, as well as the joints and skin. Histologically, fibrinoid degeneration is seen in the collagen of connective tissues. Aschoff nodules are pathognomonic and occur only in the heart. They are composed of multinucleated giant cells surrounded by

macrophages and T lymphocytes, and are not seen until the subacute or chronic phases of rheumatic carditis.

Clinical features

Acute rheumatic fever is a multisystem disorder that usually presents with fever, anorexia, lethargy and joint pain, 2–3 weeks after an episode of streptococcal pharyngitis. There may, however, be no history of sore throat. Arthritis occurs in approximately 75% of patients. Other features include rashes, carditis and neurological changes (Fig. 18.86). The diagnosis, made using the revised Jones criteria (Box 18.98), is based upon two or more major manifestations, or one major and two or more minor manifestations, along with evidence of preceding streptococcal infection. Only about 25% of patients will have a positive culture for group A streptococcus at the time of diagnosis because there is a latent period between infection and presentation. Serological evidence of recent streptococcal infection with a raised antistreptolysin O (ASO) antibody titre is helpful. A presumptive diagnosis of acute rheumatic fever can be made without evidence of preceding streptococcal infection in cases of isolated chorea or pancarditis, if other causes for these have been excluded. In cases of established rheumatic heart disease or prior rheumatic fever, a diagnosis of acute rheumatic fever can be made based only on the presence of

Fig. 18.86 Clinical features of rheumatic fever. Bold labels indicate Jones major criteria. (CCF = congestive cardiac failure)

18.98 Jones criteria for the diagnosis of rheumatic fever

Major manifestations

- Carditis
- Polyarthritis
- Chorea
- Erythema marginatum
- Subcutaneous nodules

Minor manifestations

- Fever
- Arthralgia
- Previous rheumatic fever
- Raised ESR or CRP
- Leucocytosis
- First-degree AV block

Plus

- Supporting evidence of preceding streptococcal infection: recent scarlet fever, raised antistreptolysin O or other streptococcal antibody titre, positive throat culture

N.B. Evidence of recent streptococcal infection is particularly important if there is only one major manifestation.

multiple minor criteria and evidence of preceding group A streptococcal pharyngitis.

Carditis

A 'pancarditis' involves the endocardium, myocardium and pericardium to varying degrees. Its incidence declines with increasing age, ranging from 90% at 3 years to around 30% in adolescence. It may manifest as breathlessness (due to heart failure or pericardial effusion), palpitations or chest pain (usually due to pericarditis or pancarditis). Other features include tachycardia, cardiac enlargement and new or changed cardiac murmurs. A soft systolic murmur due to mitral regurgitation is very common. A soft mid-diastolic murmur (the Carey Coombs murmur) is typically due to valvulitis, with nodules forming on the mitral valve leaflets. Aortic regurgitation occurs in about 50% of cases but the tricuspid and pulmonary valves are rarely involved. Pericarditis may cause chest pain, a pericardial friction rub and precordial tenderness. Cardiac failure may be due to myocardial dysfunction or valvular regurgitation. ECG changes commonly include ST and T wave changes. Conduction defects sometimes occur and may cause syncope.

Arthritis

This is the most common major manifestation and tends to occur early when streptococcal antibody titres are high. An acute painful asymmetric and migratory inflammation of the large joints typically affects the knees, ankles, elbows and wrists. The joints are involved in quick succession and are usually red, swollen and tender for between a day and 4 weeks. The pain characteristically responds to aspirin; if not, the diagnosis is in doubt.

Skin lesions

Erythema marginatum occurs in < 5% of patients. The lesions start as red macules (blotches) that fade in the centre but remain red at the edges and occur mainly on the trunk and proximal extremities but not the face. The resulting red rings or 'margins' may coalesce or overlap (see Fig. 18.86). Subcutaneous nodules occur in 5–7% of patients. They are small (0.5–2.0cm), firm and painless, and are best felt over extensor surfaces of bone or tendons. They typically appear more than 3 weeks after

the onset of other manifestations and therefore help to confirm rather than make the diagnosis.

Other systemic manifestations are rare but include pleurisy, pleural effusion and pneumonia.

Sydenham's chorea (St Vitus dance)

This is a late neurological manifestation that appears at least 3 months after the episode of acute rheumatic fever, when all the other signs may have disappeared. It occurs in up to one-third of cases and is more common in females. Emotional lability may be the first feature and is typically followed by purposeless involuntary choreiform movements of the hands, feet or face. Speech may be explosive and halting. Spontaneous recovery usually occurs within a few months. Approximately one-quarter of affected patients will go on to develop chronic rheumatic valve disease.

Investigations

The ESR and CRP are useful for monitoring progress of the disease (Box 18.99). Positive throat swab cultures are obtained in only 10–25% of cases. ASO titres are normal in one-fifth of adult cases of rheumatic fever and most cases of chorea. Echocardiography typically shows mitral regurgitation with dilatation of the mitral annulus and prolapse of the anterior mitral leaflet, and may also show aortic regurgitation and pericardial effusion.

18.99 Investigations in acute rheumatic fever	
Evidence of a systemic illness (non-specific)	
<ul style="list-style-type: none"> Leucocytosis, raised ESR and CRP 	
Evidence of preceding streptococcal infection (specific)	
<ul style="list-style-type: none"> Throat swab culture: group A β-haemolytic streptococci (also from family members and contacts) Antistreptolysin O antibodies (ASO titres): rising titres, or levels of > 200 U (adults) or > 300 U (children) 	
Evidence of carditis	
<ul style="list-style-type: none"> Chest X-ray: cardiomegaly; pulmonary congestion ECG: first- and rarely second-degree AV block; features of pericarditis; T-wave inversion; reduction in QRS voltages Echocardiography: cardiac dilatation and valve abnormalities 	

Management of the acute attack

A single dose of benzyl penicillin 1.2 million U i.m. or oral phenoxymethylpenicillin 250 mg 6-hourly for 10 days should be given on diagnosis to eliminate any residual streptococcal infection. If the patient is penicillin-allergic, erythromycin or a cephalosporin can be used. Treatment is then directed towards limiting cardiac damage and relieving symptoms.

Bed rest and supportive therapy

Bed rest is important, as it lessens joint pain and reduces cardiac workload. The duration should be guided by symptoms along with temperature, leucocyte count and ESR, and should be continued until these have settled. Patients can then return to normal physical activity but strenuous exercise should be avoided in those who have had carditis.

Cardiac failure should be treated as necessary. Some patients, particularly those in early adolescence, develop a fulminant form of the disease with severe mitral

regurgitation and sometimes concomitant aortic regurgitation. If heart failure in these cases does not respond to medical treatment, valve replacement may be necessary and is often associated with a dramatic decline in rheumatic activity. AV block is seldom progressive and pacemaker insertion rarely needed.

Aspirin

This will usually relieve the symptoms of arthritis rapidly and a response within 24 hours helps to confirm the diagnosis. A reasonable starting dose is 60 mg/kg body weight/day, divided into six doses. In adults, 100 mg/kg per day may be needed up to the limits of tolerance or a maximum of 8 g per day. Mild toxic effects include nausea, tinnitus and deafness; vomiting, tachypnoea and acidosis are more serious. Aspirin should be continued until the ESR has fallen and then gradually tailed off.

Corticosteroids

These produce more rapid symptomatic relief than aspirin and are indicated in cases with carditis or severe arthritis. There is no evidence that long-term steroids are beneficial. Prednisolone, 1.0–2.0 mg/kg per day in divided doses, should be continued until the ESR is normal then tailed off.

Secondary prevention

Patients are susceptible to further attacks of rheumatic fever if another streptococcal infection occurs, and long-term prophylaxis with penicillin should be given as benzathine penicillin 1.2 million U i.m. monthly (if compliance is in doubt) or oral phenoxymethylpenicillin 250 mg 12-hourly. Sulfadiazine or erythromycin may be used if the patient is allergic to penicillin; sulphonamides prevent infection but are not effective in the eradication of group A streptococci. Further attacks of rheumatic fever are unusual after the age of 21, when treatment may be stopped. However, it should be extended if an attack has occurred in the last 5 years, or if the patient lives in an area of high prevalence or has an occupation (e.g. teaching) with high exposure to streptococcal infection. In those with residual heart disease, prophylaxis should continue until 10 years after the last episode or 40 years of age, whichever is longer. Long-term antibiotic prophylaxis prevents another attack of acute rheumatic fever but does not protect against infective endocarditis.

Chronic rheumatic heart disease

Chronic valvular heart disease develops in at least half of those affected by rheumatic fever with carditis. Two-thirds of cases occur in women. Some episodes of rheumatic fever pass unrecognised and it is only possible to elicit a history of rheumatic fever or chorea in about half of all patients with chronic rheumatic heart disease.

The mitral valve is affected in more than 90% of cases; the aortic valve is the next most frequently affected, followed by the tricuspid and then the pulmonary valve. Isolated mitral stenosis accounts for about 25% of all cases of rheumatic heart disease, and an additional 40% have mixed mitral stenosis and regurgitation. Valve disease may be symptomatic during fulminant forms of acute rheumatic fever but may remain asymptomatic for many years.

Pathology

The main pathological process in chronic rheumatic heart disease is progressive fibrosis. The heart valves are predominantly affected but involvement of the pericardium and myocardium may contribute to heart failure and conduction disorders. Fusion of the mitral valve commissures and shortening of the chordae tendineae may lead to mitral stenosis with or without regurgitation. Similar changes in the aortic and tricuspid valves produce distortion and rigidity of the cusps, leading to stenosis and regurgitation. Once a valve has been damaged, the altered haemodynamic stresses perpetuate and extend the damage, even in the absence of a continuing rheumatic process.

Mitral valve disease

Mitral stenosis

Aetiology and pathophysiology

Mitral stenosis is almost always rheumatic in origin, although in older people it can be caused by heavy calcification of the mitral valve apparatus. There is also a rare form of congenital mitral stenosis.

In rheumatic mitral stenosis, the mitral valve orifice is slowly diminished by progressive fibrosis, calcification of the valve leaflets, and fusion of the cusps and subvalvular apparatus. The flow of blood from LA to LV is restricted and left atrial pressure rises, leading to pulmonary venous congestion and breathlessness. There is dilatation and hypertrophy of the LA, and left ventricular filling becomes more dependent on left atrial contraction.

Any increase in heart rate shortens diastole when the mitral valve is open and produces a further rise in left atrial pressure. Situations that demand an increase in cardiac output also increase left atrial pressure, so exercise and pregnancy are poorly tolerated.

The mitral valve orifice is normally about 5 cm² in diastole and may be reduced to 1 cm² in severe mitral stenosis. Patients usually remain asymptomatic until the stenosis is < 2 cm². Reduced lung compliance, due to chronic pulmonary venous congestion, contributes to breathlessness and a low cardiac output may cause fatigue.

Atrial fibrillation due to progressive dilatation of the LA is very common. Its onset often precipitates pulmonary oedema because the accompanying tachycardia and loss of atrial contraction lead to marked haemodynamic deterioration with a rapid rise in left atrial pressure. In contrast, a more gradual rise in left atrial pressure tends to cause an increase in pulmonary vascular resistance, which leads to pulmonary hypertension that may protect the patient from pulmonary oedema. Pulmonary hypertension leads to right ventricular hypertrophy and dilatation, tricuspid regurgitation and right heart failure.

Fewer than 20% of patients remain in sinus rhythm; many of these have a small fibrotic LA and severe pulmonary hypertension.

Clinical features

Effort-related dyspnoea is usually the dominant symptom (Box 18.100). Exercise tolerance typically diminishes very slowly over many years and patients often do not appreciate the extent of their disability.

18.100 Clinical features (and their causes) in mitral stenosis

Symptoms

- Breathlessness (pulmonary congestion)
- Fatigue (low cardiac output)
- Oedema, ascites (right heart failure)
- Palpitation (atrial fibrillation)
- Haemoptysis (pulmonary congestion, pulmonary embolism)
- Cough (pulmonary congestion)
- Chest pain (pulmonary hypertension)
- Thromboembolic complications (e.g. stroke, ischaemic limb)

Signs

- Atrial fibrillation
- Mitral facies
- Auscultation
 - Loud first heart sound, opening snap
 - Mid-diastolic murmur
- Crepitations, pulmonary oedema, effusions (raised pulmonary capillary pressure)
- RV heave, loud P₂ (pulmonary hypertension)

Eventually symptoms occur at rest. Acute pulmonary oedema or pulmonary hypertension can lead to haemoptysis. All patients with mitral stenosis, and particularly those with atrial fibrillation, are at risk from left atrial thrombosis and systemic thromboembolism. Prior to the advent of anticoagulant therapy, emboli caused one-quarter of all deaths.

The physical signs of mitral stenosis are often found before symptoms develop and their recognition is of particular importance in pregnancy. The forces that open and close the mitral valve increase as left atrial pressure rises. The first heart sound (S₁) is therefore loud and can be palpable (tapping apex beat). An opening snap may be audible and moves closer to the second sound (S₂) as the stenosis becomes more severe and left atrial pressure rises. However, the first heart sound and opening snap may be inaudible if the valve is heavily calcified.

Turbulent flow produces the characteristic low-pitched mid-diastolic murmur and sometimes a thrill (Fig. 18.87). The murmur is accentuated by exercise and during atrial systole (pre-systolic accentuation). Early in the disease, a pre-systolic murmur may be the only auscultatory abnormality, but in patients with symptoms the murmur extends from the opening snap to the first heart sound. Coexisting mitral regurgitation causes a pansystolic murmur that radiates towards the axilla.

Pulmonary hypertension may ultimately lead to right ventricular hypertrophy and dilatation with secondary tricuspid regurgitation, which causes a systolic murmur and giant 'v waves' in the venous pulse.

Investigations

The ECG may show either atrial fibrillation or bifid P waves (P mitrale) associated with left atrial hypertrophy (Box 18.101). A typical chest X-ray is shown in Figure 18.10 (p. 532). Doppler echocardiography provides the definitive evaluation of mitral stenosis (see Fig. 18.87). Cardiac catheterisation is used in the assessment of coexisting conditions.

Fig. 18.87 Mitral stenosis: murmur and the diastolic pressure gradient between LA and LV. (Mean gradient is reflected by the area between LA and LV in diastole.) The first heart sound is loud, and there is an opening snap (OS) and mid-diastolic murmur (MDM) with pre-systolic accentuation. **A** Echocardiogram showing reduced opening of the mitral valve in diastole. **B** Colour Doppler showing turbulent flow.

18.101 Investigations in mitral stenosis

ECG

- P mitrale or atrial fibrillation
- Right ventricular hypertrophy: tall R waves in V_1 – V_3

Chest X-ray

- Enlarged LA and appendage
- Signs of pulmonary venous congestion

Echo

- Thickened immobile cusps
- Reduced valve area
- Reduced rate of diastolic filling of LV
- Enlarged LA

Doppler

- Pressure gradient across mitral valve
- Pulmonary artery pressure
- Left ventricular function

Cardiac catheterisation

- Coronary artery disease
- Mitral stenosis and regurgitation
- Pulmonary artery pressure

Management

Patients with minor symptoms should be treated medically. Intervention by balloon valvuloplasty, mitral valvotomy or mitral valve replacement should be considered if the patient remains symptomatic despite medical treatment or if pulmonary hypertension develops.

Medical management

This consists of anticoagulation to reduce the risk of systemic embolism, ventricular rate control (digoxin, β -blockers or rate-limiting calcium antagonists) in atrial fibrillation, and diuretic therapy to control pulmonary congestion. Antibiotic prophylaxis against infective endocarditis is no longer routinely recommended.

Mitral balloon valvuloplasty and valve replacement

Valvuloplasty is the treatment of choice if specific criteria are fulfilled (Box 18.102 and Fig. 18.15, p. 536), although surgical closed or open mitral valvotomy are acceptable alternatives. Patients who have undergone mitral valvuloplasty or valvotomy should be followed up at 1–2-yearly intervals because restenosis may occur. Clinical symptoms and signs are a guide to the severity of mitral restenosis but Doppler echocardiography provides a more accurate assessment.

18.102 Criteria for mitral valvuloplasty*

- Significant symptoms
- Isolated mitral stenosis
- No (or trivial) mitral regurgitation
- Mobile, non-calcified valve/subvalve apparatus on echo
- LA free of thrombus

*For comprehensive guidelines on valvular heart disease see www.acc.org.

Valve replacement is indicated if there is substantial mitral reflux or if the valve is rigid and calcified (p. 628).

Mitral regurgitation

Aetiology and pathophysiology

Rheumatic disease is the principal cause in countries where rheumatic fever is common but elsewhere, including in the UK, other causes are more important (Box 18.103). Mitral regurgitation may also follow mitral valvotomy or valvuloplasty.

Chronic mitral regurgitation causes gradual dilatation of the LA with little increase in pressure and therefore relatively few symptoms. Nevertheless, the LV dilates slowly and the left ventricular diastolic and left atrial

18.103 Causes of mitral regurgitation

- Mitral valve prolapse
- Dilatation of the LV and mitral valve ring (e.g. coronary artery disease, cardiomyopathy)
- Damage to valve cusps and chordae (e.g. rheumatic heart disease, endocarditis)
- Ischaemia or infarction of the papillary muscle
- MI

pressures gradually increase as a result of chronic volume overload of the LV. In contrast, acute mitral regurgitation causes a rapid rise in left atrial pressure (because left atrial compliance is normal) and marked symptomatic deterioration.

Mitral valve prolapse

This is also known as 'floppy' mitral valve and is one of the more common causes of mild mitral regurgitation (Fig. 18.88). It is caused by congenital anomalies or degenerative myxomatous changes, and is sometimes a feature of connective tissue disorders such as Marfan's syndrome (p. 602).

Fig. 18.88 Mitral regurgitation: murmur and systolic wave in left atrial pressure. The first sound is normal or soft and merges with a pansystolic murmur (PSM) extending to the second heart sound. A third heart sound occurs with severe regurgitation. **[A]** A transoesophageal echocardiogram shows mitral valve prolapse, with one leaflet bulging towards the LA (arrow). **[B]** This results in a jet of mitral regurgitation on colour Doppler (arrow).

In its mildest forms, the valve remains competent but bulges back into the atrium during systole, causing a midsystolic click but no murmur. In the presence of a regurgitant valve, the click is followed by a late systolic murmur which lengthens as the regurgitation becomes more severe. A click is not always audible and the physical signs may vary with both posture and respiration. Progressive elongation of the chordae tendineae leads to increasing mitral regurgitation, and if chordal rupture occurs, regurgitation suddenly becomes severe. This is rare before the fifth or sixth decade of life.

Mitral valve prolapse is associated with a variety of typically benign arrhythmias, atypical chest pain and a very small risk of embolic stroke or TIA. Nevertheless, the overall long-term prognosis is good.

Other causes of mitral regurgitation

Mitral valve function depends on the chordae tendineae and their papillary muscles; dilatation of the LV distorts the geometry of these and may cause mitral regurgitation (see Box 18.103). Dilated cardiomyopathy and heart failure from coronary artery disease are common causes of so-called 'functional' mitral regurgitation. Endocarditis is an important cause of acute mitral regurgitation.

Clinical features

Symptoms depend on how suddenly the regurgitation develops (Box 18.104). Chronic mitral regurgitation produces a symptom complex that is similar to that of mitral stenosis but sudden-onset mitral regurgitation usually presents with acute pulmonary oedema.

The regurgitant jet causes an apical systolic murmur (see Fig. 18.88) which radiates into the axilla and may be accompanied by a thrill. Increased forward flow through the mitral valve causes a loud third heart sound and even a short mid-diastolic murmur. The apex beat feels active and rocking due to left ventricular volume overload and is usually displaced to the left as a result of left ventricular dilatation.

Investigations

Atrial fibrillation is common, as a consequence of atrial dilatation. At cardiac catheterisation (Box 18.105), the severity of mitral regurgitation can be assessed by left ventriculography and by the size of the *v* (systolic) waves in the left atrial or pulmonary artery wedge pressure trace.

18.104 Clinical features (and their causes) in mitral regurgitation

Symptoms

- Dyspnoea (pulmonary venous congestion)
- Fatigue (low cardiac output)
- Palpitation (atrial fibrillation, increased stroke volume)
- Oedema, ascites (right heart failure)

Signs

- Atrial fibrillation/flutter
- Cardiomegaly: displaced hyperdynamic apex beat
- Apical pansystolic murmur \pm thrill
- Soft S1, apical S3
- Signs of pulmonary venous congestion (crepitations, pulmonary oedema, effusions)
- Signs of pulmonary hypertension and right heart failure

18.105 Investigations in mitral regurgitation

ECG

- Left atrial hypertrophy (if not in AF)
- Left ventricular hypertrophy

Chest X-ray

- Enlarged LA
- Enlarged LV
- Pulmonary venous congestion
- Pulmonary oedema (if acute)

Echo

- Dilated LA, LV
- Dynamic LV (unless myocardial dysfunction predominates)
- Structural abnormalities of mitral valve (e.g. prolapse)

Doppler

- Detects and quantifies regurgitation

Cardiac catheterisation

- Dilated LA, dilated LV, mitral regurgitation
- Pulmonary hypertension
- Coexisting coronary artery disease

Management

Mitral regurgitation of moderate severity can be treated medically (Box 18.106). In all patients with mitral regurgitation, high afterload may worsen the degree of regurgitation and hypertension should be treated with vasodilators such as ACE inhibitors. Patients should be reviewed at regular intervals because worsening symptoms, progressive cardiomegaly or echocardiographic evidence of deteriorating left ventricular function are indications for mitral valve replacement or repair. Mitral valve repair is used to treat mitral valve prolapse and offers many advantages when compared to mitral valve replacement, such that it is now advocated for severe regurgitation, even in asymptomatic patients, because results are excellent and early repair prevents irreversible left ventricular damage. Mitral regurgitation often accompanies the ventricular dilatation and dysfunction that are concomitants of coronary artery disease. If such patients are to undergo coronary bypass graft surgery, it is common practice to repair the valve and restore mitral valve function by inserting an annuloplasty ring to overcome annular dilatation and to bring the valve leaflets closer together. It can be difficult, however, to determine whether it is the ventricular dilatation or the mitral regurgitation that is the predominant problem. If ventricular dilatation is the underlying cause of mitral regurgitation, then mitral valve repair or replacement may actually worsen ventricular function, as the ventricle can no longer empty into the low-pressure LA.

18.106 Medical management of mitral regurgitation

- Diuretics
- Vasodilators, e.g. ACE inhibitors
- Digoxin if atrial fibrillation is present
- Anticoagulants if atrial fibrillation is present

Aortic valve disease

Aortic stenosis

Aetiology and pathophysiology

The likely aetiology depends on the age of the patient (Box 18.107). In congenital aortic stenosis, obstruction is present from birth or becomes apparent in infancy. With bicuspid aortic valves, obstruction may take years to develop as the valve becomes fibrotic and calcified. The aortic valve is the second most frequently affected by rheumatic fever, and commonly both the aortic and mitral valves are involved. In older people, a structurally normal tricuspid aortic valve may be affected by fibrosis and calcification, in a process that is histologically similar to that of atherosclerosis affecting the arterial wall. Haemodynamically significant stenosis develops slowly, typically occurring at 30–60 years in those with rheumatic disease, 50–60 in those with bicuspid aortic valves and 70–90 in those with degenerative calcific disease.

Cardiac output is initially maintained at the cost of a steadily increasing pressure gradient across the aortic valve. The LV becomes increasingly hypertrophied and coronary blood flow may then be inadequate; patients may therefore develop angina, even in the absence of concomitant coronary disease. The fixed outflow obstruction limits the increase in cardiac output required on exercise. Eventually, the LV can no longer overcome the outflow tract obstruction and pulmonary oedema supervenes. In contrast to mitral stenosis, which tends to progress very slowly, patients with aortic stenosis typically remain asymptomatic for many years but deteriorate rapidly when symptoms develop, and death usually ensues within 3–5 years of these.

18.107 Causes of aortic stenosis

Infants, children, adolescents

- Congenital aortic stenosis
- Congenital subvalvular aortic stenosis
- Congenital supravulvular aortic stenosis

Young adults to middle-aged

- Calcification and fibrosis of congenitally bicuspid aortic valve
- Rheumatic aortic stenosis

Middle-aged to elderly

- Senile degenerative aortic stenosis
- Calcification of bicuspid valve
- Rheumatic aortic stenosis

Clinical features

Aortic stenosis is commonly picked up in asymptomatic patients at routine clinical examination but the three cardinal symptoms are angina, breathlessness and syncope (Box 18.108). Angina arises because of the increased demands of the hypertrophied LV working against the high-pressure outflow tract obstruction, leading to a mismatch between oxygen demand and supply, but may also be due to coexisting coronary artery disease, especially in old age when it affects over 50% of patients. Exertional breathlessness suggests cardiac decompensation as a consequence of the excessive pressure overload

18.108 Clinical features of aortic stenosis

Symptoms

- Mild or moderate stenosis: usually asymptomatic
- Exertional dyspnoea
- Angina
- Exertional syncope
- Sudden death
- Episodes of acute pulmonary oedema

Signs

- Ejection systolic murmur
- Slow-rising carotid pulse
- Narrow pulse pressure
- Thrusting apex beat (LV pressure overload)
- Signs of pulmonary venous congestion (e.g. crepitations)

placed on the LV. Syncope usually occurs on exertion when cardiac output fails to rise to meet demand, leading to a fall in BP.

The characteristic clinical signs of severe aortic stenosis are shown in Box 18.108. A harsh ejection systolic murmur radiates to the neck, with a soft second heart sound, particularly in those with calcific valves. The murmur is often likened to a saw cutting wood and may (especially in older patients) have a musical quality like the 'mew' of a seagull (Fig. 18.89). The severity of aortic stenosis may be difficult to gauge clinically, as older patients with a non-compliant 'stiff' arterial system may have an apparently normal carotid upstroke in the presence of severe aortic stenosis. Milder degrees of stenosis may be difficult to distinguish from aortic sclerosis in which the valve is thickened or calcified but not obstructed. A careful examination should be made for other valve lesions, particularly in rheumatic heart disease when there is frequently concomitant mitral valve disease.

Investigations

In advanced cases, ECG features of hypertrophy (Box 18.109) are often gross (Fig. 18.90), and down-sloping ST segments and T inversion ('strain pattern') are seen in leads reflecting the LV. Nevertheless, especially in old age, the ECG can be normal despite severe stenosis. Echocardiography demonstrates restricted valve opening (Fig. 18.91) and Doppler assessment permits calculation of the systolic gradient across the aortic valve, from which the severity of stenosis can be assessed (see Fig. 18.12, p. 533). In patients with an impaired left ventricle, velocities across the aortic valve may be diminished because of a reduced stroke volume, while in those in whom aortic regurgitation is present, velocities are increased because of an increased stroke volume. In these circumstances, aortic valve area calculated from Doppler measurements is a more accurate assessment of severity. CT and MRI are useful in assessing the degree of valve calcification and stenosis respectively but are rarely necessary.

Management

Irrespective of the severity of valve stenosis, patients with asymptomatic aortic stenosis have a good immediate prognosis and conservative management is appropriate. Such patients should be kept under review, as the development of angina, syncope, symptoms of low cardiac output or heart failure has a poor prognosis and is an

Fig. 18.89 Aortic stenosis. Pressure traces show the systolic gradient between LV and aorta. The 'diamond-shaped' murmur is heard best with the diaphragm in the aortic outflow and also at the apex. An ejection click (EC) may be present in young patients with a bicuspid aortic valve but not in older patients with calcified valves. Aortic stenosis may lead to left ventricular hypertrophy with a fourth sound at the apex and post-stenotic dilatation of the aortic arch. Figure 18.12 (p. 533) shows the typical Doppler signal with aortic stenosis.

indication for prompt surgery. In practice, patients with moderate or severe stenosis are evaluated every 1–2 years with Doppler echocardiography to detect progression in severity; this is more rapid in older patients with heavily calcified valves.

Patients with symptomatic severe aortic stenosis should have prompt aortic valve replacement. Old age is not a contraindication to valve replacement and results are very good in experienced centres, even for those in their eighties (Box 18.110). Delay exposes the patient to the risk of sudden death or irreversible

18.109 Investigations in aortic stenosis

ECG

- Left ventricular hypertrophy (usually)
- Left bundle branch block

Chest X-ray

- May be normal; sometimes enlarged LV and dilated ascending aorta on PA view, calcified valve on lateral view

Echo

- Calcified valve with restricted opening, hypertrophied LV (see Fig. 18.91)

Doppler

- Measurement of severity of stenosis
- Detection of associated aortic regurgitation

Cardiac catheterisation

- Mainly to identify associated coronary artery disease
- May be used to measure gradient between LV and aorta

18.110 Aortic stenosis in old age

- **Incidence:** the most common form of valve disease affecting the very old.
- **Symptoms:** a common cause of syncope, angina and heart failure in the very old.
- **Signs:** because of increasing stiffening in the central arteries, low pulse pressure and a slow rising pulse may not be present.
- **Surgery:** can be successful in those aged 80 or more in the absence of comorbidity, but with a higher operative mortality. The prognosis without surgery is poor once symptoms have developed.
- **Valve replacement type:** a biological valve is often preferable to a mechanical, because this obviates the need for anticoagulation, and the durability of biological valves usually exceeds the patient's anticipated life expectancy.

Fig. 18.90 Left ventricular hypertrophy. QRS complexes in limb leads have increased amplitude with a very large R wave in V_5 and S wave in V_2 . There is ST depression and T-wave inversion in leads II, III, aVF, V_5 and V_6 : a 'left ventricular strain' pattern.

deterioration in ventricular function. Some patients with severe aortic stenosis deny symptoms, and if this could be due to a sedentary lifestyle, a careful exercise test may reveal symptoms on modest exertion. Aortic balloon valvuloplasty is useful in congenital aortic stenosis but is of no value in older patients with calcific aortic stenosis.

Anticoagulants are only required in patients who have atrial fibrillation or those who have had a valve replacement with a mechanical prosthesis.

Aortic regurgitation

Aetiology and pathophysiology

This condition is due to disease of the aortic valve cusps or dilatation of the aortic root (Box 18.111). The LV dilates and hypertrophies to compensate for the regurgitation. The stroke volume of the LV may eventually be doubled or trebled, and the major arteries are then conspicuously pulsatile. As the disease progresses, left ventricular diastolic pressure rises and breathlessness develops.

Clinical features

Until the onset of breathlessness, the only symptom may be an awareness of the heart beat (Box 18.112), particularly when lying on the left side, which results from the increased stroke volume. Paroxysmal nocturnal dyspnoea is sometimes the first symptom, and peripheral oedema or angina may occur. The characteristic murmur

Fig. 18.91 Two-dimensional echocardiogram comparing a normal subject with a patient with calcific aortic stenosis. **A** Normal subject in diastole; the aortic leaflets are closed and thin, and a point of coaptation is seen (arrow). **B** Calcific aortic stenosis in diastole; the aortic leaflets are thick and calcified (arrow). **C** Normal in systole; the aortic leaflets are open (arrows). **D** Calcific aortic stenosis in systole; the thickened leaflets have barely moved (arrows).

18.111 Causes of aortic regurgitation

Congenital

- Bicuspid valve or disproportionate cusps

Acquired

- Rheumatic disease
- Infective endocarditis
- Trauma
- Aortic dilatation (Marfan's syndrome, aneurysm, dissection, syphilis, ankylosing spondylitis)

is best heard to the left of the sternum during held expiration (Fig. 18.92); a thrill is rare. A systolic murmur due to the increased stroke volume is common and does not necessarily indicate stenosis. The regurgitant jet causes fluttering of the mitral valve and, if severe, causes partial closure of the anterior mitral leaflet leading to functional mitral stenosis and a soft mid-diastolic (Austin Flint) murmur.

In acute severe regurgitation (e.g. perforation of aortic cusp in endocarditis) there may be no time for compensatory left ventricular hypertrophy and dilatation to develop and the features of heart failure may predominate. In this situation, the classical signs of aortic regurgitation may be masked by tachycardia and an abrupt rise in left ventricular end-diastolic pressure; thus, the pulse pressure may be near normal and the diastolic murmur may be short or even absent.

Investigations

Regurgitation is detected by Doppler echocardiography (Box 18.113). In severe acute aortic regurgitation, the rapid rise in left ventricular diastolic pressure may cause premature mitral valve closure. Cardiac

18.112 Clinical features of aortic regurgitation (AR)

Symptoms**Mild to moderate AR**

- Often asymptomatic
- Awareness of heart beat, 'palpitations'

Severe AR

- Breathlessness
- Angina

Signs**Pulses**

- Large-volume or 'collapsing' pulse
- Low diastolic and increased pulse pressure
- Bounding peripheral pulses
- Capillary pulsation in nail beds: Quincke's sign
- Femoral bruit ('pistol shot'): Duroziez's sign
- Head nodding with pulse: de Musset's sign

Murmurs

- Early diastolic murmur
- Systolic murmur (increased stroke volume)
- Austin Flint murmur (soft mid-diastolic)

Other signs

- Displaced, heaving apex beat (volume overload)
- Presystolic impulse
- Fourth heart sound
- Crepitations (pulmonary venous congestion)

catheterisation and aortography can help in assessing the severity of regurgitation, and dilatation of the aorta and the presence of coexisting coronary artery disease. MRI is useful in assessing the degree and extent of aortic dilatation.

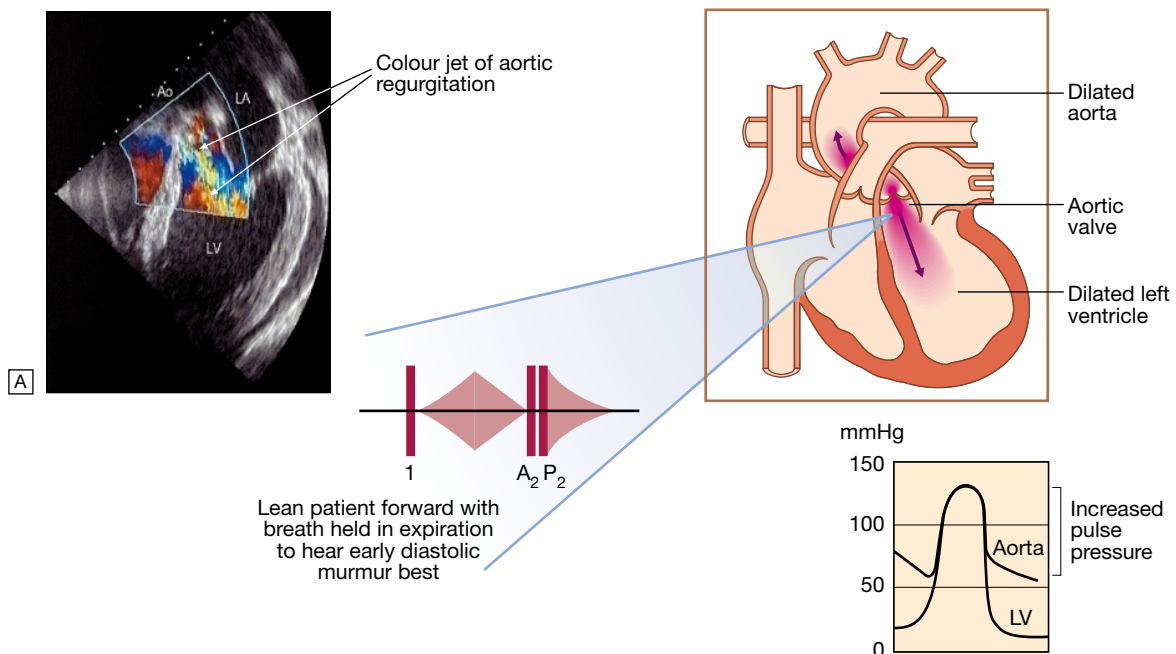

Fig. 18.92 Aortic regurgitation. The early diastolic murmur is best heard at the left sternal edge and may be accompanied by an ejection systolic murmur ('to and fro' murmur). The aortic arch and LV may become dilated. [A] Doppler echocardiogram with the regurgitant jet (arrows).

	18.113 Investigations in aortic regurgitation
ECG	<ul style="list-style-type: none"> Initially normal, later left ventricular hypertrophy and T-wave inversion
Chest X-ray	<ul style="list-style-type: none"> Cardiac dilatation, maybe aortic dilatation Features of left heart failure
Echo	<ul style="list-style-type: none"> Dilated LV Hyperdynamic LV Fluttering anterior mitral leaflet Doppler detects reflux
Cardiac catheterisation (may not be required)	<ul style="list-style-type: none"> Dilated LV Aortic regurgitation Dilated aortic root

Management

Treatment may be required for underlying conditions such as endocarditis or syphilis. Aortic valve replacement is indicated if aortic regurgitation causes symptoms, and this may need to be combined with aortic root replacement and coronary bypass surgery. Those with chronic aortic regurgitation can remain asymptomatic for many years because compensatory ventricular dilatation and hypertrophy occur, but should be advised to report the development of any symptoms of breathlessness or angina. Asymptomatic patients should also be followed up annually with echocardiography for evidence of increasing ventricular size. If this occurs or if the end-systolic dimension increases to ≥ 55 mm, then aortic valve replacement should be undertaken. Systolic BP should be controlled with vasodilating drugs such as nifedipine or ACE inhibitors. There is conflicting evidence regarding the need for aortic valve replacement in asymptomatic patients with severe aortic regurgitation. When aortic root dilatation is the cause of aortic regurgitation (e.g. Marfan's syndrome), aortic root replacement is usually necessary.

Tricuspid valve disease

Tricuspid stenosis

Aetiology

Tricuspid stenosis is usually rheumatic in origin and is seldom seen in developed countries. Tricuspid disease occurs in fewer than 5% of patients with rheumatic heart disease and nearly always in association with mitral and aortic valve disease. Tricuspid stenosis and regurgitation are also features of the carcinoid syndrome (p. 782).

Clinical features and investigations

Although the symptoms of mitral and aortic valve disease predominate, tricuspid stenosis may cause symptoms of right heart failure, including hepatic discomfort and peripheral oedema.

The main clinical feature is a raised JVP with a prominent *a* wave, and a slow *y* descent due to the loss of normal rapid right ventricular filling (p. 523). There is also a mid-diastolic murmur best heard at the lower left or right sternal edge. This is generally higher-pitched than the murmur of mitral stenosis and is increased by inspiration. Right heart failure causes hepatomegaly with pre-systolic pulsation (large *a* wave), ascites and peripheral oedema. On Doppler echocardiography, the valve has similar appearances to those of rheumatic mitral stenosis.

Management

In patients who require surgery to other valves, either the tricuspid valve is replaced or valvotomy is performed at the time of surgery. Balloon valvuloplasty can be used to treat rare cases of isolated tricuspid stenosis.

Tricuspid regurgitation

Aetiology, clinical features and investigations

Tricuspid regurgitation is common, and is most frequently 'functional' as a result of right ventricular dilatation (Box 18.114).

Symptoms are usually non-specific, with tiredness related to reduced forward flow, and oedema and hepatic enlargement due to venous congestion. The most prominent sign is a 'giant' *v* wave in the jugular venous pulse (a *cv* wave replaces the normal *x* descent). Other features include a pansystolic murmur at the left sternal edge and a pulsatile liver. Echocardiography may reveal dilatation of the RV. If the valve has been affected by rheumatic disease, the leaflets will appear thickened, and in endocarditis vegetations may be seen. Ebstein's anomaly (see Box 18.125, p. 634) is a congenital abnormality in which the tricuspid valve is displaced towards the right ventricular apex, with consequent enlargement of the RA. It is commonly associated with tricuspid regurgitation.

Management

Tricuspid regurgitation due to right ventricular dilatation often improves when the cause of right ventricular overload is corrected, with diuretic and vasodilator treatment of congestive cardiac failure. Patients with a normal pulmonary artery pressure tolerate isolated tricuspid reflux well, and valves damaged by endocarditis do not usually need to be replaced. Patients undergoing mitral valve replacement who have tricuspid regurgitation due to marked dilatation of the tricuspid annulus benefit from repair of the valve with an annuloplasty ring to bring the leaflets closer together. Those with rheumatic damage may require tricuspid valve replacement.

	18.114 Causes of tricuspid regurgitation
Primary	<ul style="list-style-type: none"> Rheumatic heart disease Endocarditis, particularly in injection drug-users Ebstein's congenital anomaly (see Box 18.125, p. 634)
Secondary	<ul style="list-style-type: none"> Right ventricular dilatation due to chronic left heart failure ('functional tricuspid regurgitation') Right ventricular infarction Pulmonary hypertension (e.g. cor pulmonale)

Pulmonary valve disease

Pulmonary stenosis

This can occur in the carcinoid syndrome but is usually congenital, in which case it may be isolated or associated with other abnormalities such as Fallot's tetralogy (p. 633).

The principal finding on examination is an ejection systolic murmur, loudest at the left upper sternum and radiating towards the left shoulder. There may be a thrill, best felt when the patient leans forward and breathes out. The murmur is often preceded by an ejection sound (click). Delay in right ventricular ejection may cause wide splitting of the second heart sound. Severe pulmonary stenosis is characterised by a loud harsh murmur, an inaudible pulmonary closure sound (P_2), an increased right ventricular heave, prominent *a* waves in the jugular pulse, ECG evidence of right ventricular hypertrophy, and post-stenotic dilatation in the pulmonary artery on the chest X-ray. Doppler echocardiography is the definitive investigation.

Mild to moderate isolated pulmonary stenosis is relatively common and does not usually progress or require treatment. Severe pulmonary stenosis (resting gradient > 50 mmHg with a normal cardiac output) is treated by percutaneous pulmonary balloon valvuloplasty or, if this is not available, by surgical valvotomy. Long-term results are very good. Post-operative pulmonary regurgitation is common but benign.

Pulmonary regurgitation

This is rare in isolation and is usually associated with pulmonary artery dilatation due to pulmonary hypertension. It may complicate mitral stenosis, producing an early diastolic decrescendo murmur at the left sternal edge that is difficult to distinguish from aortic regurgitation (Graham Steell murmur). The pulmonary hypertension may be secondary to other disease of the left side of the heart, primary pulmonary vascular disease or Eisenmenger's syndrome (p. 630). Trivial pulmonary regurgitation is a frequent finding in normal individuals and has no clinical significance.

Infective endocarditis

This is due to microbial infection of a heart valve (native or prosthetic), the lining of a cardiac chamber or blood vessel, or a congenital anomaly (e.g. septal defect). The causative organism is usually a bacterium, but may be a rickettsia, chlamydia or fungus.

Pathophysiology

Infective endocarditis typically occurs at sites of pre-existing endocardial damage, but infection with particularly virulent or aggressive organisms (e.g. *Staphylococcus aureus*) can cause endocarditis in a previously normal heart; staphylococcal endocarditis of the tricuspid valve is a common complication of intravenous drug misuse. Many acquired and congenital cardiac lesions are vulnerable to endocarditis, particularly areas of endocardial damage caused by a high-pressure jet of blood, such as ventricular septal defect, mitral regurgitation and aortic regurgitation, many of which are haemodynamically insignificant. In contrast,

the risk of endocarditis at the site of haemodynamically important low-pressure lesions, such as a large atrial septal defect, is minimal.

Infection tends to occur at sites of endothelial damage because they attract deposits of platelets and fibrin that are vulnerable to colonisation by blood-borne organisms. The avascular valve tissue and presence of fibrin and platelet aggregates help to protect proliferating organisms from host defence mechanisms. When the infection is established, vegetations composed of organisms, fibrin and platelets grow and may become large enough to cause obstruction or embolism. Adjacent tissues are destroyed and abscesses may form. Valve regurgitation may develop or increase if the affected valve is damaged by tissue distortion, cusp perforation or disruption of chordae. Extracardiac manifestations such as vasculitis and skin lesions are due to emboli or immune complex deposition. Mycotic aneurysms may develop in arteries at the site of infected emboli. At autopsy, infarction of the spleen and kidneys, and sometimes an immune glomerulonephritis are found.

Microbiology

Over three-quarters of cases are due to streptococci or staphylococci. The *viridans* group of streptococci (*Strep. mitis*, *Strep. sanguis*) are commensals in the upper respiratory tract that may enter the blood stream on chewing or teeth-brushing, or at the time of dental treatment, and are common causes of subacute endocarditis (Box 18.115). Other organisms, including *Enterococcus faecalis*, *E. faecium* and *Strep. bovis*, may enter the blood from the bowel or urinary tract. *Strep. milleri* and *Strep. bovis* endocarditis is associated with large-bowel neoplasms.

Staph. aureus has now overtaken streptococci as the most common cause of acute endocarditis. It originates from skin infections, abscesses or vascular access sites (e.g. intravenous and central lines), or from intravenous

18.115 Microbiology of infective endocarditis

Pathogen	Of native valve (n = 280)	In i.v. drug users (n = 87)	Of prosthetic valve Early (n = 15)	Late (n = 72)

drug misuse. It is a highly virulent and invasive organism, usually producing florid vegetations, rapid valve destruction and abscess formation. Other causes of acute endocarditis include *Strep. pneumoniae* and *Strep. pyogenes*.

Post-operative endocarditis after cardiac surgery may affect native or prosthetic heart valves or other prosthetic materials. The most common organism is a coagulase-negative staphylococcus (*Staph. epidermidis*), a normal skin commensal. There is frequently a history of post-operative wound infection with the same organism. *Staph. epidermidis* occasionally causes endocarditis in patients who have not had cardiac surgery, and its presence in blood cultures may be erroneously dismissed as contamination. Another coagulase-negative staphylococcus, *Staph. lugdenensis*, causes a rapidly destructive acute endocarditis that is associated with previously normal valves and multiple emboli. Unless accurately identified, it may also be overlooked as a contaminant.

In Q fever endocarditis due to *Coxiella burnetii*, the patient often has a history of contact with farm animals. The aortic valve is usually affected and there may be hepatic complications and purpura. Life-long antibiotic therapy may be required.

Gram-negative bacteria of the so-called HACEK group (*Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* spp. and *Kingella kingae*) are slow-growing fastidious organisms that are only revealed after prolonged culture and may be resistant to penicillin.

Brucella is associated with a history of contact with goats or cattle and often affects the aortic valve.

Yeasts and fungi (*Candida*, *Aspergillus*) may attack previously normal or prosthetic valves, particularly in immunocompromised patients or those with indwelling intravenous lines. Abscesses and emboli are common, therapy is difficult (surgery is often required) and mortality is high. Concomitant bacterial infection may be present.

Incidence

The incidence of infective endocarditis in community-based studies ranges from 5 to 15 cases per 100 000 per annum. More than 50% of affected patients are over 60 years of age (Box 18.116). In a large British study, the underlying condition was rheumatic heart disease in 24% of patients, congenital heart disease in 19%, and some other cardiac abnormality (e.g. calcified aortic valve, floppy mitral valve) in 25%. The remaining 32% were not thought to have a pre-existing cardiac abnormality.

Clinical features

Endocarditis occurs as either an acute or a more insidious 'subacute' form. However, there is considerable overlap

because the clinical pattern is influenced not only by the organism, but also by the site of infection, prior antibiotic therapy and the presence of a valve or shunt prosthesis. The subacute form may abruptly develop acute life-threatening complications such as valve disruption or emboli.

Subacute endocarditis

This should be suspected when a patient with congenital or valvular heart disease develops a persistent fever, complains of unusual tiredness, night sweats or weight loss, or develops new signs of valve dysfunction or heart failure. Less often, it presents as an embolic stroke or peripheral arterial embolism. Other features (Fig. 18.93) include purpura and petechial haemorrhages in the skin and mucous membranes, and splinter haemorrhages under the fingernails or toe nails. Osler's nodes are painful tender swellings at the fingertips that are probably the product of vasculitis; they are rare. Digital clubbing is a late sign. The spleen is frequently palpable; in *Coxiella* infections the spleen and the liver may be considerably enlarged. Microscopic haematuria is common. The finding of any of these features in a patient with persistent fever or malaise is an indication for re-examination to detect hitherto unrecognised heart disease.

Acute endocarditis

This presents as a severe febrile illness with prominent and changing heart murmurs and petechiae. Clinical stigmata of chronic endocarditis are usually absent. Embolic events are common, and cardiac or renal failure may develop rapidly. Abscesses may be detected on echocardiography. Partially treated acute endocarditis behaves like subacute endocarditis.

Post-operative endocarditis

This may present as an unexplained fever in a patient who has had heart valve surgery. The infection usually affects the valve ring and may resemble subacute or acute endocarditis, depending on the virulence of the organism. Morbidity and mortality are high and redo surgery is often required. The range of organisms is similar to that seen in native valve disease, but when endocarditis occurs during the first few weeks after surgery, it is usually due to infection with a coagulase-negative staphylococcus that was introduced during the perioperative period. A clinical diagnosis of endocarditis can be made on the presence of two major, one major and three minor, or five minor criteria (Box 18.117).

Investigations

Blood culture is the crucial investigation because it may identify the infection and guide antibiotic therapy. Three to six sets of blood cultures should be taken prior to commencing therapy and should not wait for episodes of pyrexia. The first two specimens will detect bacteraemia in 90% of culture-positive cases. Aseptic technique is essential and the risk of contaminants should be minimised by sampling from different venepuncture sites. An in-dwelling line should not be used to take cultures. Aerobic and anaerobic cultures are required.

Echocardiography is key for detecting and following the progress of vegetations, for assessing valve damage and for detecting abscess formation. Vegetations as

18.116 Endocarditis in old age

- **Symptoms and signs:** may be non-specific, e.g. confusion, weight loss, malaise and weakness, and the diagnosis may not be suspected.
- **Common causative organisms:** often enterococci (from the urinary tract) and *Strep. bovis* (from a colonic source).
- **Morbidity and mortality:** much higher.

Fig. 18.93 Clinical features which may be present in endocarditis.

i

18.117 Diagnosis of infective endocarditis (modified Duke criteria)

Major criteria

- Positive blood culture
Typical organism from two cultures
Persistent positive blood cultures taken > 12 hrs apart
Three or more positive cultures taken over > 1 hr
- Endocardial involvement
Positive echocardiographic findings of vegetations
New valvular regurgitation

Minor criteria

- Predisposing valvular or cardiac abnormality
- Intravenous drug misuse
- Pyrexia $\geq 38^{\circ}\text{C}$
- Embolic phenomenon
- Vasculitic phenomenon
- Blood cultures suggestive: organism grown but not achieving major criteria
- Suggestive echocardiographic findings

Definite endocarditis = two major, or one major and three minor, or five minor

Possible endocarditis = one major and one minor, or three minor

small as 2–4 mm can be detected by transthoracic echocardiography, and even smaller ones (1–1.5 mm) can be visualised by transoesophageal echocardiography, which is particularly valuable for identifying abscess formation and investigating patients with prosthetic heart valves. Vegetations may be difficult to distinguish in the presence of an abnormal valve; the sensitivity of transthoracic echo is approximately 65% but that of transoesophageal echo is more than 90%. Failure to detect vegetations does not exclude the diagnosis.

Elevation of the ESR, a normocytic normochromic anaemia, and leucocytosis are common but not invariable. Measurement of serum CRP is more reliable than the ESR in monitoring progress. Proteinuria may occur and microscopic haematuria is usually present.

The ECG may show the development of AV block (due to aortic root abscess formation) and occasionally infarction due to emboli. The chest X-ray may show evidence of cardiac failure and cardiomegaly.

Management

The case fatality of bacterial endocarditis is approximately 20% and even higher in those with prosthetic valve endocarditis and those infected with antibiotic-

resistant organisms. A multidisciplinary approach with cooperation between the physician, surgeon and bacteriologist increases the chance of a successful outcome. Any source of infection should be removed as soon as possible; for example, a tooth with an apical abscess should be extracted.

Empirical treatment depends on the mode of presentation, the suspected organism, and whether the patient has a prosthetic valve or penicillin allergy (Box 18.118). If the presentation is acute, flucloxacillin and gentamicin are recommended, while for a subacute or indolent presentation, benzyl penicillin and gentamicin are preferred. In those with penicillin allergy, a prosthetic valve or suspected meticillin-resistant *Staph. aureus* (MRSA) infection, triple therapy with vancomycin, gentamicin and oral rifampicin should be considered. Following identification of the causal organism, determination of the minimum inhibitory concentration (MIC) for the organism is essential to guide antibiotic therapy.

A 2-week treatment regimen may be sufficient for fully sensitive strains of *Strep. viridans* and *Strep. bovis*, provided specific conditions are met (Box 18.119). For the empirical treatment of bacterial endocarditis, penicillin plus gentamicin is the regimen of choice for most patients; however, when staphylococcal infection is suspected, vancomycin plus gentamicin is recommended.

Cardiac surgery (débridement of infected material and valve replacement) is advisable in a substantial proportion of patients, particularly those with *Staph. aureus* and fungal infections (Box 18.120). Antimicrobial therapy must be started before surgery.

18.119 Conditions to be met for the short-course treatment of *Strep. viridans* and *Strep. bovis* endocarditis

- Native valve infection
- MIC \leq 0.1 mg/L
- No adverse prognostic factors (e.g. heart failure, aortic regurgitation, conduction defect)
- No evidence of thromboembolic disease
- No vegetations > 5 mm diameter
- Clinical response within 7 days

18.120 Indications for cardiac surgery in infective endocarditis

- Heart failure due to valve damage
- Failure of antibiotic therapy (persistent or uncontrolled infection)
- Large vegetations on left-sided heart valves with evidence or 'high risk' of systemic emboli
- Abscess formation

N.B. Patients with prosthetic valve endocarditis or fungal endocarditis often require cardiac surgery.

Prevention

Until recently, antibiotic prophylaxis was routinely given to people at risk of infective endocarditis undergoing interventional procedures. However, as this has not been proven to be effective and the link between episodes of infective endocarditis and interventional

18.118 Antimicrobial treatment of common causative organisms in infective endocarditis

Table 1 Antimicrobial treatment of common causative organisms in infective endocarditis				
Organism	Antimicrobial	Dose	Duration	
			Native valve	Prosthetic valve
<i>Viridans</i> streptococci and <i>Strep. bovis</i>				
MIC ≤ 0.1 mg/L	Benzyl penicillin i.v.	1.2 g 4-hourly	4 wks ¹	6 wks
	and gentamicin i.v.	1 mg/kg 8–12-hourly	2 wks	2 wks
MIC > 0.1 to < 0.5 mg/L	Benzyl penicillin i.v.	1.2 g 4-hourly	4 wks	6 wks
	and gentamicin i.v.	1 mg/kg 8–12-hourly	2 wks	4–6 wks
MIC ≥ 0.5 mg/L	Benzyl penicillin i.v.	1.2 g 4-hourly	4 wks	6 wks
	and gentamicin i.v.	1 mg/kg 8–12-hourly	4 wks	4–6 wks
Enterococci				
Ampicillin-sensitive	Ampicillin i.v.	2 g 4-hourly	4 wks	6 wks
	and gentamicin i.v. ²	1 mg/kg 8–12-hourly	4 wks	6 wks
Ampicillin-resistant	Vancomycin i.v.	1 g 12-hourly	4 wk	6 wks
	and gentamicin i.v. ²	1 mg/kg 8–12-hourly	4 wks	6 wks
Staphylococci				
Penicillin-sensitive	Benzyl penicillin i.v.	1.2 g 4-hourly	4 wks	6 wks
Penicillin-resistant	Flucloxacillin i.v.	2 g 4-hourly (< 85 kg 6-hourly)	4 wks	6 wks ³
Meticillin-sensitive				
Penicillin-resistant	Vancomycin i.v. and	1 g 12-hourly	4 wks	6 wks ³
Meticillin-resistant	gentamicin i.v.	1 mg/kg 8-hourly	4 wks	6 wks ³

¹When conditions in Box 18.119 are met, 2 wks of benzyl penicillin.

²In high-level gentamicin resistance, consider streptomycin.

³Consider additional rifampicin 300–600 mg 12-hourly orally for 2 wks. (MIC = minimum inhibitory concentration)

procedures has not been demonstrated, antibiotic prophylaxis is no longer offered routinely for defined interventional procedures.

Valve replacement surgery

Diseased heart valves can be replaced with mechanical or biological prostheses. The three most commonly used types of mechanical prosthesis are the ball and cage, tilting single disc and tilting bi-leaflet valves. All generate prosthetic sounds or clicks on auscultation. Pig or allograft valves mounted on a supporting stent are the most commonly used biological valves. They generate normal heart sounds. All prosthetic valves used in the aortic position produce a systolic flow murmur.

All mechanical valves require long-term anticoagulation because they can cause systemic thromboembolism or may develop valve thrombosis or obstruction (Box 18.121); the prosthetic clicks may become inaudible if the valve malfunctions. Biological valves have the advantage of not requiring anticoagulants to maintain proper function; however, many patients undergoing valve replacement surgery, especially mitral valve replacement, will have atrial fibrillation that requires anticoagulation anyway. Biological valves are less durable than mechanical valves and may degenerate 7 or more years after implantation, particularly when used in the mitral position. They are more durable in the aortic position and in older patients, so are particularly appropriate for patients over 65 undergoing aortic valve replacement.

Symptoms or signs of unexplained heart failure in a patient with a prosthetic heart valve may be due to valve dysfunction, and urgent assessment is required. Biological valve dysfunction is usually associated with the development of a regurgitant murmur.

18.121 Prosthetic heart valves: optimal anticoagulant control

Mechanical valves	Target INR
Ball and cage (e.g. Starr–Edwards)	3.5
Tilting disc (e.g. Bjork–Shiley)	
Bi-leaflet (e.g. St Jude)	3.0
Biological valves with atrial fibrillation	2.5

CONGENITAL HEART DISEASE

Congenital heart disease usually manifests in childhood but may pass unrecognised and not present until adult life. Defects that are well tolerated, such as atrial septal defect, may cause no symptoms until adult life or may be detected incidentally on routine examination or chest X-ray. Congenital defects that were previously fatal in childhood can now be corrected, or at least partially, so that survival to adult life is the norm. Such patients remain well for many years but subsequently re-present in later life with related problems such as arrhythmia or ventricular dysfunction (Box 18.122).

18.122 Presentation of congenital heart disease throughout life

Birth and neonatal period	
• Cyanosis	• Heart failure
Infancy and childhood	
• Cyanosis	• Murmur
• Heart failure	• Failure to thrive
• Arrhythmia	
Adolescence and adulthood	
• Heart failure	• Hypertension (coarctation)
• Murmur	• Late consequences of previous cardiac surgery, e.g. arrhythmia, heart failure
• Arrhythmia	
• Cyanosis due to shunt reversal (Eisenmenger's syndrome)	

The fetal circulation

Understanding the fetal circulation helps clarify how some forms of congenital heart disease occur. The fetus has only a small flow of blood through the lungs, as it does not breathe in utero. The fetal circulation allows oxygenated blood from the placenta to pass directly to the left side of the heart through the foramen ovale without having to flow through the lungs (Fig. 18.94).

Congenital defects may arise if the changes from fetal circulation to the extrauterine circulation are not properly completed. Atrial septal defects occur at the site of the foramen ovale. A patent ductus arteriosus may remain if it fails to close after birth. Failure of the aorta to develop at the point of the aortic isthmus and where the ductus arteriosus attaches can lead to narrowing or coarctation of the aorta.

In fetal development, the heart develops as a single tube which folds back on itself and then divides into two separate circulations. Failure of septation can lead to some forms of atrial and ventricular septal defect. Failure of alignment of the great vessels with the ventricles contributes to transposition of the great arteries, tetralogy of Fallot and truncus arteriosus.

Aetiology and incidence

The incidence of haemodynamically significant congenital cardiac abnormalities is about 0.8% of live births (Box 18.123). Maternal infection or exposure to drugs or toxins may cause congenital heart disease. Maternal rubella infection is associated with persistent ductus arteriosus, pulmonary valvular and/or artery stenosis, and atrial septal defect. Maternal alcohol misuse is associated with septal defects, and maternal lupus erythematosus with congenital complete heart block. Genetic or chromosomal abnormalities such as Down's syndrome may cause septal defects, and gene defects have also been identified as causing specific abnormalities, such as Marfan's syndrome (p. 602) and DiGeorge's (deletion in chromosome 22q) syndrome.

Clinical features

Symptoms may be absent, or the child may be breathless or fail to attain normal growth and development. Some defects are not compatible with extrauterine life, or only for a short time. Clinical signs vary with the anatomical lesion. Murmurs, thrills or signs of cardiomegaly

Fig. 18.94 Changes in the circulation at birth. **A** In the fetus, oxygenated blood comes through the umbilical vein where it enters the inferior vena cava via the ductus venosus (red). The oxygenated blood streams from the RA through the open foramen ovale to the LA and via the LV into the aorta. Venous blood from the superior vena cava (blue) crosses under the main blood stream into the RA and then, partly mixed with oxygenated blood (purple), into the RV and pulmonary artery. The pulmonary vasculature has a high resistance and so little blood passes to the lungs; most blood passes through the ductus arteriosus to the descending aorta. The aortic isthmus is a constriction in the aorta that lies in the aortic arch before the junction with the ductus arteriosus and limits the flow of oxygen-rich blood to the descending aorta. This configuration means that less oxygen-rich blood is supplied to organ systems that take up their function mainly after birth, e.g. the kidneys and intestinal tract. **B** At birth, the lungs expand with air and pulmonary vascular resistance falls, so that blood now flows to the lungs and back to the LA. The left atrial pressure rises above right atrial pressure and the flap valve of the foramen ovale closes. The umbilical arteries and the ductus venosus close. In the next few days, the ductus arteriosus closes under the influence of hormonal changes (particularly prostaglandins) and the aortic isthmus expands.

18.123 Incidence and relative frequency of congenital cardiac malformations	
Lesion	% of all CHD defects
Ventricular septal defect	30
Atrial septal defect	10
Patent ductus arteriosus	10
Pulmonary stenosis	7
Coarctation of aorta	7
Aortic stenosis	6
Tetralogy of Fallot	6
Complete transposition of great arteries	4
Others	20

may be present. In coarctation of the aorta, radio-femoral delay may be noted (Fig. 18.95) and some female patients have the features of Turner's syndrome (p. 761). Features of other congenital conditions such as Marfan's syndrome or Down's syndrome may also be apparent. Cerebrovascular accidents and cerebral abscesses may complicate severe cyanotic congenital disease.

Early diagnosis is important because many types of congenital heart disease are amenable to surgical treatment, but this opportunity is lost if secondary changes such as pulmonary vascular damage occur.

Central cyanosis and digital clubbing

Central cyanosis of cardiac origin occurs when desaturated blood enters the systemic circulation without passing through the lungs (i.e. a right-to-left shunt). In the neonate, the most common cause is transposition of the great arteries, in which the aorta arises from the RV and the pulmonary artery from the LV. In older children, cyanosis is usually the consequence of a ventricular septal defect combined with severe pulmonary stenosis (tetralogy of Fallot) or with pulmonary vascular disease (Eisenmenger's syndrome). Prolonged cyanosis is associated with finger and toe clubbing (p. 522).

Growth retardation and learning difficulties

These may occur with large left-to-right shunts at ventricular or great arterial level, and also with other defects, especially if they form part of a genetic syndrome.

Fig. 18.95 Radio-femoral delay. The difference in pulse pressures is shown.

Major intellectual impairment is uncommon in children with isolated congenital heart disease; however, minor learning difficulties can occur and may complicate cardiac surgery if cerebral perfusion is compromised.

Syncope

In the presence of increased pulmonary vascular resistance or severe left or right ventricular outflow obstruction, exercise may provoke syncope as systemic vascular resistance falls but pulmonary vascular resistance rises, worsening right-to-left shunting and cerebral oxygenation. Syncope can also occur because of associated arrhythmias.

Pulmonary hypertension and Eisenmenger's syndrome

Persistently raised pulmonary flow (e.g. with left-to-right shunt) causes increased pulmonary resistance followed by pulmonary hypertension. Progressive changes, including obliteration of distal vessels, occur and are irreversible. Central cyanosis appears and digital clubbing develops. The chest X-ray shows enlarged central pulmonary arteries and peripheral 'pruning' of the pulmonary vessels. The ECG shows right ventricular hypertrophy. If severe pulmonary hypertension develops, a left-to-right shunt may reverse, resulting in right-to-left shunt and marked cyanosis (Eisenmenger's syndrome), which may be more apparent in the feet and toes than in the upper part of the body: differential cyanosis. This is more common with large ventricular septal defects or persistent ductus arteriosus than with atrial septal defects. Patients with Eisenmenger's syndrome are at particular risk from abrupt changes in afterload that exacerbate right-to-left shunting, such as vasodilatation, anaesthesia and pregnancy.

Pregnancy

During pregnancy, there is a 50% increase in plasma volume, a 40% increase in whole blood volume and a similar increase in cardiac output, so problems may arise in women with congenital heart disease (Box 18.124). However, many with palliated or untreated disease will tolerate pregnancy well. Pregnancy is particularly hazardous in the presence of conditions associated with cyanosis or severe pulmonary hypertension; maternal mortality in patients with Eisenmenger's syndrome is more than 50%.

18.124 Pregnancy in women with congenital heart disease

- **Obstructive lesions** (e.g. severe aortic stenosis): poorly tolerated and associated with significant maternal morbidity and mortality.
- **Cyanotic conditions** (e.g. Eisenmenger's syndrome): especially poorly tolerated and pregnancy should be avoided.
- **Surgically corrected disease**: patients often tolerate pregnancy well.
- **Children of patients with congenital heart disease**: 2–5% will be born with cardiac abnormalities, especially if the mother is affected.

Persistent ductus arteriosus

Aetiology

During fetal life, before the lungs begin to function, most of the blood from the pulmonary artery passes through the ductus arteriosus into the aorta (see Fig. 18.94). Normally, the ductus closes soon after birth but sometimes fails to do so. Persistence of the ductus is associated with other abnormalities and is more common in females.

Since the pressure in the aorta is higher than that in the pulmonary artery, there will be a continuous arterio-venous shunt, the volume of which depends on the size of the ductus. As much as 50% of the left ventricular output is recirculated through the lungs, with a consequent increase in the work of the heart (Fig. 18.96).

Clinical features

With small shunts there may be no symptoms for years, but when the ductus is large, growth and development may be retarded. Usually there is no disability in infancy but cardiac failure may eventually ensue, dyspnoea being the first symptom. A continuous 'machinery' murmur is heard with late systolic accentuation, maximal in the second left intercostal space below the clavicle (see Fig. 18.96). It is frequently accompanied by a thrill. Pulses are increased in volume.

A large left-to-right shunt in infancy may cause a considerable rise in pulmonary artery pressure, and sometimes this leads to progressive pulmonary vascular damage. Enlargement of the pulmonary artery may be detected radiologically. The ECG is usually normal.

Persistent ductus with reversed shunting

If pulmonary vascular resistance increases, pulmonary artery pressure may rise until it equals or exceeds aortic pressure. The shunt through the defect may then

reverse, causing Eisenmenger's syndrome. The murmur becomes quieter, may be confined to systole or may disappear. The ECG shows evidence of right ventricular hypertrophy.

Management

A patent ductus is closed at cardiac catheterisation with an implantable occlusive device. Closure should be undertaken in infancy if the shunt is significant and pulmonary resistance not elevated, but this may be delayed until later childhood in those with smaller shunts, for whom closure remains advisable to reduce the risk of endocarditis.

Pharmacological treatment in the neonatal period

When the ductus is structurally intact, a prostaglandin synthetase inhibitor (indometacin or ibuprofen) may be used in the first week of life to induce closure. However, in the presence of a congenital defect with impaired lung perfusion (e.g. severe pulmonary stenosis and left-to-right shunt through the ductus), it may be advisable to improve oxygenation by keeping the ductus open with prostaglandin treatment. Unfortunately, these treatments do not work if the ductus is intrinsically abnormal.

Coarctation of the aorta

Aetiology

Narrowing of the aorta occurs in the region where the ductus arteriosus joins the aorta, i.e. at the isthmus just below the origin of the left subclavian artery (see Fig. 18.94). The condition is twice as common in males and occurs in 1 in 4000 children. It is associated with other abnormalities, most frequently bicuspid aortic valve and 'berry' aneurysms of the cerebral circulation (p. 1145). Acquired coarctation of the aorta is rare but may follow trauma or occur as a complication of a progressive arteritis (Takayasu's disease, p. 1113).

Clinical features and investigations

Aortic coarctation is an important cause of cardiac failure in the newborn, but symptoms are often absent when it is detected in older children or adults. Headaches may occur from hypertension proximal to the coarctation, and occasionally weakness or cramps in the legs may result from decreased circulation in the lower part of the body. The BP is raised in the upper body but normal or low in the legs. The femoral pulses are weak, and delayed in comparison with the radial pulse (see Fig. 18.95). A systolic murmur is usually heard posteriorly, over the coarctation. There may also be an ejection click and systolic murmur in the aortic area due to a bicuspid aortic valve. As a result of the aortic narrowing, collaterals form and mainly involve the periscapular, internal mammary and intercostal arteries, and may result in localised bruits.

Chest X-ray in early childhood is often normal but later may show changes in the contour of the aorta (indentation of the descending aorta, '3 sign') and notching of the under-surfaces of the ribs from collaterals. MRI is ideal for demonstrating the lesion (Fig. 18.97). The ECG may show left ventricular hypertrophy.

Management

In untreated cases, death may occur from left ventricular failure, dissection of the aorta or cerebral haemorrhage.

Fig. 18.96 Persistent ductus arteriosus. There is a connection between the aorta and the pulmonary artery with left-to-right shunting.

Fig. 18.97 MRI scan of coarctation of the aorta. The aorta is severely narrowed just beyond the arch at the start of the descending aorta (arrow A). Extensive collaterals have developed with a large internal mammary artery shown (arrow B), and several intercostal arteries (arrows C). Unusually, in this case there is also a coarctation of the abdominal aorta (arrow D).

Surgical correction is advisable in all but the mildest cases. If this is carried out sufficiently early in childhood, persistent hypertension can be avoided. Patients repaired in late childhood or adult life often remain hypertensive or develop recurrent hypertension later on. Recurrence of stenosis may occur as the child grows and this may be managed by balloon dilatation, which can also be used as the primary treatment in some cases. Coexistent bicuspid aortic valve, which occurs in over 50% of cases, may lead to progressive aortic stenosis or regurgitation, and also requires long-term follow-up.

Atrial septal defect

Aetiology

Atrial septal defect is one of the most common congenital heart defects and occurs twice as frequently in females. Most are 'ostium secundum' defects, involving the fossa ovalis that in utero was the foramen ovale (see Fig. 18.94). 'Ostium primum' defects result from a defect in the atrioventricular septum and are associated with a 'cleft mitral valve' (split anterior leaflet).

Since the normal RV is more compliant than the LV, a large volume of blood shunts through the defect from the LA to the RA, and then to the RV and pulmonary arteries (Fig. 18.98). As a result there is gradual enlargement of the right side of the heart and of the pulmonary arteries. Pulmonary hypertension and shunt reversal sometimes complicate atrial septal defect, but are less common and tend to occur later in life than with other types of left-to-right shunt.

Clinical features and investigations

Most children are asymptomatic for many years and the condition is often detected at routine clinical examination

Fig. 18.98 Atrial septal defect. Blood flows across the atrial septum (arrow) from left to right. The murmur is produced by increased flow velocity across the pulmonary valve, as a result of left-to-right shunting and a large stroke volume. The density of shading is proportional to velocity of blood flow.

or following a chest X-ray. Dyspnoea, chest infections, cardiac failure and arrhythmias, especially atrial fibrillation, are other possible manifestations. The characteristic physical signs are the result of the volume overload of the RV:

- wide fixed splitting of the second heart sound: wide because of delay in right ventricular ejection (increased stroke volume and right bundle branch block) and fixed because the septal defect equalises left and right atrial pressures throughout the respiratory cycle
- a systolic flow murmur over the pulmonary valve.

In children with a large shunt, there may be a diastolic flow murmur over the tricuspid valve. Unlike a mitral flow murmur, this is usually high-pitched.

The chest X-ray typically shows enlargement of the heart and the pulmonary artery, as well as pulmonary plethora. The ECG usually shows incomplete right bundle branch block because right ventricular depolarisation is delayed as a result of ventricular dilatation (with a 'primum' defect there is also left axis deviation). Echocardiography can directly demonstrate the defect and typically shows RV dilatation, RV hypertrophy and pulmonary artery dilatation. The precise size and location of the defect can be shown by transoesophageal echocardiography (Fig. 18.99).

Management

Atrial septal defects in which pulmonary flow is increased 50% above systemic flow (i.e. flow ratio of 1.5:1) are often large enough to be clinically recognisable and should be closed surgically. Closure can also be accomplished at cardiac catheterisation using implantable closure devices (see Fig. 18.15, p. 536). The long-term prognosis thereafter is excellent unless pulmonary hypertension has

Fig. 18.99 Transoesophageal echocardiogram of an atrial septal defect (ASD). The defect is clearly seen (arrow) between the LA above and RA below. Doppler colour-flow imaging shows flow (blue) across the defect.

developed. Severe pulmonary hypertension and shunt reversal are both contraindications to surgery.

Ventricular septal defect

Aetiology

Congenital ventricular septal defect occurs as a result of incomplete septation of the ventricles. Embryologically, the interventricular septum has a membranous and a muscular portion, and the latter is further divided into inflow, trabecular and outflow portions. Most congenital defects are 'perimembranous', i.e. at the junction of the membranous and muscular portions.

Ventricular septal defects are the most common congenital cardiac defect, occurring once in 500 live births. The defect may be isolated or part of complex congenital heart disease. Acquired ventricular septal defect may result from rupture as a complication of acute MI, or rarely from trauma.

Clinical features

Flow from the high-pressure LV to the low-pressure RV during systole produces a pansystolic murmur usually heard best at the left sternal edge but radiating all over the precordium (Fig. 18.100). A small defect often produces a loud murmur (maladie de Roger) in the absence of other haemodynamic disturbance. Conversely, a large defect produces a softer murmur, particularly if pressure in the RV is elevated. This may be found immediately after birth, while pulmonary vascular resistance remains high, or when the shunt is reversed in Eisenmenger's syndrome.

Congenital ventricular septal defect may present as cardiac failure in infants, as a murmur with only minor haemodynamic disturbance in older children or adults, or rarely as Eisenmenger's syndrome. In a proportion of infants, the murmur gets quieter or disappears due to spontaneous closure of the defect.

If cardiac failure complicates a large defect, it is usually absent in the immediate postnatal period and only becomes apparent in the first 4–6 weeks of life. In addition to the murmur, there is prominent parasternal pulsation, tachypnoea and indrawing of the lower ribs on inspiration. The chest X-ray shows pulmonary plethora and the ECG shows bilateral ventricular hypertrophy.

Fig. 18.100 Ventricular septal defect. In this example a large left-to-right shunt (arrows) has resulted in chamber enlargement.

Management and prognosis

Small ventricular septal defects require no specific treatment. Cardiac failure in infancy is initially treated medically with digoxin and diuretics. Persisting failure is an indication for surgical repair of the defect. Percutaneous closure devices are under development.

Doppler echocardiography helps to predict the small septal defects that are likely to close spontaneously. Eisenmenger's syndrome is avoided by monitoring for signs of rising pulmonary resistance (serial ECG and echocardiography) and carrying out surgical repair when appropriate. Surgical closure is contraindicated in fully developed Eisenmenger's syndrome when heart-lung transplantation may be the only effective treatment.

Except in Eisenmenger's syndrome, long-term prognosis is very good in congenital ventricular septal defect. Many patients with Eisenmenger's syndrome die in the second or third decade of life, but a few survive to the fifth decade without transplantation.

Tetralogy of Fallot

The RV outflow obstruction is most often subvalvular (infundibular) but may be valvular, supravalvular or a combination of these (Fig. 18.101). The ventricular septal defect is usually large and similar in aperture to the aortic orifice. The combination results in elevated right ventricular pressure and right-to-left shunting of cyanotic blood across the ventricular septal defect.

Aetiology

The embryological cause is abnormal development of the bulbar septum which separates the ascending aorta from the pulmonary artery, and which normally aligns and fuses with the outflow part of the interventricular septum. The defect occurs in about 1 in 2000 births and is the most common cause of cyanosis in infancy after the first year of life.

Fig. 18.101 Tetralogy of Fallot. The tetralogy comprises (1) pulmonary stenosis, (2) overriding of the ventricular septal defect by the aorta, (3) a ventricular septal defect and (4) right ventricular hypertrophy.

Clinical features

Children are usually cyanosed but this may not be the case in the neonate because it is only when right ventricular pressure rises to equal or exceed left ventricular pressure that a large right-to-left shunt develops. The subvalvular component of the RV outflow obstruction is dynamic and may increase suddenly under adrenergic stimulation. The affected child suddenly becomes increasingly cyanosed, often after feeding or a crying attack, and may become apnoeic and unconscious. These attacks are called 'Fallot's spells'. In older children, Fallot's spells are uncommon but cyanosis becomes increasingly apparent, with stunting of growth, digital clubbing and polycythaemia. Some children characteristically obtain relief by squatting after exertion, which increases the afterload of the left heart and reduces the right-to-left shunting: Fallot's sign. The natural history before the development of surgical correction was variable but most patients died in infancy or childhood.

On examination the most characteristic feature is the combination of cyanosis with a loud ejection systolic murmur in the pulmonary area (as for pulmonary stenosis). However, cyanosis may be absent in the newborn or in patients with only mild right ventricular outflow obstruction ('acyanotic tetralogy of Fallot').

Investigations and management

The ECG shows right ventricular hypertrophy and the chest X-ray shows an abnormally small pulmonary artery and a 'boot-shaped' heart. Echocardiography is diagnostic and demonstrates that the aorta is not continuous with the anterior ventricular septum.

The definitive management is total correction of the defect by surgical relief of the pulmonary stenosis and closure of the ventricular septal defect. Primary surgical correction may be undertaken prior to age 5. If the pulmonary arteries are too hypoplastic then palliative treatment in the

form of a Blalock-Taussig shunt may be performed, with an anastomosis created between the pulmonary artery and subclavian artery. This improves pulmonary blood flow and pulmonary artery development, and may facilitate definitive correction at a later stage.

The prognosis after total correction is good, especially if the operation is performed in childhood. Follow-up is needed to identify residual shunting, recurrent pulmonary stenosis and rhythm disorders.

Other causes of cyanotic congenital heart disease

Other causes of cyanotic congenital heart disease occur (Box 18.125) and echocardiography is usually the definitive diagnostic procedure, supplemented if necessary by cardiac catheterisation.

Adult congenital heart disease

There are increasing numbers of children who have had surgical correction of congenital defects and who may have further cardiological problems as adults. Those who have undergone correction of coarctation of the aorta may develop hypertension in adult life. Those with transposition of the great arteries who have had a 'Mustard' repair, where blood is redirected at atrial level leaving the RV connected to the aorta, may develop right ventricular failure in adult life. The RV is unsuited for function at systemic pressures and may begin to dilate and fail when patients are in their twenties or thirties.

Those who have had surgery involving the atria may develop atrial arrhythmias, and those who have ventricular scars may develop ventricular arrhythmias and need consideration for implantation of an ICD device. Such patients require careful follow-up from the

18.125 Other causes of cyanotic congenital heart disease

Defect	Features
Tricuspid atresia	Absent tricuspid orifice, hypoplastic RV, RA to LA shunt, ventricular septal defect shunt, other anomalies Surgical correction may be possible
Transposition of the great vessels	Aorta arises from the morphological RV, pulmonary artery from LV Shunt via atria, ductus and possibly ventricular septal defect Palliation by balloon atrial septostomy/enlargement Surgical correction possible
Pulmonary atresia	Pulmonary valve atretic and pulmonary artery hypoplastic RA to LA shunt, pulmonary flow via ductus Palliation by balloon atrial septostomy Surgical correction may be possible
Ebstein's anomaly	Tricuspid valve is dysplastic and displaced into RV, RV 'atrialised' Tricuspid regurgitation and RA to LA shunt Wide spectrum of severity Arrhythmias Surgical repair possible but significant risks

teenage years throughout adult life so that problems can be identified early and appropriate medical or surgical treatment instituted. The management of these adult or 'grown-up' congenital heart disease patients has developed as a cardiological subspecialty.

DISEASES OF THE MYOCARDIUM

Although the myocardium is involved in most types of heart disease, the terms 'myocarditis' and 'cardiomyopathy' are usually reserved for conditions that primarily affect the heart muscle.

Myocarditis

This is an acute inflammatory condition that can have an infectious, toxic or autoimmune aetiology. Myocarditis can complicate many infections in which inflammation may be due directly to infection of the myocardium or the effects of circulating toxins. Viral infections are the most common causes, such as Coxsackie (35 cases per 1000 infections) and influenza A and B (25 cases per 1000 infections) viruses. Myocarditis may occur several weeks after the initial viral symptoms and susceptibility is increased by corticosteroid treatment, immunosuppression, radiation, previous myocardial damage and exercise. Some bacterial and protozoal infections may be complicated by myocarditis; for example, approximately 5% of patients with Lyme disease (*Borrelia burgdorferi*, p. 329) develop myopericarditis, which is often associated with AV block. Toxic aetiologies include drugs, which may directly injure the myocardium (e.g. cocaine, lithium and anticancer drugs such as doxorubicin) or which may cause a hypersensitivity reaction and associated myocarditis (e.g. penicillins and sulphonamides), lead and carbon monoxide. Occasionally, autoimmune conditions such as systemic lupus erythematosus and rheumatoid arthritis are associated with myocarditis.

The clinical picture ranges from a symptomless disorder, sometimes recognised by the presence of an inappropriate tachycardia or abnormal ECG, to fulminant heart failure. Myocarditis may be heralded by an influenza-like illness. ECG changes are common but non-specific. Biochemical markers of myocardial injury (e.g. troponin I and T, creatine kinase) are elevated in proportion to the extent of damage. Echocardiography may reveal left ventricular dysfunction that is sometimes regional (due to focal myocarditis), and if the diagnosis is uncertain it can be confirmed by endomyocardial biopsy.

In most patients, the disease is self-limiting and the immediate prognosis is excellent. However, death may occur due to a ventricular arrhythmia or rapidly progressive heart failure. Myocarditis has been reported as a cause of sudden and unexpected death in young athletes. There is strong evidence that some forms of myocarditis may lead to chronic low-grade myocarditis or dilated cardiomyopathy (see below); for example, in Chagas disease (p. 354) the patient frequently recovers from the acute infection but goes on to develop a chronic dilated cardiomyopathy 10 or 20 years later.

Specific antimicrobial therapy may be used if a causative organism has been identified; however, this is rare and in most cases only supportive therapy is available. Treatment for cardiac failure or arrhythmias may be

required and patients should be advised to avoid intense physical exertion because there is some evidence that this can induce potentially fatal ventricular arrhythmias. There is no evidence for any benefit from treatment with corticosteroids and immunosuppressive agents.

Cardiomyopathy

The aetiology of most intrinsic disorders of the myocardium has not been elucidated and a functional classification is used (Fig. 18.102).

Dilated cardiomyopathy

This is characterised by dilatation and impaired contraction of the LV (and sometimes the RV); left ventricular mass is increased but wall thickness is normal or reduced (see Fig. 18.102). Histological changes are variable but include myofibrillary loss, interstitial fibrosis and T-cell infiltrates. The differential diagnosis includes coronary artery disease and some specific disorders of heart muscle (see below), and a diagnosis of dilated cardiomyopathy should only be made when these have been excluded.

The pathogenesis is not clear but dilated cardiomyopathy probably encompasses a heterogeneous group of conditions. Alcohol is an important aetiological factor in a significant proportion of patients. At least 25% of cases are inherited as an autosomal dominant trait and a variety of single gene mutations have been identified. Most of these mutations affect proteins in the cytoskeleton of the myocyte (e.g. dystrophin, lamin A and C, emerin and metavinculin) and many are associated with minor skeletal muscle abnormalities. Most of the X-linked inherited skeletal muscular dystrophies (e.g. Becker and Duchenne, p. 1233) are associated with cardiomyopathy. Finally, a late autoimmune reaction to viral myocarditis is thought to be the main aetiological factor in a substantial subgroup of patients with dilated cardiomyopathy; a similar mechanism is thought to be responsible for the heart muscle disease that occurs in up to 10% of patients with advanced HIV infection.

In North America and Europe, symptomatic dilated cardiomyopathy has an incidence of 20 per 100 000 and a prevalence of 38 per 100 000. Men are affected more than twice as often as women. Most patients present with heart failure or are found to have the condition during routine investigation. Arrhythmia, thromboembolism and sudden death are common and may occur at any stage; sporadic chest pain is a surprisingly frequent symptom. The ECG usually shows non-specific changes but echocardiography is useful in establishing the diagnosis. Treatment is aimed at controlling the resulting heart failure. Although some patients remain well for many years, the prognosis is variable and cardiac transplantation may be indicated. Patients with dilated cardiomyopathy and moderate or severe heart failure may be at risk of sudden arrhythmic death. This risk is substantially reduced by rigorous medical therapy with β -blockers and angiotensin receptor antagonists. Some patients may be considered for implantation of a cardiac defibrillator and/or cardiac resynchronisation therapy (p. 576).

Hypertrophic cardiomyopathy

This is the most common form of cardiomyopathy, with a prevalence of approximately 100 per 100 000 and is char-

Fig. 18.102 Types of cardiomyopathy. [A] Normal. [B] Hypertrophic cardiomyopathy: asymmetric septal hypertrophy (ASH) with systolic anterior motion of the mitral valve (SAM), causing mitral reflux and dynamic left ventricular outflow tract obstruction. [C] Hypertrophic cardiomyopathy: concentric hypertrophy. [D] Hypertrophic cardiomyopathy: apical hypertrophy. [E] Dilated cardiomyopathy. [F] Arrhythmogenic right ventricular cardiomyopathy. [G] Obliterative cardiomyopathy. [H] Restrictive cardiomyopathy.

acterised by inappropriate and elaborate left ventricular hypertrophy with malalignment of the myocardial fibres. The hypertrophy may be generalised or confined largely to the interventricular septum (asymmetric septal hypertrophy, see Fig. 18.102) or other regions (e.g. apical hypertrophic cardiomyopathy, a variant which is common in the Far East).

Heart failure may develop because the stiff non-compliant ventricles impede diastolic filling. Septal hypertrophy may also cause dynamic left ventricular outflow tract obstruction (hypertrophic obstructive cardiomyopathy, or HOCM) and mitral regurgitation due to abnormal systolic anterior motion of the anterior mitral valve leaflet. Effort-related symptoms (angina and breathlessness), arrhythmia and sudden death are the dominant clinical problems.

The condition is a genetic disorder, usually with autosomal dominant transmission, a high degree of penetrance and variable expression. In most patients, it appears to be due to a single point mutation in one of the genes that encode sarcomeric contractile proteins. There are three common groups of mutation with different phenotypes. Beta-myosin heavy chain mutations are associated with elaborate ventricular hypertrophy. Troponin mutations are associated with little, and sometimes even no hypertrophy but marked myocardial fibre disarray, an abnormal vascular response (e.g. exercise-induced hypotension) and a high risk of sudden death. Myosin-binding protein C mutations tend to present late in life and are often associated with hypertension and arrhythmia.

Symptoms and signs are similar to those of aortic stenosis, except that in hypertrophic cardiomyopathy the character of the arterial pulse is jerky (Box 18.126).

18.126 Clinical features of hypertrophic cardiomyopathy

Symptoms

- Angina on effort
- Dyspnoea on effort
- Syncope on effort
- Sudden death

Signs

- Jerky pulse*
- Palpable left ventricular hypertrophy
- Double impulse at the apex (palpable fourth heart sound due to left atrial hypertrophy)
- Midsystolic murmur at the base*
- Pansystolic murmur (due to mitral regurgitation) at the apex

*Signs of left ventricular outflow tract obstruction may be augmented by standing up (reduced venous return), inotropes and vasodilators (e.g. sublingual nitrate).

The ECG is abnormal and shows features of left ventricular hypertrophy with a wide variety of often bizarre abnormalities (e.g. pseudo-infarct pattern, deep T-wave inversion). Echocardiography is diagnostic, although the diagnosis may be difficult when another cause of left ventricular hypertrophy is present (e.g. physical training—athletes' heart, hypertension) but the degree of hypertrophy is greater than expected. Genetic testing may facilitate diagnosis.

The natural history is variable but clinical deterioration is often slow. The annual mortality from sudden death is 2–3% among adults and 4–6% in children and adolescents (Box 18.127). Sudden death typically occurs

18.127 Risk factors for sudden death in hypertrophic cardiomyopathy

- A history of previous cardiac arrest or sustained ventricular tachycardia
- Recurrent syncope
- An adverse genotype and/or family history
- Exercise-induced hypotension
- Non-sustained ventricular tachycardia on ambulatory ECG monitoring
- Marked increase in left ventricular wall thickness

during or just after vigorous physical activity; indeed, hypertrophic cardiomyopathy is the most common cause of sudden death in young athletes. Ventricular arrhythmias are thought to be responsible for many of these deaths.

Beta-blockers, rate-limiting calcium antagonists (e.g. verapamil) and disopyramide can help to relieve symptoms and sometimes prevent syncopal attacks; however, there is no pharmacological treatment that is definitely known to improve prognosis. Arrhythmias are common and often respond to treatment with amiodarone. Outflow tract obstruction can be improved by partial surgical resection (myectomy) or by iatrogenic infarction of the basal septum (septal ablation) using a catheter-delivered alcohol solution. An ICD should be considered in patients with clinical risk factors for sudden death (see Box 18.127). Digoxin and vasodilators may increase outflow tract obstruction and should be avoided.

Arrhythmogenic right ventricular cardiomyopathy

In this condition, patches of the right ventricular myocardium are replaced with fibrous and fatty tissue (see Fig. 18.102). It is inherited as an autosomal dominant trait and has a prevalence of approximately 10 per 100 000. The dominant clinical problems are ventricular arrhythmias, sudden death and right-sided cardiac failure. The ECG typically shows a slightly broadened QRS complex and inverted T waves in the right precordial leads. MRI is a useful diagnostic tool and is often used to screen the first-degree relatives of affected individuals. Patients at high risk of sudden death can be offered an ICD.

Obliterative cardiomyopathy

This disease involves the endocardium of one or both ventricles and is characterised by thrombosis and elaborate fibrosis with gradual obliteration of the ventricular cavities (e.g. endomyocardial fibroelastosis, see Fig. 18.102). The mitral and tricuspid valves become regurgitant. Heart failure and pulmonary and systemic embolism are prominent features. It can sometimes be associated with eosinophilia (e.g. eosinophilic leukaemia, Churg–Strauss syndrome, p. 1114). In tropical countries, the disease can be responsible for up to 10% of cardiac deaths. Mortality is high at 50% at 2 years. Anticoagulation and antiplatelet therapy are usually advisable, and diuretics may help symptoms of heart failure. Surgery (tricuspid and/or mitral valve replacement with decortication of the endocardium) may be helpful in selected cases.

Restrictive cardiomyopathy

In this rare condition, ventricular filling is impaired because the ventricles are 'stiff' (see Fig. 18.102). This leads to high atrial pressures with atrial hypertrophy, dilatation and later atrial fibrillation. Amyloidosis is the most common cause of restrictive cardiomyopathy in the UK, although other forms of infiltration (e.g. glycogen storage diseases), idiopathic perimyocyte fibrosis and a familial form of restrictive cardiomyopathy do occur. Diagnosis can be very difficult and requires complex Doppler echocardiography, CT or MRI, and endomyocardial biopsy. Treatment is symptomatic but the prognosis is usually poor and transplantation may be indicated.

Specific diseases of heart muscle

Many forms of specific heart muscle disease produce a clinical picture that is indistinguishable from dilated cardiomyopathy (e.g. connective tissue disorders, sarcoidosis, haemochromatosis, alcoholic heart muscle disease, Box 18.128). In contrast, amyloidosis and eosinophilic heart disease produce symptoms and signs similar to those found in restrictive or obliterative cardiomyopathy, whereas the heart disease associated with Friedreich's ataxia (p. 1203) can mimic hypertrophic cardiomyopathy.

Treatment and prognosis are determined by the underlying disorder. Abstinence from alcohol may lead to a dramatic improvement in patients with alcoholic heart muscle disease.

18.128 Specific diseases of heart muscle

Infections

- Viral, e.g. Coxsackie A and B, influenza, HIV
- Bacterial, e.g. diphtheria, *Borrelia burgdorferi*
- Protozoal, e.g. trypanosomiasis

Endocrine and metabolic disorders

- Diabetes, hypo- and hyperthyroidism, acromegaly, carcinoid syndrome, pheochromocytoma, inherited storage diseases

Connective tissue diseases

- Systemic sclerosis, systemic lupus erythematosus, polyarteritis nodosa

Infiltrative disorders

- Haemochromatosis, haemosiderosis, sarcoidosis, amyloidosis

Toxins

- Doxorubicin, alcohol, cocaine, irradiation

Neuromuscular disorders

- Dystrophin myotonia, Friedreich's ataxia

Cardiac tumours

Primary cardiac tumours are rare (< 0.2% of autopsies) but the heart and mediastinum may be the site of metastases. Most primary tumours are benign (75%) and, of these, the majority are myxomas. The remainder are fibromas, lipomas, fibroelastomas and haemangiomas.

Atrial myxoma

Myxomas most commonly arise in the LA as single or multiple polypoid tumours, attached by a pedicle to the interatrial septum. They are usually gelatinous but may be solid and even calcified, with superimposed thrombus.

On examination the first heart sound is usually loud, and there may be a murmur of mitral regurgitation with a variable diastolic sound (tumour 'plop') due to prolapse of the mass through the mitral valve. The tumour can be detected incidentally on echocardiography, or following investigation of pyrexia, syncope, arrhythmias or emboli. Occasionally, the condition presents with malaise and features suggestive of a connective tissue disorder, including a raised ESR.

Treatment is by surgical excision. If the pedicle is removed, fewer than 5% of tumours recur.

DISEASES OF THE PERICARDIUM

The normal pericardial sac contains about 50 mL of fluid, similar to lymph, which lubricates the surface of the heart. The pericardium limits distension of the heart, contributes to the haemodynamic interdependence of the ventricles, and acts as a barrier to infection. Nevertheless, congenital absence of the pericardium does not appear to result in significant clinical or functional limitations.

Acute pericarditis

Aetiology

Pericardial inflammation may be due to a number of pathologies (Box 18.129) but sometimes remains unexplained. Pericarditis and myocarditis often coexist, and all forms of pericarditis may produce a pericardial effusion (see below) that, depending on the aetiology, may be fibrinous, serous, haemorrhagic or purulent.

A fibrinous exudate may eventually lead to varying degrees of adhesion formation, whereas serous pericarditis often produces a large effusion of turbid, straw-coloured fluid with a high protein content.

A haemorrhagic effusion is often due to malignant disease, particularly carcinoma of the breast or bronchus, and lymphoma.

Purulent pericarditis is rare and may occur as a complication of septicaemia, by direct spread from an intra-thoracic infection, or from a penetrating injury.

18.129 Aetiology of acute pericarditis

Common

- Viral (e.g. Coxsackie B but often not identified)
- Acute MI

Less common

- Uraemia
- Connective tissue disease (e.g. SLE)
- Malignant disease
- Trauma (e.g. blunt chest injury)

Rare (in UK)

- Bacterial infection
- Tuberculosis
- Rheumatic fever

Clinical features

The characteristic pain of pericarditis is retrosternal, radiates to the shoulders and neck, and is typically aggravated by deep breathing, movement, a change of position, exercise and swallowing. A low-grade fever is common.

A pericardial friction rub is a high-pitched superficial scratching or crunching noise produced by movement of the inflamed pericardium and is diagnostic of pericarditis; it is usually heard in systole but may also be audible in diastole and frequently has a 'to-and-fro' quality.

Investigations and management

The ECG shows ST elevation with upward concavity (Fig. 18.103) over the affected area, which may be widespread. PR interval depression is a very specific indicator of acute pericarditis. Later, there may be T-wave inversion, particularly if there is a degree of myocarditis.

The pain is usually relieved by aspirin (600mg 4-hourly) but a more potent anti-inflammatory agent such as indometacin (25mg 8-hourly) may be required. Corticosteroids may suppress symptoms but there is no evidence that they accelerate cure.

In viral pericarditis, recovery usually occurs within a few days or weeks but there may be recurrences (chronic relapsing pericarditis). Purulent pericarditis requires treatment with antimicrobial therapy, pericardiocentesis and, if necessary, surgical drainage.

Fig. 18.103 ECG in viral pericarditis. Widespread ST elevation (leads I, II, aVL and V₁–V₆) is shown. The upward concave shape of the ST segments (see leads II and V₆) and the unusual distribution of changes (involving anterior and inferior leads) help to distinguish pericarditis from acute MI.

Pericardial effusion

If a pericardial effusion develops, there is sometimes a sensation of retrosternal oppression. An effusion is difficult to detect clinically. The heart sounds may become quieter, although a pericardial friction is not always abolished.

The QRS voltages on the ECG are often reduced in the presence of a large effusion. The QRS complexes may alternate in amplitude due to a to-and-fro motion of the heart within the fluid-filled pericardial sac (electrical alternans). Serial chest X-rays may show a rapid increase in the size of the cardiac shadow over days or even hours, and when there is a large effusion the heart often has a globular or pear-shaped appearance. Echocardiography is the definitive investigation (Fig. 18.104).

Cardiac tamponade

This term is used to describe acute heart failure due to compression of the heart by a large or rapidly developing effusion and is described in detail on page 542. Typical physical findings are of a markedly raised jugular venous pulse, hypotension, pulsus paradoxus (p. 528) and oliguria. Atypical presentations may occur when the effusion is loculated as a result of previous pericarditis or cardiac surgery.

Pericardial aspiration

Aspiration of a pericardial effusion is indicated for diagnostic purposes or for the treatment of cardiac tamponade. A needle is inserted under echocardiographic guidance medial to the cardiac apex or below the xiphoid process, directing upwards towards the left shoulder. The route of choice will depend on the experience of the operator, the shape of the patient and the position of the effusion. A few millilitres of fluid aspirated through the needle may be sufficient for diagnostic purposes but a drain is needed for symptom relief.

Complications of pericardiocentesis include arrhythmias, damage to a coronary artery, and bleeding with exacerbation of tamponade as a result of injury to the

RV. When tamponade is due to cardiac rupture or aortic dissection, pericardial aspiration may precipitate further potentially fatal bleeding and in these situations emergency surgery is the treatment of choice. A viscous, loculated or recurrent effusion may also require formal surgical drainage.

Tuberculous pericarditis

Tuberculous pericarditis may complicate pulmonary tuberculosis but may also be the first manifestation of the infection. In Africa, a tuberculous pericardial effusion is a common feature of AIDS (p. 396).

The condition typically presents with chronic malaise, weight loss and a low-grade fever. An effusion usually develops and the pericardium may become thick and unyielding, leading to pericardial constriction or tamponade. An associated pleural effusion is often present.

The diagnosis may be confirmed by aspiration of the fluid and direct examination or culture for tubercle bacilli. Treatment requires specific antituberculous chemotherapy (p. 693); in addition, a 3-month course of prednisolone (initial dose 60 mg a day, tapering down rapidly) improves outcome.

Chronic constrictive pericarditis

Constrictive pericarditis is due to progressive thickening, fibrosis and calcification of the pericardium. In effect, the heart is encased in a solid shell and cannot fill properly. The calcification may extend into the myocardium, so there may also be impaired myocardial contraction. The condition often follows an attack of tuberculous pericarditis but can also complicate haemopericardium, viral pericarditis, rheumatoid arthritis and purulent pericarditis. It is often impossible to identify the original insult.

Clinical features and management

The symptoms and signs of systemic venous congestion are the hallmarks of constrictive pericarditis. Atrial fibrillation is common and there is often dramatic ascites and hepatomegaly (Box 18.130). Breathlessness is not a prominent symptom because the lungs are seldom congested.

The condition is sometimes overlooked but should be suspected in any patient with unexplained right heart failure and a small heart. A chest X-ray, which may show pericardial calcification (Fig. 18.105), and

Fig. 18.104 Pericardial effusion (EFF). Echocardiogram (apical view).

18.130 Clinical features of constrictive pericarditis

- Fatigue
- Rapid, low-volume pulse
- Elevated JVP with a rapid y descent
- Kussmaul's sign (a paradoxical rise in the JVP during inspiration)
- Loud early third heart sound or 'pericardial knock'
- Hepatomegaly
- Ascites
- Peripheral oedema
- Pulsus paradoxus (excessive fall in BP during inspiration): present in some cases

Fig. 18.105 Lateral chest X-ray from a patient with severe heart failure due to chronic constrictive pericarditis. There is heavy calcification of the pericardium.

echocardiography often help to establish the diagnosis. CT and MRI are also useful techniques for imaging the pericardium.

Constrictive pericarditis is often difficult to distinguish from restrictive cardiomyopathy and the final diagnosis may depend on complex echo-Doppler studies and cardiac catheterisation. Surgical resection of the diseased pericardium can lead to a dramatic improvement but carries a high morbidity with disappointing results in up to 50% of patients.

Respiratory disease is responsible for a major burden of morbidity and untimely death, and conditions such as tuberculosis, pandemic influenza and pneumonia are the most important conditions in world health terms. In addition, the increasing prevalence of allergy, asthma and chronic obstructive pulmonary disease (COPD) contribute to the overall burden of chronic disease in the community. By 2025, the number of cigarette smokers world-wide is anticipated to increase to 1.5 billion, ensuring a growing burden of tobacco-related respiratory conditions.

The approach to respiratory disease embraces the basic medical sciences and covers a breadth of pathologies, including infectious, inflammatory, neoplastic and degenerative processes. The practice of respiratory medicine thus requires the collaboration of a range of disciplines. Recent advances have improved the lives of many patients with obstructive lung disease, cystic fibrosis, obstructive sleep apnoea and pulmonary hypertension, but the outlook remains poor for lung and other respiratory cancers, and for some of the fibrosing lung conditions.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

The lungs occupy the upper two-thirds of the bony thorax, bounded medially by the spine, the heart and the mediastinum and inferiorly by the diaphragm. During breathing, free movement of the lung surface relative to the chest wall is facilitated by sliding contact between

the parietal and visceral pleura, which cover the inner surface of the chest wall and the lung respectively, and are normally in close apposition. Inspiration involves downward contraction of the dome-shaped diaphragm (innervated by the phrenic nerves originating from C3, 4 and 5) and upward, outward movement of the ribs on the costovertebral joints, caused by contraction of the external intercostal muscles (innervated by the corresponding intercostal nerves originating from the thoracic spinal cord). Expiration is largely passive, driven by elastic recoil of the lungs. The control of this 'respiratory cycle' is described below.

The conducting airways from the nose to the alveoli connect the external environment with the extensive, thin and vulnerable alveolar surface. As air is inhaled through the upper airways, it is filtered in the nose, heated to body temperature and fully saturated with water vapour; partial recovery of this heat and moisture occurs on expiration. Total airway cross-section is smallest in the glottis and trachea, which means that airflow is rapid here and the airway is particularly vulnerable to obstruction by foreign bodies and tumours. Normal breath sounds originate mainly from the rapid turbulent airflow in the larynx and in these central airways.

The multitude of small airways within the lung parenchyma have a very large combined cross-sectional area (over 300 cm² in the third-generation respiratory bronchioles), resulting in very slow flow rates. Airflow is normally silent here, and gas transport occurs largely by diffusion in the final generations. Major bronchial and pulmonary divisions are shown in Figure 19.1.

Fig. 19.1 The major bronchial divisions and the fissures, lobes and segments of the lungs. The angle of the oblique fissure means that the left upper lobe is largely anterior to the lower lobe. On the right, the transverse fissure separates the upper from the anteriorly placed middle lobe, which is matched by the lingular segment on the left side. The site of a lobe determines whether physical signs are mainly anterior or posterior. Each lobe is composed of two or more bronchopulmonary segments which are supplied by the main branches of each lobar bronchus. *Bronchopulmonary segments:* **Right**—Upper lobe: (1) Anterior, (2) Posterior, (3) Apical. Middle lobe: (1) Lateral, (2) Medial. Lower lobe: (1) Apical, (2) Posterior basal, (3) Lateral basal, (4) Anterior basal, (5) Medial basal. **Left**—Upper lobe: (1) Anterior, (2) Apical, (3) Posterior, (4) Lingular. Lower lobe: (1) Apical, (2) Posterior basal, (3) Lateral basal, (4) Anterior basal.

The acinus is the gas exchange unit of the lung (Fig. 19.2) and comprises branching respiratory bronchioles and clusters of alveoli. The filtered, moistened and heated air makes close contact here with the blood in the pulmonary capillaries (gas-to-blood distance $< 0.4 \mu\text{m}$), and oxygen uptake and CO_2 excretion occur. The alveoli are lined with flattened epithelial cells (type I pneumocytes) and a few, more cuboidal, type II pneumocytes. The latter produce surfactant, which is a mixture of phospholipids that reduces surface tension and counteracts the tendency of alveoli to collapse. Type II pneumocytes can also divide to reconstitute type I pneumocytes after lung injury.

Lung mechanics

Healthy lung parenchyma contains a fine network of elastin and collagen fibres within the alveolar walls (see Fig. 19.2). At the end of a tidal breath out, the inward elastic recoil of the lungs (resulting from stretch of the elastin fibres and surface tension in the alveolar lining fluid) is balanced by resistance of the chest wall to inward distortion, resulting in a negative pleural pressure. The arrangement of fibres results in the lung being easily distended (elastin) at physiological lung volumes, but increasingly stiff (collagen) as full inflation is approached. The elastic forces are distributed evenly throughout the parenchyma, maintaining airway patency by radial traction on small airway walls. Even in health, however, these airways narrow during

exhalation because they are surrounded by alveoli at higher pressure. Airway collapse is prevented by radial elastic traction, so in health the minimum lung volume achievable is limited by the capacity of the respiratory muscles to distort the chest wall inwards. In emphysema, loss of alveolar walls leaves the small airways unsupported and collapsible, resulting in expiratory air trapping and hyperinflation (p. 672).

Control of breathing

The respiratory motor neurons in the medulla oblongata discharge rhythmically and are the origin of the respiratory cycle. These neurons receive information on the state of the respiratory system from multiple inputs in health and in disease (see Fig. 19.9, p. 653):

- Central chemoreceptors in the ventrolateral medulla sense the pH of the cerebrospinal fluid (CSF) and are indirectly stimulated by a rise in arterial PCO_2 .
- The carotid bodies sense hypoxaemia but are mainly activated by arterial PO_2 values below 8 KPa (60 mmHg).
- Muscle spindles in the respiratory muscles sense changes in mechanical load.
- Vagal sensory fibres from the lung may be stimulated by stretch or by various disease processes in the interstitium.
- Cortical influences can override the automatic control of breathing.

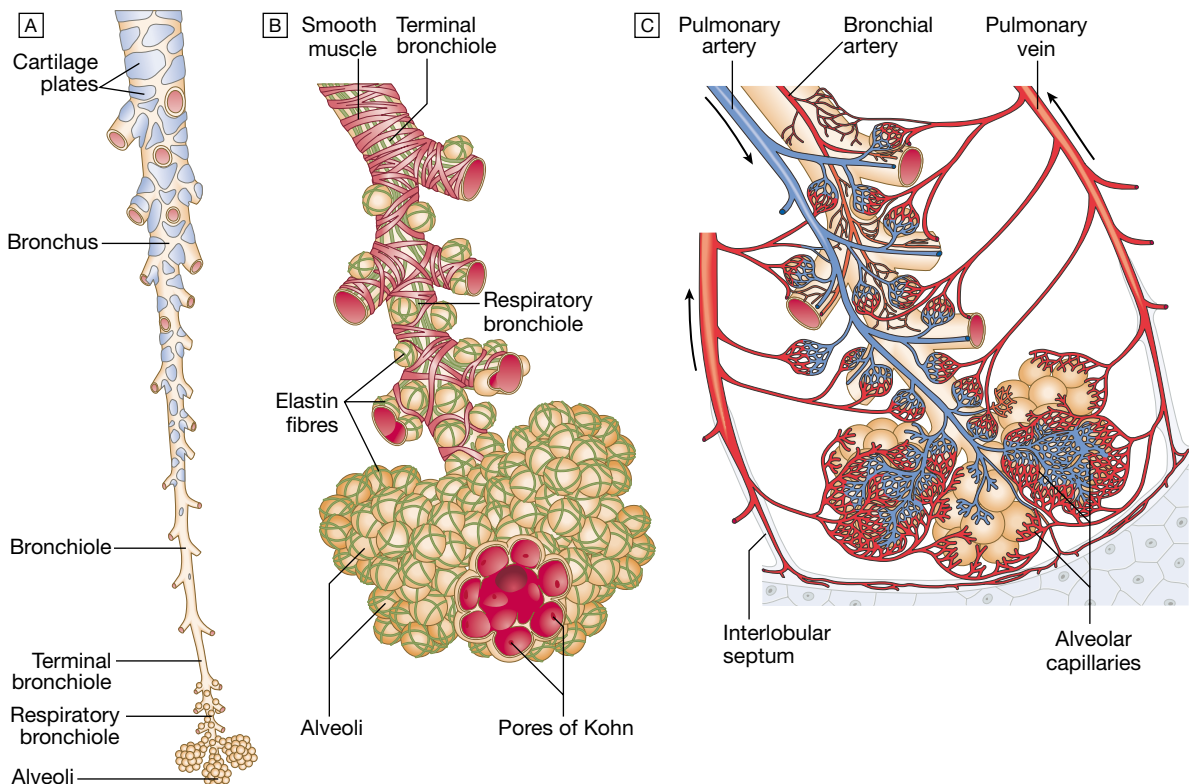

Fig. 19.2 Functional anatomy of the lung. **A** The tapering, branching bronchus is armoured against compression by plates of cartilage. The more distal bronchioles are collapsible, but held patent by surrounding elastic tissue. **B** The unit of lung supplied by a terminal bronchiole is called an acinus. The bronchiolar wall contains smooth muscle and elastin fibres. The latter also run through the alveolar walls. Gas exchange occurs in the alveoli, which are connected to each other by the pores of Kohn. **C** Vascular anatomy of an acinus. Both the pulmonary artery (carrying desaturated blood) and the bronchial artery (systemic supply to airway tissue) run along the bronchus. The venous drainage to the left atrium follows the interlobular septa.

Ventilation/perfusion matching and the pulmonary circulation

To achieve optimal gas exchange within the lungs, the regional distribution of ventilation and perfusion must be matched. Gravity determines the distribution of ventilation and blood flow in the lungs, with most of both going to the dependent zones. Within each lung, hypoxia constricts pulmonary arterioles and airway CO_2 dilates bronchi, helping to maintain good matching of ventilation and perfusion within pulmonary segments. Lung disease may create regions of relative underventilation or underperfusion, which disturb this physiological matching of regional ventilation and perfusion, causing respiratory failure (pp. 660–662). In addition to causing ventilation–perfusion mismatch, diseases that destroy or thicken the alveolar capillary membrane (e.g. emphysema or fibrosis) can impair gas diffusion directly.

The pulmonary circulation in health operates at low pressure (approximately 24/9 mmHg), and can accommodate large increases in flow without much rise in pressure, e.g. during exercise. Pulmonary hypertension occurs when pulmonary vessels are destroyed by emphysema, obstructed by thrombus or involved in interstitial inflammation or fibrosis. The right ventricle responds by hypertrophy, with right axis deviation and P pulmonale on the ECG. Pulmonary hypertension with hypoxia and hypercapnia is associated with generalised salt and water retention ('cor pulmonale'), with elevation of the jugular venous pressure (JVP) and peripheral oedema. This is thought to result mainly from a failure of the hypoxic and hypercapnic kidney to excrete sufficient salt and water.

Lung defences

Upper airway defences

Large airborne particles are trapped by nasal hairs, and smaller particles settling on the mucosa are cleared towards the oropharynx by the columnar ciliated epithelium which covers the turbinates and septum (Fig. 19.3). During cough, expiratory muscle effort against a closed glottis results in high intrathoracic pressure, which is then released explosively. The flexible posterior tracheal wall is pushed inwards by the high surrounding pressure, reducing tracheal cross-section and maximising

Fig. 19.3 The mucociliary escalator. Scanning electron micrograph of the respiratory epithelium showing large numbers of cilia (C) overlaid by the mucus 'raft' (M).

19.1 Respiratory function in old age

- **Reserve capacity:** a significant reduction in function can occur with ageing with only minimal effect on normal breathing, although the ability to combat acute intercurrent disease is reduced.
- **Decline in FEV_1 :** the FEV_1/FVC (forced expiratory volume/forced vital capacity) ratio falls by around 0.2% per year from 70% at the age of 40–45 years, due to a decline in elastic recoil in the small airways with age. Smoking accelerates this decline threefold on average. Symptoms usually only occur when FEV_1 drops below 50% of predicted.
- **Increasing ventilation–perfusion mismatch:** the reduction in elastic recoil causes a tendency for the small airways to collapse during expiration, particularly in dependent areas of the lungs, thus reducing ventilation.
- **Reduced ventilatory responses to hypoxia and hypercapnia:** older people may be less tachypnoeic for any given fall in PaO_2 or rise in PaCO_2 .
- **Impaired defences against infection:** due to reduced numbers of glandular epithelial cells which lead to a reduction in protective mucus.
- **Decline in maximum oxygen uptake:** due to a combination of changes in muscle, and the respiratory and cardiovascular systems. This leads to a reduction in cardiorespiratory reserve and exercise capacity.
- **Loss of chest wall compliance:** due to reduced intervertebral disc spaces and ossification of the costal cartilages; respiratory muscle strength and endurance also decline. These changes only become important in the presence of other respiratory disease.

the airspeed to achieve effective expectoration. The larynx also acts as a sphincter protecting the airway during swallowing and vomiting.

Lower airway defences

The sterility, structure and function of the lower airways are maintained by close cooperation between the innate and adaptive immune responses (pp. 70–76).

The innate response in the lungs is characterised by a number of non-specific defence mechanisms. Inhaled particulate matter is trapped in airway mucus and cleared by the mucociliary escalator. Cigarette smoke increases mucus secretion but reduces mucociliary clearance and predisposes towards lower respiratory tract infections, including pneumonia. Defective mucociliary transport is also a feature of several rare diseases, including Kartagener's syndrome, Young's syndrome and ciliary dysmotility syndrome, which are characterised by repeated sino-pulmonary infections and bronchiectasis.

Airway secretions contain an array of antimicrobial peptides (such as defensins, immunoglobulin A (IgA) and lysozyme), antiproteases and antioxidants. Many of these assist with the opsonisation and killing of bacteria, and the regulation of the powerful proteolytic enzymes secreted by inflammatory cells. In particular, α_1 -antiprotease (A1Pi) regulates neutrophil elastase, and deficiency of this may be associated with premature emphysema.

Macrophages engulf microbes, organic dusts and other particulate matter. They are unable to digest inorganic agents such as asbestos or silica, which result in their death and the release of powerful proteolytic enzymes that cause parenchymal damage. Neutrophil numbers in the airway are low, but the pulmonary circulation contains a margined pool that may be recruited rapidly in response to bacterial infection. This may explain the prominence of lung injury in sepsis syndromes and trauma.

Adaptive immunity is characterised by the specificity of the response and the development of memory. Lung dendritic cells facilitate antigen presentation to T- and B-lymphocytes.

INVESTIGATION OF RESPIRATORY DISEASE

A detailed history, thorough examination and basic haematological and biochemical tests usually suggest the likely diagnosis and key differentials. However, a number of further investigations are usually required to confirm the diagnosis and/or monitor disease activity.

Imaging

The 'plain' chest X-ray

This is performed on the majority of patients suspected of having chest disease. A postero-anterior (PA) film provides information on the lung fields, heart, mediastinum, vascular structures and the thoracic cage (Fig. 19.4). Additional information may be obtained from a lateral film, particularly if pathology is suspected behind the heart shadow or deep in the diaphragmatic sulci. An approach to interpreting the chest X-ray is given in Box 19.2, and common abnormalities in Box 19.3.

19.2 How to interpret a chest X-ray

Name, date, orientation	Films are postero-anterior (PA) unless marked AP to denote antero-posterior
Lung fields	Equal translucency? Check horizontal fissure from right hilum to sixth rib at the anterior axillary line Masses? Consolidation? Cavitation?
Lung apices	Check behind the clavicles Masses? Consolidation? Cavitation?
Trachea	Central? (Midway between the clavicular heads) Paratracheal mass? Goitre?
Heart	Normal shape? Cardiothoracic ratio (should be < half the intrathoracic diameter) Retrocardiac mass?
Hila	Left should be higher than right Shape? (Should be concave laterally; if convex, consider mass or lymphadenopathy) Density?
Diaphragms	Right should be higher than left Hyperinflation? No more than 10 ribs should be visible posteriorly above the diaphragm)
Costophrenic angles	Acute and well-defined? (Pleural fluid or thickening, if not)
Soft tissues	Breast shadows in females Chest wall for masses or subcutaneous emphysema
Bones	Ribs, vertebrae, scapulae and clavicles Any fracture visible at bone margins or lucencies?

Fig. 19.4 The normal chest X-ray.

Note lung markings consist of branching and tapering lines radiating out from the hila; where airways and vessels turn towards the film they can appear as open or filled circles (see upper pole of right hilum). The scapulae may overlie the lung fields; trace the edge of bony structures to avoid mistaking them for pleural or pulmonary shadows. To check for hyperinflation, count the ribs; if more than 10 are visible posteriorly above the diaphragm, the lungs are hyperinflated.

19.3 Common chest X-ray abnormalities

Pulmonary and pleural shadowing

- **Consolidation:** infection, infarction, inflammation, and rarely bronchoalveolar cell carcinoma
- **Lobar collapse:** mucus plugging, tumour, compression by lymph nodes
- **Solitary nodule:** see pages 657–658
- **Multiple nodules:** miliary tuberculosis (TB), dust inhalation, metastatic malignancy, healed varicella pneumonia, rheumatoid disease
- **Ring shadows, tramlines and tubular shadows:** bronchiectasis
- **Cavitating lesions:** tumour, abscess, infarct, pneumonia (*Staphylococcus/Klebsiella*), Wegener's granulomatosis
- **Reticular, nodular and reticulonodular shadows:** diffuse parenchymal lung disease, infection
- **Pleural abnormalities:** fluid, plaques, tumour

Increased translucency

- Bullae
- Pneumothorax
- Oligaemia

Hilar abnormalities

- **Unilateral hilar enlargement:** TB, bronchial carcinoma, lymphoma
- **Bilateral hilar enlargement:** sarcoid, lymphoma, TB, silicosis

Other abnormalities

- Hiatus hernia
- Surgical emphysema

Increased shadowing may represent accumulation of fluid, lobar collapse or consolidation. Uncomplicated consolidation should not change the position of the mediastinum and the presence of an air bronchogram means that proximal bronchi are patent. Collapse (implying obstruction of the proximal bronchus) is accompanied by loss of volume and displacement of the mediastinum towards the affected side (see Fig. 19.43, p. 700).

The presence of ring shadows (diseased bronchi seen end-on), tramline shadows (diseased bronchi side-on) or tubular shadows (bronchi filled with secretions) suggests bronchiectasis. The presence of pleural fluid is suggested by a dense basal shadow which, in the erect patient, ascends towards the axilla. In large pulmonary embolism, relative oligoemia may cause a lung field to appear abnormally dark.

Computed tomography (CT)

CT provides detailed images of the pulmonary parenchyma, mediastinum, pleura and bony structures (Figs 19.5 and 19.57, p. 714). The displayed range of densities can be adjusted to highlight different structures such as the lung parenchyma, the mediastinal vascular structures or bone. Sophisticated software facilitates three-dimensional reconstruction of the thorax and virtual bronchoscopy.

CT is superior to chest radiography in determining the position and size of a pulmonary lesion and whether calcification or cavitation is present. It is now routinely used in the assessment of patients with suspected lung cancer and facilitates guided percutaneous

Fig. 19.5 CT and positron emission tomography (PET) combined to reveal intrathoracic metastases. In a patient with lung cancer, CT **A** shows some posterior pleural thickening. PET scanning **B** reveals FDG uptake in two pleural lesions (arrows), highlighted in yellow in the combined PET/CT image **C**.

needle biopsy. Information on tumour stage may be gained by examining the mediastinum, liver and adrenal glands.

High-resolution CT (HRCT) uses thin sections to provide detailed images of the pulmonary parenchyma and is particularly useful in assessing diffuse parenchymal lung disease, identifying bronchiectasis (see Fig. 19.28, p. 677), and assessing the type and extent of emphysema.

CT pulmonary angiography (CTPA) is used increasingly in the diagnosis of pulmonary thromboembolism (see Fig. 19.60, p. 719), when it may either confirm the suspected embolism or highlight an alternative diagnosis.

Ultrasound

Ultrasound is sensitive at detecting pleural fluid and may also be employed to direct and improve the diagnostic yield from pleural biopsy. It is also used to investigate

the anatomy of an empyema cavity to facilitate directed drainage, and to guide needle biopsy of superficial lymph node or chest wall masses. Endobronchial ultrasound is now possible using specialised bronchoscopes, and is used for imaging and sampling peribronchial lymph nodes.

Ventilation-perfusion imaging

In this technique, the lungs are imaged using a gamma camera that is able to distinguish two isotopes, inhaled ^{133}Xe (yielding ventilation images) and injected macroaggregates of $^{99\text{m}}\text{Tc}$ -albumin (yielding perfusion images). Pulmonary emboli appear as perfusion defects with preserved ventilation. However, the utility of this technique is limited in patients with underlying lung disease, in whom up to 70% of scans may be indeterminate. It is increasingly being replaced by CTPA.

Positron emission tomography (PET)

PET scanners exploit the avid ability of malignant tissue to absorb and metabolise glucose. The radiotracer ^{18}F -fluorodeoxyglucose (FDG) is administered and rapidly taken up by malignant tissue. It is then phosphorylated but cannot be metabolised further, becoming 'trapped' in the cell. PET is useful in the investigation of pulmonary nodules, and in staging mediastinal lymph nodes and distal metastatic disease in patients with lung cancer. The negative predictive value is high; however, the positive predictive value is poor. Co-registration of PET and CT (PET-CT) enhances localisation and characterisation of metabolically active deposits (see Fig. 19.5C).

Pulmonary angiography

Images taken with contrast medium in the main pulmonary artery are rarely used, particularly now that CTPA is widely available. Right heart catheterisation remains useful in the investigation of patients with pulmonary hypertension, providing information on pulmonary and right heart pressures.

Endoscopic examination

Laryngoscopy

The larynx may be inspected indirectly with a mirror or directly with a laryngoscope. Fibreoptic instruments allow a magnified view to be obtained.

Bronchoscopy

The trachea and larger bronchi may be inspected using either a flexible or a rigid bronchoscope. Flexible bronchoscopy may be performed under local anaesthesia with sedation on an outpatient basis. Structural changes, such as distortion or obstruction, can be seen. Abnormal tissue in the bronchial lumen or wall can be biopsied, and bronchial brushings, washings or aspirates can be taken for cytological or bacteriological examination. Small biopsy specimens of lung tissue, taken by forceps passed through the bronchial wall (transbronchial biopsies), may reveal sarcoid granulomas or malignant diseases and may be helpful in diagnosing certain bronchocentric disorders (e.g. hypersensitivity pneumonitis, cryptogenic organising pneumonia), but are generally too small to be of diagnostic value in other diffuse parenchymal pulmonary disease (p. 705). Transbronchial needle aspiration

(TBNA) may be used to sample mediastinal lymph nodes and in the staging of lung cancer.

Rigid bronchoscopy requires general anaesthesia and is reserved for specific situations such as massive haemoptysis or removal of foreign bodies (see Fig. 19.8, p. 652). Endobronchial laser therapy and endobronchial stenting may be performed more easily with rigid bronchoscopy.

Assessment of the mediastinum

Lymph nodes down to the main carina can be sampled using a mediastinoscope passed through a small incision at the suprasternal notch under general anaesthetic. This procedure is particularly useful in lung cancer as a means of determining whether nodal disease is present. Endobronchial ultrasound (EBUS) using a specialised bronchoscope allows directed needle aspiration from peribronchial nodes but is not yet widely available. Lymph nodes in the lower mediastinum may be biopsied via the oesophagus using endoscopic ultrasound (EUS), an oesophageal endoscope equipped with an ultrasound transducer and biopsy needle.

Investigation of pleural disease

The traditional method of pleural biopsy using an Abram's needle is largely being replaced by the use of core biopsy guided by either ultrasound or CT. Thoracoscopy, which involves the insertion of an endoscope through the chest wall, facilitates biopsy under direct vision and is practised by many surgeons and an increasing number of physicians.

Skin tests

The tuberculin test (pp. 694–695) may be of value in the diagnosis of tuberculosis. Skin hypersensitivity tests are useful in the investigation of allergic diseases (p. 88).

Immunological and serological tests

The presence of pneumococcal antigen (revealed by counter-immunoelectrophoresis) in sputum, blood or urine may be of diagnostic importance in pneumonia. Exfoliated cells colonised by influenza A virus can be detected by fluorescent antibody techniques. In blood, high or rising antibody titres to specific organisms (such as *Legionella*, *Mycoplasma*, *Chlamydia* or viruses) may eventually clinch a diagnosis suspected on clinical grounds. Precipitating antibodies may be found as a reaction to fungi such as *Aspergillus* (p. 697) or to antigens involved in hypersensitivity pneumonitis (p. 710).

Microbiological investigations

Sputum, pleural fluid, throat swabs, blood and bronchial washings and aspirates can be examined for bacteria, fungi and viruses. In some cases, as when *Mycobacterium tuberculosis* is isolated, the information is diagnostically conclusive, but in others the findings must be interpreted in conjunction with the results of clinical and radiological examination.

Induced sputum

The use of hypertonic saline to induce expectoration of sputum is useful in facilitating the collection of specimens for microbiology, particularly in patients in whom

more invasive procedures such as bronchoscopy are not possible. The technique also allows assessment of the inflammatory cell constituency of the airway, which is a useful research tool in many conditions including asthma, COPD and interstitial lung disease.

Histopathological and cytological examination

Histopathological examination of biopsy material obtained from pleura, lymph node or lung often allows a 'tissue diagnosis' to be made. This is of particular importance in suspected malignancy or in elucidating the pathological changes in interstitial lung disease. Important causative organisms, such as *M. tuberculosis*, *Pneumocystis jirovecii* or fungi, may be identified in bronchial washings, brushings or transbronchial biopsies.

Cytological examination of exfoliated cells in sputum, pleural fluid or bronchial brushings and washings, or of fine needle aspirates from lymph nodes or pulmonary lesions can support a diagnosis of malignancy, but if this is indeterminate a tissue biopsy is necessary. Cellular patterns in bronchial lavage fluid may help to distinguish pulmonary changes due to sarcoidosis (p. 708) from those caused by idiopathic pulmonary fibrosis (p. 707) or hypersensitivity pneumonitis (p. 710).

Respiratory function testing

Respiratory function tests are used to aid diagnosis, assess functional impairment, and monitor treatment or progression of disease. Airway narrowing, lung volume and gas exchange capacity are quantified and compared with normal values adjusted for age, gender, height and ethnic origin. Typical laboratory traces are illustrated in Figure 19.6.

Forced expiratory volume (FEV₁) and forced vital capacity (FVC)

In diseases characterised by airway narrowing (e.g. asthma, bronchitis and emphysema), maximum expiratory flow is limited by dynamic compression of small intrathoracic airways, some of which close completely during expiration, limiting the volume which can be expired (obstructive defect). Hyperinflation of the chest results, and can become extreme if elastic recoil is also lost due to parenchymal destruction, as in emphysema. In contrast, diseases which cause interstitial inflammation and/or fibrosis lead to progressive loss of lung volume (restrictive defect) with normal expiratory flow rates.

Airway narrowing is assessed by asking patients to blow out as hard and as fast as they can into a peak flow meter or a spirometer. Peak flow meters are

Fig. 19.6 Respiratory function tests in health and disease. **A** Volume/time traces from forced expiration in a normal subject, a patient with COPD and a patient with fibrosis. COPD causes slow, prolonged and limited exhalation. In fibrosis, forced expiration results in rapid expulsion of a reduced forced vital capacity (FVC). Forced expiratory volume (FEV₁) is reduced in both diseases but is disproportionately reduced compared to FVC in COPD. **B** The same data plotted as flow/volume loops. In COPD, collapse of intrathoracic airways limits flow, particularly during mid- and late expiration. The blue trace illustrates large airway obstruction, which particularly limits peak flow rates. **C** Lung volume measurement. Volume/time graphs during quiet breathing with a single maximal breath in and out. COPD causes hyperinflation with increased residual volume. Fibrosis causes a proportional reduction in all lung volumes.

cheap and convenient for home monitoring of peak expiratory flow (PEF) in the detection and monitoring of asthma, but values are effort-dependent. The FEV_1 and FVC are obtained from a maximal forced expiration into a spirometer. FEV_1 is disproportionately reduced in airflow obstruction, resulting in FEV_1/FVC ratios of less than 70%. When airflow obstruction is seen, spirometry should be repeated following inhaled short-acting β_2 -adrenoceptor agonists (e.g. salbutamol); reversibility to normal is suggestive of asthma (p. 665).

Flow/volume loops

To distinguish large airway narrowing (e.g. tracheal stenosis or compression) from small airway narrowing, flow/volume loops are recorded using spirometry. These display flow as it relates to lung volume (rather than time) during maximum expiration and inspiration, and the pattern of flow reveals the site of airflow obstruction (see Fig. 19.6).

Lung volumes

Tidal volume and vital capacity (VC) can be measured by spirometry. Total lung capacity (TLC) can be measured by asking the patient to rebreath an inert non-absorbed gas (usually helium) and recording the dilution of test gas by lung gas. This measures the volume of intrathoracic gas which mixes quickly with tidal breaths. Alternatively, lung volume may be measured by body plethysmography, which determines the pressure/volume relationship of the thorax. This method measures total intrathoracic gas volume, including poorly ventilated areas such as bullae.

Transfer factor

To measure the capacity of the lungs to exchange gas, patients inhale a test mixture of 0.3% carbon monoxide, which is avidly bound to haemoglobin in pulmonary capillaries. After a short breath-hold, the rate of disappearance of CO into the circulation is calculated from a sample of expirate, and expressed as the TL_{CO} or carbon monoxide transfer factor. Helium is also included in the test breath to allow calculation of the volume of lung examined by the test breath. Transfer factor expressed per unit lung volume is termed K_{CO} . Common respiratory function abnormalities are summarised in Box 19.4.

19.4 How to interpret respiratory function abnormalities

	Asthma	Chronic bronchitis	Emphysema	Pulmonary fibrosis
FEV_1	↓↓	↓↓	↓↓	↓
VC	↓	↓	↓	↓↓
FEV_1/VC	↓	↓	↓	→/↑
TL_{CO}	→	→	↓↓	↓↓
K_{CO}	→/↑	→	↓	→/↓
TLC	→/↑	↑	↑↑	↓
RV	→/↑	↑	↑↑	↓

(RV = residual volume; see text for other abbreviations)

Fig. 19.7 Changes in blood $[H^+]$, $PaCO_2$ and plasma $[HCO_3^-]$ in acid-base disorders. The rectangle indicates limits of normal reference ranges for $[H^+]$ and $PaCO_2$. The bands represent 95% confidence limits of single disturbances in human blood *in vivo*. When the point obtained by plotting $[H^+]$ against $PaCO_2$ does not fall within one of the labelled bands, compensation is incomplete or a mixed disorder is present.

Arterial blood gases and oximetry

The measurement of hydrogen ion concentration, PaO_2 and $PaCO_2$, and derived bicarbonate concentration in an arterial blood sample is essential in assessing the degree and type of respiratory failure and for measuring acid-base status. This is discussed in detail on pages 660 and 442. Interpretation of results is made easier by blood gas diagrams (Fig. 19.7), which indicate whether any acidosis or alkalosis is due to acute or chronic respiratory derangements of $PaCO_2$, or to metabolic causes. Pulse oximeters with finger or ear probes allow non-invasive continuous assessment of oxygen saturation in patients, in order to assess hypoxaemia and its response to therapy. They measure the difference in absorbance of light by oxygenated and deoxygenated blood to calculate its oxygen saturation (SaO_2).

Exercise tests

Resting measurements are sometimes unhelpful in early disease or in patients complaining only of exercise-induced symptoms. Exercise testing with spirometry before and after can be helpful in demonstrating exercise-induced asthma. Walk tests include the self-paced 6-minute walk and the externally paced incremental 'shuttle' test, where patients walk at increasing pace between two cones 10 m apart. These provide simple, repeatable assessments of disability and response to treatment. Cardiopulmonary bicycle or treadmill exercise testing with measurement of metabolic gas exchange, ventilation and cardiac responses is useful for quantifying exercise limitation and for detecting occult cardiovascular or respiratory limitation in the breathless patient.

PRESENTING PROBLEMS IN RESPIRATORY DISEASE

Cough

Cough is the most frequent symptom of respiratory disease. It is caused by stimulation of sensory nerves in the mucosa of the pharynx, larynx, trachea and bronchi. Acute sensitisation of the normal cough reflex occurs in a number of conditions, and it is typically induced by changes in air temperature or exposure to irritants such as cigarette smoke or perfumes. The characteristics of cough originating at various levels of the respiratory tract are detailed in Box 19.5.

The explosive quality of a normal cough is lost in patients with respiratory muscle paralysis or vocal cord palsy. Paralysis of a single vocal cord gives rise to a prolonged, low-pitched, inefficient 'bovine' cough accompanied by hoarseness. Coexistence of an inspiratory noise (stridor) indicates partial obstruction of a major airway (e.g. laryngeal oedema, tracheal tumour, scarring, compression or inhaled foreign body) and requires urgent investigation and treatment. Sputum production is common in patients with acute or chronic cough, and its nature and appearance can provide clues to the aetiology (p. 642).

19.5 Cough

Origin	Common causes	Clinical features
Pharynx	Post-nasal drip	History of chronic rhinitis
Larynx	Laryngitis, tumour, whooping cough, croup	Voice or swallowing altered, harsh or painful cough Paroxysms of cough, often associated with stridor
Trachea	Tracheitis	Raw retrosternal pain with cough
Bronchi	Bronchitis (acute) and COPD	Dry or productive, worse in mornings
	Asthma	Usually dry, worse at night
	Eosinophilic bronchitis	Features similar to asthma but no airway hyper-reactivity (AHR)
	Bronchial carcinoma	Persistent (often with haemoptysis)
Lung parenchyma	Tuberculosis	Productive, often with haemoptysis
	Pneumonia	Dry initially, productive later
	Bronchiectasis	Productive, changes in posture induce sputum production
	Pulmonary oedema	Often at night (may be productive of pink, frothy sputum)
	Interstitial fibrosis	Dry, irritant and distressing
Drug side-effect	ACE inhibitors	Dry cough

Fig. 19.8 Bronchoscopic appearance of inhaled foreign body (tooth) with a covering mucous film.

Causes of cough

Acute transient cough is most commonly caused by viral lower respiratory tract infection, post-nasal drip resulting from rhinitis or sinusitis, aspiration of a foreign body or throat-clearing secondary to laryngitis or pharyngitis. When it occurs in the context of more serious diseases such as pneumonia, aspiration, congestive heart failure or pulmonary embolism, it is usually easy to diagnose from other clinical features.

Patients with chronic cough present more of a diagnostic challenge, especially when physical examination, chest X-ray and lung function studies are normal. In this context, it is most often explained by cough-variant asthma (where cough may be the principal or exclusive clinical manifestation), post-nasal drip secondary to nasal or sinus disease, or gastro-oesophageal reflux with aspiration. Diagnosis of the latter may require ambulatory pH monitoring or a prolonged trial of anti-reflux therapy (p. 863). Between 10 and 15% of patients (particularly women) taking angiotensin-converting enzyme (ACE) inhibitors develop a drug-induced chronic cough. *Bordetella pertussis* infection in adults (p. 681) can also result in protracted cough and should be suspected in those in close contact with children. While most patients with a bronchogenic carcinoma have an abnormal chest X-ray on presentation, fiberoptic bronchoscopy or thoracic CT is advisable in most adults (especially smokers) with otherwise unexplained cough of recent onset, as this may reveal a small endobronchial tumour or unexpected foreign body (Fig. 19.8). In a small percentage of patients, dry cough may be the presenting feature of interstitial lung disease.

Breathlessness

Breathlessness or dyspnoea can be defined as the feeling of an uncomfortable need to breathe. It is unusual

among sensations in having no defined receptors, no localised representation in the brain, and multiple causes both in health (e.g. exercise) and in diseases of the lungs, heart or muscles.

Pathophysiology

Stimuli to breathing resulting from disease processes are summarised in Figure 19.9. Respiratory diseases can stimulate breathing and dyspnoea by:

- stimulating intrapulmonary sensory nerves (e.g. pneumothorax, interstitial inflammation and pulmonary embolus)
- increasing the mechanical load on the respiratory muscles (e.g. airflow obstruction or pulmonary fibrosis)
- causing hypoxia, hypercapnia or acidosis, stimulating chemoreceptors.

In cardiac failure, pulmonary congestion reduces lung compliance and can also obstruct the small airways. In addition, during exercise, reduced cardiac output limits oxygen supply to the skeletal muscles, causing early lactic acidemia and further stimulating breathing via the central chemoreceptors.

Breathlessness and the effects of treatment can be quantified using a symptom scale. Patients tend to report breathlessness in proportion to the sum of the above stimuli to breathe. Individual patients differ greatly in the intensity of breathlessness reported for a given set of

circumstances, but breathlessness scores during exercise within individuals are reproducible, and can be used to monitor the effects of therapy.

Differential diagnosis

Patients with breathlessness present either with chronic exertional breathlessness or as an emergency with acute breathlessness with prominent symptoms even at rest, and the causes are most easily classified accordingly (Box 19.6).

Chronic exertional breathlessness

The cause of breathlessness is often apparent from a careful clinical history. Key questions include:

How is your breathing at rest and overnight?

In COPD, there is a fixed, structural limit to maximum ventilation, and a tendency for progressive hyperinflation during exercise. Breathlessness is mainly apparent during mobilisation, and patients usually report minimal symptoms at rest and overnight. In contrast, patients with significant asthma are often woken from their sleep by breathlessness with chest tightness and wheeze.

Orthopnoea, however, is common in COPD as well as in heart disease, because airflow obstruction is made worse by cranial displacement of the diaphragm by the abdominal contents when recumbent, so many patients

Fig. 19.9 Respiratory stimuli contributing to breathlessness. Mechanisms by which disease can stimulate the respiratory motor neurons in the medulla. Breathlessness is usually felt in proportion to the sum of these stimuli.

19.6 Causes of breathlessness

System	Acute dyspnoea	Chronic exertional dyspnoea
Cardiovascular	*Acute pulmonary oedema (p. 540)	Chronic heart failure (p. 540) Myocardial ischaemia (angina equivalent) (p. 541)
Respiratory	*Acute severe asthma *Acute exacerbation of COPD *Pneumothorax *Pneumonia *Pulmonary embolus Acute respiratory distress syndrome (ARDS) Inhaled foreign body (especially in the child) Lobar collapse Laryngeal oedema (e.g. anaphylaxis)	*COPD *Chronic asthma Bronchial carcinoma Interstitial lung disease (sarcoidosis, fibrosing alveolitis, extrinsic allergic alveolitis, pneumoconiosis) Chronic pulmonary thromboembolism Lymphatic carcinomatosis (may cause intolerable breathlessness) Large pleural effusion(s)
Others	Metabolic acidosis (e.g. diabetic ketoacidosis, lactic acidosis, uraemia, overdose of salicylates, ethylene glycol poisoning) Psychogenic hyperventilation (anxiety or panic-related)	Severe anaemia Obesity Deconditioning

*Denotes a common cause.

choose to sleep propped up. It may thus not be a useful differentiating symptom, unless there is a clear history of previous angina or infarction to suggest cardiac disease.

How much can you do on a good day?

Noting 'breathless on exertion' is not enough; the approximate distance the patient can walk on the level should be documented, along with capacity to climb inclines or stairs. Variability within and between days is a hallmark of asthma; in mild asthma the patient may be free of symptoms and signs when well. Gradual, progressive loss of exercise capacity over months and years with consistent disability over days is typical of COPD. When asthma is suspected, the degree of variability is best documented by home peak flow monitoring.

Relentless, progressive breathlessness that is also present at rest, often accompanied by a dry cough, suggests interstitial fibrosis. Impaired left ventricular function can also cause chronic exertional breathlessness, cough and wheeze. A history of angina, hypertension or myocardial infarction may be useful in implicating a cardiac cause. The suspicion of cardiac impairment may be confirmed by a displaced apex beat, a raised JVP and cardiac murmurs (although these signs can occur in severe cor pulmonale). The chest X-ray may show cardiomegaly and an electrocardiogram (ECG) and echocardiogram may provide evidence of left ventricular disease. Measurement of arterial blood gases may be of value, since in the absence of an intracardiac shunt or pulmonary oedema the PaO_2 in cardiac disease is normal and the $PaCO_2$ is low or normal.

Did you have breathing problems in childhood or at school?

When present, a history of childhood wheeze increases the likelihood of asthma, although this history may be absent in late-onset asthma. Similarly, a history of atopic allergy increases the likelihood of asthma.

Do you have other symptoms along with your breathlessness?

Digital or perioral paraesthesiae and a feeling that 'I cannot get a deep enough breath in' are typical features of psychogenic hyperventilation, but this cannot be diagnosed until investigations have excluded other potential causes of breathlessness. Additional symptoms include lightheadedness, central chest discomfort or even carpopedal spasm due to acute respiratory alkalosis. These alarming symptoms may provoke further anxiety and exacerbate hyperventilation. Psychogenic breathlessness rarely disturbs sleep, frequently occurs at rest, may be provoked by stressful situations and may even be relieved by exercise. The Nijmegen questionnaire can be used to enumerate some of the typical symptoms of hyperventilation (Box 19.7). Arterial blood gases show normal PO_2 , low PCO_2 and alkalosis.

Pleuritic chest pain in a patient with chronic breathlessness, particularly if it occurs in more than one site over time, should raise suspicion of thromboembolic disease. Thromboembolism may occasionally present as chronic breathlessness with no other specific features, and should always be considered before a diagnosis of psychogenic hyperventilation is made.

Morning headache is an important symptom in patients with breathlessness, as it may signal the onset of carbon dioxide retention and respiratory failure. This

19.7 Factors suggesting psychogenic hyperventilation

- 'Inability to take a deep breath'
- Frequent sighing/erratic ventilation at rest
- Short breath-holding time in the absence of severe respiratory disease
- Difficulty in performing/inconsistent spirometry manoeuvres
- High score (over 26) on Nijmegen questionnaire
- Induction of symptoms during submaximal hyperventilation
- Resting end-tidal $CO_2 < 4.5\%$
- Associated digital paraesthesiae

is particularly significant in patients with musculoskeletal disease impairing respiratory function (e.g. kyphoscoliosis or muscular dystrophy).

Acute severe breathlessness

This is one of the most common and dramatic medical emergencies. Although there are a number of possible causes, the history and a rapid but careful examination will usually suggest a diagnosis which can be confirmed by routine investigations, including chest X-ray, ECG and arterial blood gases. Specific features that aid the diagnosis of the important causes are shown in Box 19.8.

History

It is important to establish the rate of onset and severity of the breathlessness and whether associated cardiovascular symptoms (chest pain, palpitations, sweating and nausea) or respiratory symptoms (cough, wheeze, haemoptysis, stridor—Fig. 19.10) are present. A previous history of repeated episodes of left ventricular failure, asthma or exacerbations of COPD is valuable. In the severely ill patient it may be necessary to obtain the history from accompanying relatives or carers. In children, the possibility of inhalation of a foreign body (see Fig. 19.8) or acute epiglottitis (p. 681) should always be considered.

Fig. 19.10 CT showing retrosternal multinodular goitre (small arrow) causing acute severe breathlessness and stridor due to tracheal compression (large arrow).

Clinical assessment

The following should be assessed and documented immediately:

- level of consciousness
- degree of central cyanosis
- evidence of anaphylaxis (urticaria or angioedema)

19.8 Differential diagnosis of acute breathlessness

Condition	History	Signs	CXR	ABG	ECG
Pulmonary oedema	Chest pain, palpitations, orthopnoea, cardiac history*	Central cyanosis, ↑JVP, sweating, cool extremities, basal crepitations*	Cardiomegaly, oedema/pleural effusions*	↓PaO ₂ ↓PaCO ₂	Sinus tachycardia, ischaemia*, arrhythmia
Massive pulmonary embolus	Risk factors, chest pain, pleurisy, syncope*, dizziness*	Central cyanosis, ↑JVP*, absence of signs in the lung*, shock (tachycardia, hypotension)	Often normal Prominent hilar vessels, oligoemic lung fields*	↓PaO ₂ ↓PaCO ₂	Sinus tachycardia, RBBB, S ₁ Q ₃ T ₃ pattern ↓T (V ₁ –V ₄)
Acute severe asthma	History of asthma, asthma medications, wheeze*	Tachycardia, pulsus paradoxus, cyanosis (late), JVP →*, ↓peak flow, wheeze*	Hyperinflation only (unless complicated by pneumothorax)*	↓PaO ₂ ↓PaCO ₂ (↑PaCO ₂ in extremis)	Sinus tachycardia (bradycardia in extremis)
Acute exacerbation of COPD	Previous episodes*, smoker. If in type II respiratory failure may be drowsy	Cyanosis, hyperinflation*, signs of CO ₂ retention (flapping tremor, bounding pulses)*	Hyperinflation*, bullae, complicating pneumothorax	↓ or ↓PaO ₂ ↑PaCO ₂ in type II failure ± ↑H ⁺ , ↑HCO ₃ in chronic type II failure	Normal, or signs of right ventricular strain
Pneumonia	Prodromal illness*, fever*, rigors*, pleurisy*	Fever, confusion, pleural rub*, consolidation*, cyanosis (if severe)	Pneumonic consolidation*	↓PaO ₂ ↓PaCO ₂ (↑ in extremis)	Tachycardia
Metabolic acidosis	Evidence of diabetes mellitus or renal disease, aspirin or ethylene glycol overdose	Fetor (ketones), hyperventilation without heart or lung signs*, dehydration*, air hunger	Normal	PaO ₂ normal ↓PaCO ₂ , ↑H ⁺	
Psychogenic	Previous episodes, digital or peri-oral dysaesthesia	No cyanosis, no heart or lung signs, carpopedal spasm	Normal	PaO ₂ normal* ↓PaCO ₂ , ↓H ⁺ *	

*Denotes a valuable discriminatory feature. (RBBB = right bundle branch block)

- patency of the upper airway
- ability to speak (in single words or sentences)
- cardiovascular status (heart rate and rhythm, blood pressure and degree of peripheral perfusion).

Pulmonary oedema is suggested by pink frothy sputum and bi-basal crackles, asthma or COPD by wheeze and prolonged expiration, pneumothorax by a silent resonant hemithorax, and pulmonary embolus by severe breathlessness with normal breath sounds. The peak expiratory flow should be measured whenever possible. Leg swelling may suggest cardiac failure or, if asymmetrical, venous thrombosis. Arterial blood gases, chest X-ray and an ECG should be obtained to confirm the clinical diagnosis, and high concentrations of oxygen given pending results. Urgent endotracheal intubation (p. 196) may become necessary if the conscious level declines or if severe respiratory acidosis is present.

Chest pain

Chest pain is a frequent manifestation of both cardiac and respiratory disease, and is considered in detail on page 535. Pleural or chest wall involvement by lung disease gives rise to sharp, peripheral pain which is exacerbated by deep breathing or coughing (Box 19.9). Central

19.9 Differential diagnosis of chest pain	
Central	
Cardiac	
• Myocardial ischaemia (angina)	• Pericarditis
• Myocardial infarction	• Mitral valve prolapse syndrome
• Myocarditis	
Aortic	
• Aortic dissection	• Aortic aneurysm
Oesophageal	
• Oesophagitis	• Mallory–Weiss syndrome
• Oesophageal spasm	
Massive pulmonary embolus	
Mediastinal	
• Tracheitis	• Malignancy
Anxiety/emotion¹	
Peripheral	
Lungs/pleura	
• Pulmonary infarct	• Tuberculosis
• Pneumonia	• Connective tissue disorders
• Pneumothorax	
• Malignancy	
Musculoskeletal²	
• Osteoarthritis	• Intercostal muscle injury
• Rib fracture/injury	• Epidemic myalgia (Bornholm disease)
• Costochondritis (Tietze's syndrome)	
Neurological	
• Prolapsed intervertebral disc	• Thoracic outlet syndrome
• Herpes zoster	

¹May also cause peripheral chest pain.

²Can sometimes cause central chest pain.

chest pain suggests heart disease but also occurs with tumours affecting the mediastinum, oesophageal disease (pp. 863–870) or disease of the thoracic aorta (p. 602). Massive pulmonary embolus may cause ischaemic cardiac pain as well as severe breathlessness. Tracheitis produces raw upper retrosternal pain, exacerbated by the accompanying cough. Musculoskeletal chest wall pain is usually exacerbated by movement and associated with local tenderness.

Haemoptysis

Coughing up blood, irrespective of the amount, is an alarming symptom and patients nearly always seek medical advice. A history should be taken to establish that it is true haemoptysis and not haematemesis, or gum or nose bleeding. Haemoptysis must always be assumed to have a serious cause until this is excluded (Box 19.10).

Many episodes of haemoptysis remain unexplained even after full investigation, and are likely to be caused by simple bronchial infection. A history of repeated small haemoptysis, or blood-streaking of sputum, is highly suggestive of bronchial carcinoma. Fever, night sweats and weight loss suggest tuberculosis. Pneumococcal pneumonia often causes 'rusty'-coloured sputum but can cause frank haemoptysis, as can all suppurative pneumonic infections including lung abscess (p. 686). Bronchiectasis (p. 676) and intracavitary mycetoma (p. 698) can cause catastrophic bronchial haemorrhage, and in these patients there may be a history of previous tuberculosis or pneumonia in early life. Finally, pulmonary thromboembolism is a common cause of haemoptysis and should always be considered.

19.10 Causes of haemoptysis	
Bronchial disease	
• Carcinoma*	• Bronchial adenoma
• Bronchiectasis*	• Foreign body
• Acute bronchitis*	
Parenchymal disease	
• Tuberculosis*	• Trauma
• Suppurative pneumonia	• Actinomycosis
• Lung abscess	• Mycetoma
• Parasites (e.g. hydatid disease, flukes)	
Lung vascular disease	
• Pulmonary infarction*	• Polyarteritis nodosa
• Goodpasture's syndrome (p. 502)	• Idiopathic pulmonary haemosiderosis
Cardiovascular disease	
• Acute left ventricular failure*	• Aortic aneurysm
• Mitral stenosis	
Blood disorders	
• Leukaemia	• Anticoagulants
• Haemophilia	

*More common causes.

Physical examination may reveal additional clues. Finger clubbing suggests bronchial carcinoma or bronchiectasis; other signs of malignancy, such as cachexia, hepatomegaly and lymphadenopathy, should also be sought. Fever, pleural rub or signs of consolidation occur in pneumonia or pulmonary infarction; a minority of patients with pulmonary infarction also have unilateral leg swelling or pain suggestive of deep venous thrombosis. Rashes, haematuria and digital infarcts suggest an underlying systemic disease such as a vasculitis, which may be associated with haemoptysis.

Management

In severe acute haemoptysis, the patient should be nursed upright (or on the side of the bleeding if this is known), and given high-flow oxygen and appropriate haemodynamic resuscitation. Bronchoscopy in the acute phase is difficult and often merely shows blood throughout the bronchial tree. If radiology shows an obvious central cause, then rigid bronchoscopy under general anaesthesia may allow intervention to stop bleeding; however, the source often cannot be visualised. Intubation with a divided endotracheal tube may allow protected ventilation of the unaffected lung to stabilise the patient. Bronchial arteriography and embolisation (Fig. 19.11), or even emergency pulmonary surgery, can be life-saving in the acute situation.

In the vast majority of cases, however, the haemoptysis itself is not life-threatening and a logical sequence of investigations should be followed:

- chest X-ray, which may give evidence of a localised lesion including pulmonary infarction, tumour (malignant or benign), pneumonia, mycetoma or tuberculosis

- full blood count and clotting screen
- bronchoscopy after acute bleeding has settled, which may reveal a central bronchial carcinoma (not visible on the chest X-ray) and permit biopsy and tissue diagnosis
- CTPA, which may reveal underlying pulmonary thromboembolic disease or alternative causes of haemoptysis not seen on the chest X-ray (e.g. pulmonary arteriovenous malformation or small or hidden tumours).

Incidental pulmonary nodule on imaging

A pulmonary nodule may be defined as a round opacity which is at least moderately well marginated and no greater than 3 cm in diameter. The increased use of imaging, particularly volumetric thin slice CT, has increased the number of pulmonary nodules reported, with non-calcified pulmonary nodules (NCN) seen in around two-thirds of thoracic CT studies performed in smokers over the age of 50 years. The majority are benign; however, the differential diagnosis is extensive (Box 19.11) and includes early malignant disease that may be treatable.

The problem is most satisfactorily resolved if it can be shown that the lesion was present on old films and has remained unchanged over 2 years of follow-up; however, if there are no previous films, or if previous films are normal, further assessment is required. Factors to take into account are the status of the patient and the characteristics of the nodule (Box 19.12). Whenever bacterial infection is a differential diagnosis, an antibiotic should be given during the period in which the investigations are being performed; the patient should then undergo a repeat X-ray to see whether there has been a reduction in size of the opacity. Tuberculous, fungal and hydatid disease may have to be considered, depending on the clinical context.

PET (p. 649) is useful in selected patients. In a patient older than 60 years a positive ^{18}F FDG-PET scan equates to a probability of malignancy of 90%; if negative, the probability of malignancy is less than 5%. However, it is unreliable when the size of the lesion is below 1 cm and false negatives may be seen with carcinoid and bronchoalveolar cell carcinomas.

Percutaneous needle biopsy under CT guidance allows tissue to be obtained with few complications,

Fig. 19.11 Bronchial artery angiography. An angiography catheter has been passed via the femoral artery and aorta into an abnormally dilated right bronchial artery (arrows). Contrast is seen flowing into the lung. This patient had post-tuberculous bronchiectasis affecting the right upper lobe and presented with massive haemoptysis. Bronchial artery embolisation was successfully performed.

19.11 Causes of pulmonary nodules

Common causes

- Bronchial carcinoma
- Single metastasis
- Localised pneumonia
- Lung abscess
- Tuberculoma
- Pulmonary infarct

Uncommon causes

- Benign tumours
- Lymphoma
- Arteriovenous malformation
- Hydatid cyst (p. 375)
- Bronchogenic cyst
- Rheumatoid nodule
- Pulmonary sequestration
- Pulmonary haematoma
- Wegener's granuloma
- 'Pseudotumour'—fluid collection in a fissure
- Aspergilloma (usually surrounded by air 'halo')

19.12 Clinical and radiographic features distinguishing benign from malignant nodules*

Risk status of patient

Age	Increasing age increases likelihood of malignancy. Lung cancer is uncommon under the age of 40 and rare under 35
Smoking history	Risk of malignancy increases in proportion to duration and amount smoked
History of malignancy	Risk of malignancy increased by history of lung cancer in a first-degree relative, and by exposure to asbestos, silica, uranium and radon

Characteristics of nodule

Size	Greater probability of malignancy with increasing size. Nearly all nodules > 3 cm are malignant; less than 1% of very small (< 4 mm) nodules are malignant, even in smokers; 10–20% in the 8 mm range will prove cancerous
Margin	Usually smooth in benign lesions; malignant lesions have a spiculated margin
Density	Most cancerous lesions are solid, but most solid lesions are non-cancerous. A partly solid lesion or one with air lucencies is more likely to be malignant than a solid lesion. Ground glass lesions with malignant potential grow very slowly and require longer follow-up
Calcification or fat	These favour benign disease, although CT may detect calcification in some malignant lesions. A laminated or central deposition of calcification is typical of a granuloma, while a 'popcorn' pattern is suggestive of a hamartoma. Fat content is consistent with a hamartoma or a lipoid granuloma
Location	70% of lung cancers occur in the upper lobes and the right lung is more commonly affected than the left lung. Benign lesions are equally distributed throughout upper and lower lobes
Contrast enhancement	Lack of contrast enhancement (< 15 HU) has a high negative predictive value for malignancy, but is non-specific with a poor positive predictive value. Not useful in lesions < 8 mm in diameter
Lymphadenopathy	Hilar or mediastinal adenopathy favours a malignant process and is important for staging

*Linear or sheet-like lung opacities are unlikely to represent neoplasms and do not require follow-up, and some nodular opacities may be judged sufficiently typical of scarring that follow-up is not warranted.

Adapted from Fleischner Society Statement Radiology 2005; 237:395–400.

e.g. pneumothorax and haemorrhage. Bronchoscopy is usually unrewarding, as the lesion is often beyond the vision of the operator and as the diagnostic yield from blind washings is low. If the lesion has a high probability of malignancy and the patient is fit for surgery, resection may be considered.

Serial imaging of an indeterminate lesion can be very helpful (Box 19.13). The doubling times of tumours are characterised; however, the limits of reproducibility in measurement on most CT scanners require an increase in diameter of at least 1.7 mm or an increase in volume of at least 25%. These changes may be difficult to measure, and may be more accurately assessed by specially adapted computer programs, particularly those that facilitate three-dimensional reconstruction of nodules.

Finally, in considering further imaging, account should be taken not only of the risks of further radiation exposure to the patient (greater in younger than in older individuals), but also of the fact that further scans may detect new nodules so that investigation may need to start all over again.

Pleural effusion

The accumulation of serous fluid within the pleural space is termed pleural effusion. The accumulation of frank pus is termed empyema (p. 725), that of blood is haemothorax, and that of chyle is chylothorax. In general, pleural fluid accumulates as a result of either increased hydrostatic pressure or decreased osmotic pressure ('transudative effusion', as seen in cardiac, liver or renal failure), or from increased microvascular pressure due to disease of the pleural surface itself or injury

19.13 Recommendations for follow-up of incidental nodules smaller than 8 mm¹

Nodule size (mm) ²	Low-risk patient ³	High-risk patient ⁴
≤ 4	No follow-up needed ⁵	Follow-up CT at 12 months; if unchanged, no further follow-up
4–6	Follow-up at 12 months; if unchanged, no further follow-up	Initial follow-up CT at 6–12 months, then at 18–24 months if no change
6–8	Initial follow-up CT at 6–12 months then at 18–24 months if no change	Initial follow-up CT at 3–6 months, then at 9–12 months if no change
> 8	Follow-up CT at around 3, 9 and 24 months, dynamic contrast-enhanced CT, PET and/or biopsy	As for low-risk patient

¹Excludes patients known to have or suspected of having malignant disease, younger patients, and patients with unexplained fever.

²Average of length and width.

³Minimal or absent history of smoking and of other known risk factors.

⁴History of smoking or of other known risk factors.

⁵Very low risk of malignancy (< 1%). Non-solid (ground glass) or partly solid nodules may require longer follow-up to exclude indolent adenocarcinoma.

in the adjacent lung ('exudative effusion'). The cause of the majority of pleural effusions (Boxes 19.14 and 19.15) can be identified through a thorough history, examination and relevant investigations.

19.14 Causes of pleural effusion

Common causes

- Pneumonia ('para-pneumonic effusion')
- Tuberculosis
- Pulmonary infarction*
- Malignant disease
- Cardiac failure*
- Subdiaphragmatic disorders (subphrenic abscess, pancreatitis etc.)

Uncommon causes

- Hypoproteinaemia* (nephrotic syndrome, liver failure, malnutrition)
- Connective tissue diseases* (particularly systemic lupus erythematosus (SLE) and rheumatoid arthritis)
- Acute rheumatic fever
- Post-myocardial infarction syndrome
- Meigs' syndrome (ovarian tumour plus pleural effusion)
- Myxoedema*
- Uraemia*
- Asbestos-related benign pleural effusion

*May cause bilateral effusions.

Clinical assessment

Symptoms (pain on inspiration and coughing) and signs of pleurisy (a pleural rub) often precede the development of an effusion, especially in patients with underlying pneumonia, pulmonary infarction or connective tissue disease. However, the onset may be insidious. Breathlessness is the only symptom related to the effusion itself, and its severity depends on the size and rate of accumulation. The physical signs are detailed on page 643.

Investigations

Imaging

The classical appearance of pleural fluid on the erect PA chest film is of a curved shadow at the lung base, blunting the costophrenic angle and ascending towards the axilla (p. 643). Fluid appears to track up the lateral chest wall. In fact, fluid surrounds the whole lung at this level, but casts a radiological shadow only where the X-ray beam passes tangentially across the fluid against the lateral chest wall. Around 200 mL of fluid is required to be detectable on a PA chest X-ray, but smaller effusions can be identified by ultrasound or CT. Previous scarring or adhesions in the pleural space can cause localised effusions. Pleural fluid localised below the lower lobe ('subpulmonary effusion') simulates an elevated hemidiaphragm. Fluid localised within an oblique fissure may produce a rounded opacity, simulating a tumour.

Ultrasonography is more accurate than plain chest radiography for determining the volume of pleural fluid and frequently provides additional helpful information. Visualisation of fluid facilitates skin marking to indicate a site for safe needle aspiration and guides pleural biopsy, increasing diagnostic yield. The presence of loculation may suggest an evolving empyema or resolving haemothorax. The technique may also distinguish pleural fluid from pleural thickening. CT displays pleural abnormalities more readily than either plain radiography or ultrasound, and may distinguish benign from malignant pleural disease.

Pleural aspiration and biopsy

In some clinical settings (e.g. left ventricular failure) it should not be necessary to sample fluid unless atypical

19.15 Pleural effusion: main causes and features

Cause	Appearance of fluid	Type of fluid	Predominant cells in fluid	Other diagnostic features
Tuberculosis	Serous, usually amber-coloured	Exudate	Lymphocytes (occasionally polymorphs)	Positive tuberculin test Isolation of <i>M. tuberculosis</i> from pleural fluid (20%) Positive pleural biopsy (80%)
Malignant disease	Serous, often blood-stained	Exudate	Serosal cells and lymphocytes Often clumps of malignant cells	Positive pleural biopsy (40%) Evidence of malignant disease elsewhere
Cardiac failure	Serous, straw-coloured	Transudate	Few serosal cells	Other evidence of left ventricular failure Response to diuretics
Pulmonary infarction	Serous or blood-stained	Exudate (rarely transudate)	Red blood cells Eosinophils	Evidence of pulmonary infarction Source of embolism Factors predisposing to venous thrombosis
Rheumatoid disease	Serous Turbid if chronic	Exudate	Lymphocytes (occasionally polymorphs)	Rheumatoid arthritis; rheumatoid factor and anti-CCP antibodies Cholesterol in chronic effusion; very low glucose in pleural fluid
SLE	Serous	Exudate	Lymphocytes and serosal cells	Other manifestations of SLE Antinuclear factor or anti-DNA in serum
Acute pancreatitis	Serous or blood-stained	Exudate	No cells predominate	High amylase in pleural fluid (greater than in serum)
Obstruction of thoracic duct	Milky	Chyle	None	Chylomicrons

19.16 Light's criteria for distinguishing pleural transudate from exudate

Pleural fluid is an exudate if one or more of the following criteria are met:

- Pleural fluid protein:serum protein ratio > 0.5
- Pleural fluid LDH:serum LDH ratio > 0.6
- Pleural fluid LDH $>$ two-thirds of the upper limit of normal serum LDH

(LDH = lactate dehydrogenase)

features are present (such as a unilateral effusion); appropriate treatment should be administered and the effusion re-evaluated. However, in most other circumstances, sampling is necessary to establish a diagnosis. Simple aspiration provides information on the colour and texture of fluid and on appearance alone may immediately suggest an empyema or chylothorax. The presence of blood is consistent with pulmonary infarction or malignancy, but may represent a traumatic tap. Biochemical analysis allows differentiation of transudates from exudates (Box 19.16) and Gram stain may indicate parapneumonic effusion. Cytological examination is essential, as the predominant cell type provides useful information. A low pH suggests infection but may also be seen in rheumatoid arthritis, ruptured oesophagus or advanced malignancy.

Combining pleural aspiration with biopsy increases the diagnostic yield, particularly when guided by either ultrasound or CT. The best results are obtained from video-assisted thoracoscopy, allowing the operator to visualise the pleura and guide the biopsy directly.

Management

Therapeutic aspiration may be required to palliate breathlessness, but removing more than 1.5 L in one episode is inadvisable as there is a small risk of re-expansion pulmonary oedema. An effusion should never be drained to dryness before establishing a diagnosis, as further biopsy may be precluded until further fluid accumulates. Treatment of the underlying cause—for example, heart failure, pneumonia, pulmonary embolism or subphrenic abscess—will often be followed by resolution of the effusion. The management of pleural effusion

in association with pneumonia, tuberculosis and malignancy is discussed in the relevant sections.

Respiratory failure

The term respiratory failure is used when pulmonary gas exchange fails to maintain normal arterial oxygen and carbon dioxide levels. Its classification into types I and II relates to the absence or presence of hypercapnia (raised $PaCO_2$).

Pathophysiology

When disease impairs ventilation of part of a lung (e.g. in asthma or pneumonia), perfusion of that underventilated region results in hypoxic and CO_2 -laden blood entering the pulmonary veins. Increased ventilation of neighbouring regions of normal lung can increase their CO_2 excretion, correcting arterial CO_2 to normal, but cannot augment their oxygen uptake because the haemoglobin flowing through these normal regions is already fully saturated. Admixture of blood from the underventilated and normal regions thus results in hypoxia with normocapnia, which is called 'type I respiratory failure'. Diseases causing this abnormality include any that impair ventilation locally, with sparing of other regions (Box 19.17).

Arterial hypoxia with hypercapnia (type II respiratory failure) is seen if there is severe generalised ventilation-perfusion mismatch (insufficient normal lung to correct $PaCO_2$) or a disease which reduces total ventilation. The latter category includes not just diseases of the lung but also disorders affecting any part of the neuromuscular mechanism of ventilation (see Box 19.17).

Management of acute respiratory failure

Prompt diagnosis and management of the underlying cause is crucial to the management of patients with acute respiratory failure. In type I respiratory failure, high concentrations of oxygen (40–60% by mask) will usually relieve hypoxia by increasing the alveolar PO_2 in poorly ventilated lung units. Occasionally, however (e.g. severe pneumonia affecting several lobes), mechanical ventilation may be needed to relieve hypoxia. Patients who

19.17 How to interpret blood gas abnormalities in respiratory failure

	Type I		Type II	
	Hypoxia ($PaO_2 < 8.0$ kPa (60 mmHg)) Normal or low $PaCO_2$ (< 6.6 kPa (50 mmHg))		Hypoxia ($PaO_2 < 8.0$ kPa (60 mmHg)) Raised $PaCO_2$ (> 6.6 kPa (50 mmHg))	
	Acute	Chronic	Acute	Chronic
H^+	\rightarrow or \uparrow	\rightarrow	\uparrow	\rightarrow or \uparrow
Bicarbonate	\rightarrow	\rightarrow	\rightarrow	\uparrow
Causes	Acute asthma Pulmonary oedema Pneumonia Lobar collapse Pneumothorax Pulmonary embolus ARDS	Emphysema Lung fibrosis Lymphangitis carcinomatosa Right-to-left shunts Brain-stem lesion	Acute severe asthma Acute exacerbation COPD Upper airway obstruction Acute neuropathies/paralysis Narcotic drugs Primary alveolar hypoventilation Flail chest injury	COPD Sleep apnoea Kyphoscoliosis Myopathies/muscular dystrophy Ankylosing spondylitis

need high concentrations of oxygen for more than a few hours should receive humidified oxygen.

Acute type II respiratory failure is an emergency, which requires immediate intervention. It is useful to distinguish between patients with high ventilatory drive (rapid respiratory rate and accessory muscle recruitment) who cannot move sufficient air, and those with reduced or inadequate respiratory effort. In the former situation, particularly if inspiratory stridor is present, acute upper airway obstruction from foreign body inhalation or laryngeal obstruction (angioedema, carcinoma or vocal cord paralysis) must be considered, as the Heimlich manoeuvre (p. 724), immediate intubation or emergency tracheostomy may be life-saving.

More commonly, however, the problem is in the lungs, with severe generalised bronchial obstruction from COPD or asthma, ARDS arising from a variety of insults (p. 187), or occasionally tension pneumothorax. In all such cases, high-concentration (e.g. 60%) oxygen should be administered pending a rapid examination of the respiratory system and measurement of arterial blood gases. Patients with the trachea deviated away from a silent and resonant hemithorax are likely to have tension pneumothorax, and air should be aspirated from the pleural space and a chest drain inserted as soon as possible. Patients with generalised wheeze, scanty breath sounds bilaterally or a history of asthma or COPD should be treated with nebulised salbutamol 2.5 mg plus oxygen, repeated until bronchospasm is relieved. Failure to respond to initial treatment, declining conscious level or worsening respiratory acidosis ($H^+ > 50 \text{ nmol/L}$, $PaCO_2 > 6.6 \text{ kPa}$ (50 mmHg)) on blood gases are all indications that supported ventilation is required (p. 196).

A small percentage of patients with severe chronic COPD and type II respiratory failure develop abnormal tolerance to raised $PaCO_2$ and may become dependent on hypoxic drive to breathe. In these patients only, lower concentrations of oxygen (24–28% by Venturi mask) should be used to avoid precipitating worsening respiratory depression (see below). In all cases, regular monitoring of arterial blood gases is important to assess progress.

Patients with acute type II respiratory failure who have reduced drive or conscious level may be suffering from sedative poisoning, CO_2 narcosis or a primary failure of neurological drive (e.g. following intracerebral haemorrhage or head injury). History from an accompanying person may be invaluable, and reversal of specific drugs with (for example) opiate antagonists is occasionally successful, but should not delay intubation and supported mechanical ventilation in appropriate cases.

Chronic and 'acute on chronic' type II respiratory failure

The most common cause of chronic type II respiratory failure is severe COPD. Although CO_2 may be persistently raised, there is no persisting acidaemia because the kidneys retain bicarbonate, correcting arterial pH to normal. This 'compensated' pattern, which may also occur in chronic neuromuscular disease or kyphoscoliosis, is maintained until there is a further pulmonary insult (see Box 19.17), such as an exacerbation of COPD which precipitates an episode of 'acute on chronic' respiratory failure, with acidaemia and initial respiratory distress followed by drowsiness and eventu-

ally coma. Because these patients have lost their chemosensitivity to elevated $PaCO_2$, they may paradoxically depend on hypoxia for respiratory drive, and are at risk of respiratory depression if given high concentrations of oxygen—for example, during ambulance transfers or in emergency departments. Moreover, in contrast to acute severe asthma, a patient with 'acute on chronic' type II respiratory failure due to COPD may not feel overtly distressed despite being critically ill with severe hypoxaemia, hypercapnia and acidaemia. While the physical signs of CO_2 retention (confusion, flapping tremor, bounding pulses etc.) can be helpful if present, they may not be, so arterial blood gases are mandatory in the assessment of initial severity and response to treatment.

Management

The principal aim of treatment in acute on chronic type II respiratory failure is to achieve a safe PaO_2 ($> 7.0 \text{ kPa}$ (52 mmHg)) without increasing $PaCO_2$ and acidosis, while identifying and treating the precipitating condition. In this patient group it is not necessary to achieve a normal PaO_2 ; even a small increase will often have a greatly beneficial effect on tissue oxygen delivery since the PaO_2 values of these patients are often on the steep part of the oxygen saturation curve (p. 181). The risks of worsening hypercapnia and coma must be balanced against those of severe hypoxaemia, which include potentially fatal arrhythmias or severe cerebral complications. Immediate treatment is shown in Box 19.18. Patients who are conscious, with adequate respiratory

19.18 Assessment and management of 'acute on chronic' type II respiratory failure

Initial assessment

Patient may not appear distressed despite being critically ill

- Conscious level (response to commands, ability to cough)
- CO_2 retention (warm periphery, bounding pulses, flapping tremor)
- Airways obstruction (wheeze, prolonged expiration, hyperinflation, intercostal indrawing, pursed lips)
- Cor pulmonale (peripheral oedema, raised JVP, hepatomegaly, ascites)
- Background functional status and quality of life
- Signs of precipitating cause (see Box 19.17)

Investigations

- Arterial blood gases (severity of hypoxaemia, hypercapnia, acidaemia, bicarbonate)
- Chest X-ray

Management

- Maintenance of airway
- Treatment of specific precipitating cause
- Frequent physiotherapy \pm pharyngeal suction
- Nebulised bronchodilators
- Controlled oxygen therapy
 - Start with 24% Venturi mask
 - Aim for a $PaO_2 > 7 \text{ kPa}$ (52 mmHg) (a $PaO_2 < 5$ (37 mmHg) is dangerous)
- Antibiotics
- Diuretics

Progress

- If $PaCO_2$ continues to rise or patient cannot achieve a safe PaO_2 without severe hypercapnia and acidaemia, mechanical ventilatory support may be required

drive, may benefit from non-invasive ventilation (NIV), which has been shown to reduce the need for intubation and shorten hospital stay. Patients who are drowsy, with low respiratory drive, require an urgent decision regarding the appropriateness of intubation and ventilation, which is likely to be the only effective treatment, although weaning off the ventilator may be difficult in severe disease. This decision is difficult, and useful factors to consider include patient and family wishes, presence of a potentially remediable precipitating condition, prior functional capacity and quality of life. The various types of non-invasive (via a face or nasal mask) or invasive (via an endotracheal tube) ventilation are detailed on pages 194–197.

Doxapram (1.5–4 mg/min by slow intravenous infusion) is a respiratory stimulant that is occasionally used in patients with acute on chronic type II respiratory failure and low respiratory drive. It causes unacceptable distress due to increased dyspnoea in those with preserved drive, and should not be used as a substitute for intubation and mechanical ventilation in suitable patients with CO₂ narcosis, as it provides only minor and transient improvements in arterial blood gases.

Home ventilation for chronic respiratory failure

NIV has proved to be of great value in the long-term treatment of respiratory failure due to skeletal deformity, neuromuscular disease and central alveolar hypoventilation. These conditions often present subacutely, with a very gradual onset of type II respiratory failure. Morning headache (due to elevated PaCO₂) and fatigue are common symptoms but in many cases the diagnosis is only revealed by sleep studies or blood gas analysis. In the initial stages, ventilation is insufficient for metabolic needs only during sleep, when ventilatory drive declines physiologically. Over time, however, CO₂ retention becomes chronic, with renal compensation of acidosis. Treatment by home-based NIV overnight is often sufficient to restore the daytime PCO₂ to normal, and to relieve fatigue and headache. In advanced muscle disease (e.g. muscular dystrophies), daytime NIV may also be required.

Lung transplantation

Lung transplantation is now an established treatment for carefully selected patients with advanced lung disease unresponsive to medical treatment (Box 19.19). Single-lung transplantation may be used for selected patients with advanced emphysema or lung fibrosis,

but is contraindicated in patients with chronic bilateral pulmonary infection, such as cystic fibrosis and bronchiectasis, because the transplanted lung is vulnerable to cross-infection. In these cases bilateral lung transplantation is the standard procedure. Combined heart-lung transplantation is still occasionally needed for patients with advanced congenital heart disease such as Eisenmenger's syndrome and is preferred by some surgeons for the treatment of primary pulmonary hypertension unresponsive to medical therapy.

The prognosis following lung transplantation is improving steadily with modern immunosuppressive drugs (over 60% 5-year survival in some UK centres); however, chronic rejection resulting in obliterative bronchiolitis continues to afflict some recipients. While corticosteroids continue to be used in the short-term management of acute rejection, maintenance treatment to prevent chronic rejection depends on drugs which inhibit cell-mediated immunity specifically, such as ciclosporin, mycophenolate and tacrolimus (p. 93). The major factor limiting the availability of lung transplantation is the shortage of donor lungs. To improve donor availability, techniques to preserve the lungs after cardiac arrest are being developed, and living donor lobar transplantation is performed in some cases.

OBSTRUCTIVE PULMONARY DISEASES

Asthma

There is no universally agreed definition of asthma. Descriptions of the condition focus on clinical, physiological and pathological characteristics stressing the central role of both chronic airway inflammation and increased airway hyper-responsiveness. Typical symptoms include wheeze, cough, chest tightness and dyspnoea which are accompanied by the presence of airflow obstruction that is variable over short periods of time, or is reversible with treatment.

Epidemiology

The prevalence of asthma increased steadily over the latter part of the last century, first in the developed and then in the developing world (Fig. 19.12). Current estimates suggest that asthma affects 300 million people world-wide and an additional 100 million persons will be diagnosed by 2025. The socio-economic impact is enormous, particularly when poor control leads to days lost from school or work, unscheduled health-care visits and hospital admissions.

Although the development, course of disease and response to treatment are influenced by genetic determinants, the rapid rise in the prevalence of asthma implies that environmental factors are critically important in terms of its expression. To date, studies have explored the potential role of microbial exposure, diet, vitamins, breastfeeding, air pollution and obesity, but no clear consensus has emerged (Fig. 19.13).

Pathophysiology

Airway hyper-reactivity (AHR) – the tendency for airways to contract too easily and too much in response to triggers that have little or no effect in normal individuals – is integral to the diagnosis of asthma

and appears to be related, although not exclusively so, to airway inflammation (Fig. 19.14). Other factors likely to be important include the degree of airway narrowing and the influence of neurogenic mechanisms.

With increasing severity and chronicity of the disease, remodelling of the airway occurs, leading to fibrosis of the airway wall, fixed narrowing of the airway and a reduced response to bronchodilator medication.

The relationship between atopy (a propensity to produce IgE) and asthma is well established, and in many individuals there is clear relationship between sensitisation (demonstration of skin prick reactivity or elevated serum specific IgE) and allergen exposure. Inhalation of an allergen into the airway is followed by a two-phase bronchoconstrictor response with both an early and a late-phase response (Fig. 19.15). Common examples include house dust mites, pets such as cats and dogs, pests such as cockroaches, and fungi (particularly *Aspergillus*: allergic bronchopulmonary aspergillosis, p. 697). Allergic mechanisms are also implicated in some cases of occupational asthma (see below).

In aspirin-sensitive asthma, symptoms follow the ingestion of salicylates. These inhibit the cyclo-oxygenase,

Fig. 19.14 Airway hyper-reactivity in asthma. This is demonstrated by bronchial challenge tests by the administration of sequentially increasing concentrations of either histamine, methacholine or mannitol. The reactivity of the airways is expressed as the concentration or dose of either chemical required to produce a certain decrease (usually 20%) in the FEV₁ (PC₂₀ or PD₂₀ respectively).

Fig. 19.15 Changes in peak flow following allergen challenge.

A similar biphasic response is observed following a variety of different challenges. Occasionally an individual will develop an isolated late response with no early reaction.

which leads to shunting of arachidonic acid metabolism through the lipoxygenase pathway, resulting in the production of the cysteinyl leukotrienes. In exercise-induced asthma, hyperventilation results in water loss from the pericellular lining fluid of the respiratory mucosa, which in turn triggers mediator release. Heat loss from the respiratory mucosa may also be important.

In persistent asthma, a chronic and complex inflammatory response ensues, which is characterised by an influx of numerous inflammatory cells, the transformation and participation of airway structural cells, and the secretion of an array of cytokines, chemokines and growth factors. Smooth muscle hypertrophy and hyperplasia, thickening of the basement membrane, mucous plugging and epithelial damage result. Examination of the inflammatory cell profile in induced sputum samples demonstrates that, although asthma is predominantly characterised by airway eosinophilia, in some patients neutrophilic inflammation predominates, and in others, scant inflammation is observed: so-called 'pauci-granulocytic' asthma.

Clinical features

Typical symptoms include recurrent episodes of wheeze, chest tightness, breathlessness and cough. Not uncommonly, asthma is mistaken for a cold or chest infection that is failing to resolve (e.g. after more than 10 days). Classical precipitants include exercise, particularly in cold weather, exposure to airborne allergens or pollutants, and viral upper respiratory tract infections. Wheeze apart, there is often little to find on examination. An inspection for nasal polyps and eczema should be performed. Rarely, a vasculitic rash may be present in Churg–Strauss syndrome (p. 1114).

Patients with mild intermittent asthma are usually asymptomatic between exacerbations. Patients with persistent asthma report on-going breathlessness and wheeze, but variability is usually present with symptoms fluctuating over the course of one day, from day to day, or from month to month.

Asthma characteristically displays a diurnal pattern, with symptoms and lung function being worse in the early morning. Particularly when poorly controlled,

symptoms such as cough and wheeze disturb sleep and have led to the use of the term 'nocturnal asthma'. Cough may be the dominant symptom in some patients, and the lack of wheeze or breathlessness may lead to a delay in reaching the diagnosis of so-called 'cough-variant asthma'.

Although the aetiology of asthma is often elusive, an attempt should be made to identify any agents that may contribute to the appearance or aggravation of the condition. With regard to potential allergens, particular enquiry should be made into exposure to a pet cat, guinea pig, rabbit or horse, pest infestation, or mould growth following water damage to a home or building.

In some circumstances, the appearance of asthma is triggered by medications. For example, β -adrenoceptor antagonists (β -blockers), even when administered topically as eye drops, may induce bronchospasm, and aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) may also induce wheeze as above. The classical aspirin-sensitive patient is female and presents in middle age with asthma, rhinosinusitis and nasal polyps. Aspirin-sensitive patients may also report symptoms following alcohol (in particular white wine) and foods containing salicylates. Other medications implicated include the oral contraceptive pill, cholinergic agents and prostaglandin F₂ α . Betel nuts contain aceroline, which is structurally similar to methacholine, and can aggravate asthma.

Some patients with asthma have a similar inflammatory response in the upper airway. Careful enquiry should be made as to a history of sinusitis, sinus headache, a blocked or runny nose, and loss of sense of smell.

An important minority of patients develop a particularly severe form of asthma; this appears to be more common in women. Allergic triggers are less important and airway neutrophilia predominates.

Diagnosis

The diagnosis of asthma is predominantly clinical and based on a characteristic history. Supportive evidence is provided by the demonstration of variable airflow obstruction, preferably by using spirometry (Box 19.20). The measurement of FEV₁ and VC identify the obstructive nature of the ventilatory defect, define its severity, and provide the basis of bronchodilator reversibility (Fig. 19.16). If spirometry is not available, a peak flow meter may be used. Patients should be instructed to record peak flow readings after rising in the morning and before retiring in the evening. A diurnal variation in PEF (the lowest values typically being recorded in the morning) of more than 20% is considered diagnostic and the magnitude of variability provides some indication of disease severity.

19.20 Making a diagnosis of asthma

Compatible clinical history *plus either/or*:

- FEV₁ \geq 15%* (and 200 mL) increase following administration of a bronchodilator/trial of corticosteroids
- > 20% diurnal variation on \geq 3 days in a week for 2 weeks on PEF diary
- FEV₁ \geq 15% decrease after 6 mins of exercise

*Global Initiative for Asthma (GINA) definition accepts an increased FEV₁ \geq 12%.

Volume expired (L)

Fig. 19.16 Reversibility test. Forced expiratory manoeuvres before and 20 minutes after inhalation of a β_2 -adrenoceptor agonist. Note the increase in FEV₁ from 1.0 to 2.5 L.

(Fig. 19.17). A trial of corticosteroids (e.g. 30 mg daily for 2 weeks) may be useful in documenting improvement in either FEV₁ or PEF to establish the diagnosis.

It is not uncommon for patients whose symptoms are suggestive of asthma to have normal lung function. In these circumstances, the demonstration of AHR by challenge tests may be useful to confirm the diagnosis (see Fig. 19.14). AHR is sensitive but non-specific; it therefore has a high negative predictive value but positive results may be seen in other conditions such as COPD,

Peak flow (L/min)

Fig. 19.17 Serial recordings of peak expiratory flow (PEF) in a patient with asthma. Note the sharp overnight fall (morning dip) and subsequent rise during the day. In this example corticosteroids have been commenced, followed by a subsequent improvement in PEF rate and loss of morning dipping.

FEV₁ (L)

Fig. 19.18 Exercise-induced asthma. Serial recordings of FEV₁ in a patient with bronchial asthma before and after 6 minutes of strenuous exercise. Note initial slight rise on completion of exercise, followed by sudden fall and gradual recovery. Adequate warm-up exercise or pre-treatment with a β_2 -adrenoceptor agonist, nedocromil sodium or a leukotriene antagonist (e.g. montelukast sodium) can protect against exercise-induced symptoms.

bronchiectasis and CF. Challenge tests using adenosine may improve specificity. When symptoms are predominantly related to exercise, an exercise challenge may be followed by a drop in lung function (Fig. 19.18).

Other useful investigations

- *Measurement of allergic status.* The presence of atopy may be demonstrated by skin prick tests. Similar information may be provided by the measurement of total and allergen-specific IgE. A full blood picture may show peripheral blood eosinophilia.
- *Radiological examination.* Chest X-ray appearances are often normal or show hyperinflation of lung fields. Lobar collapse may be seen if mucus occludes a large bronchus, and if accompanied by the presence of flitting infiltrates, may suggest that asthma has been complicated by allergic bronchopulmonary aspergillosis (p. 697). An HRCT scan may be useful to detect bronchiectasis.
- *Assessment of eosinophilic airway inflammation.* An induced sputum differential eosinophil count of greater than 2% or exhaled breath nitric oxide concentration (FE_{NO}) may support the diagnosis but is non-specific.

Management

Setting goals

Asthma is a chronic condition but effective treatment is available for the majority of patients. The goal of management should be to obtain and sustain complete control (Box 19.21). However, goals may have to be modified according to the circumstances and the patient. Unfortunately, surveys consistently demonstrate that the majority of asthmatics report suboptimal control, perhaps reflecting poor expectations of patients and their clinicians.

19.21 Levels of asthma control*

Characteristic	Controlled	Partly controlled (any present in any week)	Uncontrolled
Daytime symptoms	None (2 or less/week)	More than twice/week	3 or more features of partly controlled asthma present in any week
Limitations of activities	None	Any	
Nocturnal symptoms/awakening	None	Any	
Need for rescue/'reliever' treatment	None (2 or less/week)	More than twice/week	
Lung function (PEF or FEV₁)	Normal	< 80% predicted or personal best (if known) on any day	1 in any week
Exacerbation	None	One or more/year	

*Based on GINA guidelines.

Whenever possible, patients should be encouraged to take responsibility for managing their own disease. Time should be taken to encourage an understanding of the nature of the condition, the relationship between symptoms and inflammation, the importance of key symptoms such as nocturnal waking, the different types of medication, and, if appropriate, the use of PEF to guide management decisions. A variety of tools/questionnaires have been validated to assist in assessing asthma control. Written action plans may be helpful in developing self-management skills.

Avoidance of aggravating factors

This is particularly important in the management of occupational asthma, but may also be relevant to atopic patients where removing or reducing exposure to relevant antigens, e.g. a pet animal, may effect improvement. House dust mite exposure may be minimised by replacing carpets with floorboards and using mite-impermeable bedding, although improvements in asthma control following such measures have been difficult to demonstrate. Many patients are sensitised to several ubiquitous aeroallergens, making avoidance strategies largely impractical. Measures to reduce fungal exposure and eliminate cockroaches may be applicable in specific circumstances, and medications known to precipitate or aggravate asthma should be avoided. Smoking cessation (p. 99) is particularly important, as smoking not only encourages sensitisation but also induces a relative corticosteroid resistance in the airway.

A stepwise approach to the management of asthma (Fig. 19.19)

Step 1: Occasional use of inhaled short-acting β_2 -adrenoreceptor agonist bronchodilators

For patients with mild intermittent asthma (symptoms less than once a week for 3 months and fewer than two nocturnal episodes/month), it is usually sufficient to prescribe an inhaled short-acting β_2 -agonist (salbutamol or terbutaline), to be used on an as-required basis. However, many patients (and their physicians) underestimate the severity of asthma and these patients require careful supervision. A history of a severe exacerbation should lead to a step up in treatment.

A variety of different inhaled devices are available and choice should be guided by patient preference and competence in using the device. The metered-dose inhaler remains the most widely prescribed (Fig. 19.20).

Step 2: Introduction of regular 'preventer' therapy

Regular anti-inflammatory therapy (preferably inhaled corticosteroids (ICS) such as beclomethasone, budesonide, fluticasone or ciclesonide) should be started in addition to inhaled β_2 -agonists taken on an as-required basis in any patient who:

- has experienced an exacerbation of asthma in the last 2 years (Box 19.22)
- uses inhaled β_2 -agonists three times a week or more
- reports symptoms three times a week or more
- is awakened by asthma one night per week.

For adults, a reasonable starting dose is 400 μ g beclomethasone dipropionate (BDP) or equivalent per day, although higher doses may be required in smokers. Alternative but much less effective preventive agents include chromones, leukotriene receptor antagonists, and theophyllines.

Step 3: Add-on therapy

If a patient remains poorly controlled despite regular use of ICS, a thorough review should be undertaken focusing on adherence, inhaler technique and on-going exposure to modifiable aggravating factors. A further increase in the dose of ICS may benefit some patients, but in general, add-on therapy should be considered in adults taking 800 μ g/day BDP (or equivalent).

Long-acting β_2 -agonists (LABAs), such as salmeterol and formoterol, with a duration of action of at least 12 hours, represent the first choice of add-on therapy. They have consistently been demonstrated to improve asthma control and reduce the frequency and severity of exacerbations when compared to increasing the dose of ICS alone. Fixed combination inhalers of ICS and LABAs have been developed; these are more convenient, increase compliance, and prevent patients using a LABA as monotherapy (which may be accompanied by an increased risk of life-threatening attacks or asthma death). The onset of action of formoterol is similar to that of salbutamol, such that, in carefully selected patients, a fixed combination of

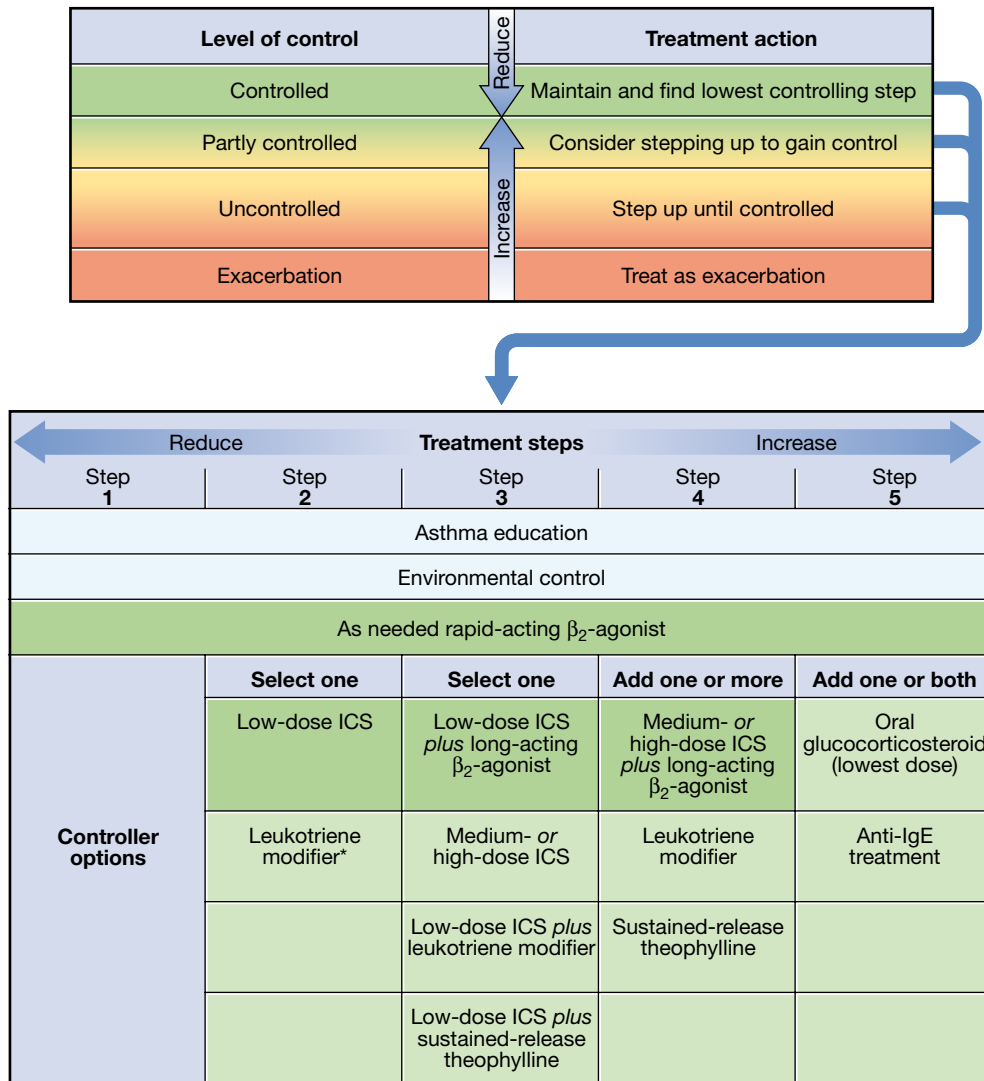

Fig. 19.19 Management approach based on asthma control. For children older than 5 years, adolescents and adults. (ICS = inhaled corticosteroid)
*Receptor antagonist or synthesis inhibitors.

budesonide and formoterol may be contemplated for use as both rescue and maintenance therapy.

Oral leukotriene receptor antagonists (e.g. montelukast 10 mg daily) are generally less effective than LABA as add-on therapy but may facilitate a reduction in the

dose of ICS and control exacerbations. Oral theophyllines may be considered in some patients but their unpredictable metabolism, propensity for drug interactions and prominent side-effect profile limit their widespread use.

Step 4: Poor control on moderate dose of inhaled steroid and add-on therapy: addition of a fourth drug

In adults, the dose of ICS may be increased to 2000 μ g BDP/budesonide (or equivalent) daily. A nasal corticosteroid preparation should be used in patients with prominent upper airway symptoms. Oral therapy with leukotriene receptor antagonists, theophyllines or a slow-release β_2 -agonist may be considered. If the trial of add-on

- Remove the cap and shake the inhaler
- Breathe out gently and place the mouthpiece into the mouth
- Incline the head backwards to minimise oropharyngeal deposition
- Simultaneously, begin a slow deep inspiration, depress the cannister and continue to inhale
- Hold the breath for 10 seconds

Fig. 19.20 How to use a metered-dose inhaler.

EBM 19.22 Inhaled corticosteroids and asthma

'Regular therapy with low-dose budesonide reduces the risk of severe exacerbations in patients with mild persistent asthma.'

• Pauwels RA, et al. Lancet 2003; 361:1066–1067.

therapy is ineffective, it should be discontinued. Oral itraconazole should be contemplated in patients with allergic bronchopulmonary aspergillosis (ABPA).

Step 5: Continuous or frequent use of oral steroids

At this stage prednisolone therapy (usually administered as a single daily dose in the morning) should be prescribed in the lowest amount necessary to control symptoms. Patients on long-term oral corticosteroids (> 3 months) or receiving more than three or four courses per year will be at risk of systemic side-effects (p. 770). Osteoporosis can be prevented in this group of patients by using bisphosphonates (p. 1119). Steroid-sparing therapies such as methotrexate, ciclosporin or oral gold may be considered. New therapies, such as omalizumab, a monoclonal antibody directed against IgE, may prove helpful in atopic patients.

Step-down therapy

Once asthma control is established, the dose of inhaled (or oral) corticosteroid should be titrated to the lowest dose at which effective control of asthma is maintained. Decreasing the dose of ICS by around 25–50% every 3 months is a reasonable strategy for most patients.

Asthma in pregnancy

The management of asthma in pregnancy is described in Box 19.23.

19.23 Asthma in pregnancy

- **Unpredictable clinical course:** one-third worsen, one-third remain stable and one-third improve.
- **Labour and delivery:** 90% have no symptoms.
- **Safety data:** good for β_2 -agonists, inhaled steroids, theophyllines, oral prednisolone, and chromones.
- **Oral leukotriene receptor antagonists:** no evidence that these harm the fetus and they should not be stopped in women who have previously demonstrated significant improvement in asthma control prior to pregnancy.
- **Steroids:** women on maintenance prednisolone > 7.5 mg/day should receive hydrocortisone 100 mg 6–8-hourly during labour.
- **Prostaglandin F₂ α :** may induce bronchospasm and should be used with extreme caution.
- **Breastfeeding:** use medications as normal.
- **Uncontrolled asthma represents the greatest danger to the fetus:** Associated with maternal (hyperemesis, hypertension, pre-eclampsia, vaginal haemorrhage, complicated labour) and fetal (intrauterine growth restriction and low birth weight, preterm birth, increased perinatal mortality, neonatal hypoxia) complications.

Exacerbations of asthma

The course of asthma may be punctuated by exacerbations characterised by increased symptoms, deterioration in lung function, and an increase in airway inflammation. Exacerbations are most commonly precipitated by viral infections, but moulds (*Alternaria* and *Cladosporium*), pollens (particularly following thunderstorms) and air pollution are also implicated. Most attacks are characterised by a gradual deterioration over several hours to days but some appear to occur with little or no warning: so-called brittle asthma. An

important minority of patients appear to have a blunted perception of airway narrowing and fail to appreciate the early signs of deterioration.

Management of mild–moderate exacerbations

The widely held view that an impending exacerbation may be avoided by doubling the dose of ICS has failed to be validated by recent studies. Short courses of 'rescue' oral corticosteroids (prednisolone 30–60 mg daily) are therefore often required to regain control of symptoms. Tapering of the dose to withdraw treatment is not necessary unless given for more than 3 weeks.

Indications for 'rescue' courses include:

- symptoms and PEF progressively worsening day by day
- fall of PEF below 60% of the patient's personal best recording
- onset or worsening of sleep disturbance by asthma
- persistence of morning symptoms until midday
- progressively diminishing response to an inhaled bronchodilator
- symptoms severe enough to require treatment with nebulised or injected bronchodilators.

Management of acute severe asthma

Initial assessment

Box 19.24 lists the features requiring immediate assessment in acute asthma. Measurement of PEF is mandatory unless the patient is too ill to cooperate, and is most easily interpreted when expressed as a percentage of the predicted normal or of the previous best value obtained on optimal treatment (Fig. 19.21). Arterial blood gas analysis is essential to determine the $PaCO_2$, a normal or elevated level being particularly dangerous. A chest X-ray is not immediately necessary unless pneumothorax is suspected.

19.24 Immediate assessment of acute severe asthma

Acute severe asthma

- PEF 33–50% predicted (< 200 L/min)
- Respiratory rate \geq 25/min
- Heart rate \geq 110/min
- Inability to complete sentences in 1 breath

Life-threatening features

- PEF < 33% predicted (< 100 L/min)
- SpO_2 < 92% or PaO_2 < 8 kPa (60 mmHg) (especially if being treated with oxygen)
- Normal or raised $PaCO_2$
- Silent chest
- Cyanosis
- Feeble respiratory effort
- Bradycardia or arrhythmias
- Hypotension
- Exhaustion
- Confusion
- Coma

Near-fatal asthma

- Raised $PaCO_2$ and/or requiring mechanical ventilation with raised inflation pressures

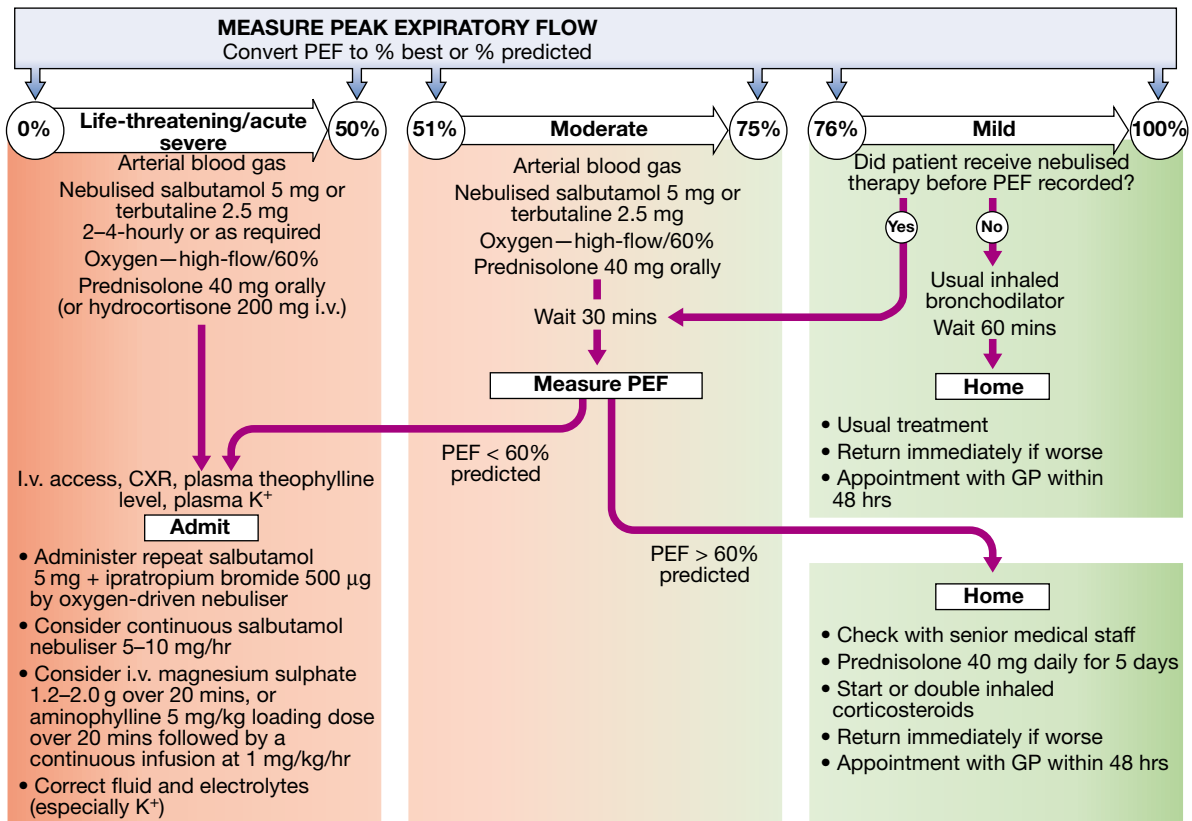

Fig. 19.21 Immediate treatment of patients with acute severe asthma.

Treatment

- **Oxygen.** High concentrations of oxygen (humidified if possible) should be administered to maintain the oxygen saturation above 92% in adults. The presence of a high $PaCO_2$ should not be taken as an indication to reduce oxygen concentration but as a warning sign of a severe or life-threatening attack. Failure to achieve appropriate oxygenation is an indication for assisted ventilation.
- **High doses of inhaled bronchodilators.** Short-acting β_2 -agonists are the agent of first choice. In hospital they are most conveniently administered via a nebuliser driven by oxygen but delivery of multiple doses of salbutamol via a metered-dose inhaler through a spacer device provides equivalent bronchodilatation and may be used in primary care. Ipratropium bromide should be added to salbutamol in patients with acute severe or life-threatening attacks.
- **Systemic corticosteroids.** Systemic corticosteroids reduce the inflammatory response and hasten the resolution of exacerbations. They should be administered to all patients experiencing an acute severe attack. They can usually be administered orally as prednisolone, but intravenous hydrocortisone may be given in patients who are vomiting or unable to swallow.
- **Intravenous fluids.** There are no controlled trials to support the use of intravenous fluids but many patients are dehydrated due to high insensible water loss and probably benefit from these. Potassium supplements may be necessary because repeated doses of salbutamol can lower serum potassium.

Subsequent management

If patients fail to improve, a number of further options may be considered. Intravenous magnesium may provide additional bronchodilatation in some patients whose presenting PEF is < 30% predicted. Some patients benefit from the use of intravenous aminophylline but careful monitoring is required. The potential for intravenous leukotriene receptor antagonists remains under investigation.

Monitoring of treatment

PEF should be recorded every 15–30 minutes and then every 4–6 hours. Pulse oximetry should ensure that SpO_2 remains > 92%, but repeat arterial blood gases are necessary if the initial $PaCO_2$ measurements were normal or raised, the PaO_2 was < 8 kPa (60 mmHg) or the patient deteriorates. Box 19.25 lists the indications for endotracheal intubation and intermittent positive pressure ventilation.

19.25 Indications for assisted ventilation in acute severe asthma

- Coma
- Respiratory arrest
- Deterioration of arterial blood gas tensions despite optimal therapy
 PaO_2 < 8 kPa (60 mmHg) and falling
 $PaCO_2$ > 6 kPa (45 mmHg) and rising
pH low and falling (H⁺ high and rising)
- Exhaustion, confusion, drowsiness

Prognosis

The outcome from acute severe asthma is generally good. Death is fortunately rare but a considerable number of deaths occur in young people and many are preventable. Failure to recognise the severity of an attack, on the part of either the assessing physician or the patient, contribute to undertreatment and delay in delivering appropriate therapy.

Prior to discharge, patients should be stable on discharge medication (nebulised therapy should have been discontinued for at least 24 hours) and the PEF should have reached 75% of predicted or personal best. The acute attack provides an opportunity to look for and address any trigger factors, for the delivery of asthma education and for the provision of a written self-management plan. The patient should be offered an appointment with a GP or asthma nurse within 2 working days of discharge and follow-up at a specialist hospital clinic within a month.

Occupational asthma

Occupational asthma is the most common form of occupational respiratory disorder and should be considered in all adult asthmatics, particularly if symptoms commenced during a particular period of employment. It is especially important to enquire whether symptoms improve during time away from work, e.g. weekends or holidays. Atopic individuals and smokers appear to be at increased risk. Numerous low and high molecular weight substances have been implicated. The most frequently reported causative agents commonly affecting workers are shown in Box 19.26.

The diagnosis of occupational asthma can be particularly difficult and requires specialist assessment. The patient should be instructed to perform 2-hourly peak flow recording which can be analysed by a computer-based programme such as Occupational Asthma System (OASYS) (Fig. 19.22). Skin prick tests or the measurement of specific IgE may confirm sensitivity to the suspected agent. Bronchial provocation tests with the suspected agent may be necessary, but require highly specialist laboratories.

Early diagnosis and removal from exposure often results in significant improvement and may occasionally cure the condition. Recognition also has important medico-legal implications and should prompt a

19.26 Occupational asthma

Most frequently reported causative agents

- Isocyanates
- Flour and grain dust
- Colophony and fluxes
- Latex
- Animals
- Aldehydes
- Wood dust

Workers most commonly reported to occupational asthma schemes

- Paint sprayers
- Bakers and pastry-makers
- Nurses
- Chemical workers
- Animal handlers
- Welders
- Food processing workers
- Timber workers

Fig. 19.22 Peak flow readings in occupational asthma. Subjects with suspected occupational asthma are asked to perform 2-hourly serial peak flows at, and away from, work. The maximum, mean and minimum values are plotted daily. Days at work are indicated by the shaded areas. The diurnal variation is displayed at the top. In this example, a period away from work is followed by a marked improvement in peak flow readings and a reduction in diurnal variation.

workplace visit to identify and rectify exposure, and to trigger screening of other employees who may also have developed the disease.

Byssinosis

Byssinosis occurs as a result of exposure to cotton brack (dried leaf and plant debris) in cotton and flax mills. An acute form of the disease occurs in about one-third of individuals on first exposure to cotton dust and is characterised by an acute bronchiolitis with symptoms and signs of airflow obstruction. Many of those affected may give up such work at this stage. Chronic byssinosis, unlike occupational asthma, usually develops after 20–30 years' exposure. The condition is more common in smokers. Typical symptoms include chest tightness or breathlessness accompanied by a drop in lung function; classically, these are most severe on the first day of the working week ('Monday fever') or following a period away from work. As the week progresses, symptoms improve and the fall in lung function becomes less dramatic (across-shift variation). Affected workers should be offered alternative employment. Continued exposure leads to the development of persistent symptoms and a progressive decline in FEV₁.

Chronic obstructive pulmonary disease (COPD)

COPD is defined as a preventable and treatable lung disease with some significant extrapulmonary effects that may contribute to the severity in individual patients. The pulmonary component is characterised

by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles or gases. Related diagnoses include chronic bronchitis (cough and sputum on most days for at least 3 consecutive months for at least 2 successive years) and emphysema (abnormal permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis). Extrapulmonary manifestations include impaired nutrition, weight loss and skeletal muscle dysfunction (Fig. 19.23).

Epidemiology

Prevalence is directly related to the prevalence of tobacco smoking and, in low- and middle-income countries, the use of biomass fuels. Current estimates suggest that 80 million people world-wide suffer from moderate to severe disease. In 2005, COPD contributed to more than 3 million deaths (5% of deaths globally), but by 2020 it is forecast to represent the third most important cause of death world-wide. The anticipated rise in morbidity and mortality from COPD will be greatest in Asian and African countries as a result of their increasing tobacco consumption.

Aetiology

Risk factors are shown in Box 19.27. Cigarette smoking represents the most significant risk factor for COPD and relates to both the amount and the duration of smoking. It is unusual to develop COPD with less than 10 pack years (1 pack year = 20 cigarettes/day/year) and not all smokers develop the condition, suggesting that individual susceptibility factors are important.

Fig. 19.23 The pulmonary and systemic features of COPD.

19.27 Risk factors for development of COPD

Exposures

- Tobacco smoke: accounts for 95% of cases in UK
- Biomass solid fuel fires: wood, animal dung, crop residues and coal lead to high levels of indoor air pollution
- Occupation: coal miners and those who work with cadmium
- Outdoor and indoor air pollution
- Low birth weight: may reduce maximally attained lung function in young adult life
- Lung growth: childhood infections or maternal smoking may affect growth of lung during childhood, resulting in a lower maximally attained lung function in adult life
- Infections: recurrent infection may accelerate decline in FEV₁; persistence of adenovirus in lung tissue may alter local inflammatory response predisposing to lung damage; HIV infection is associated with emphysema
- Low socioeconomic status
- Nutrition: role as independent risk factor unclear
- Cannabis smoking

Host factors

- Genetic factors: α_1 -antitrypsin deficiency; other COPD susceptibility genes are likely to be identified
- Airway hyper-reactivity

Pathophysiology

COPD has both pulmonary and systemic components (Fig. 19.23).

The changes in pulmonary and chest wall compliance mean that collapse of intrathoracic airways during expiration is exacerbated, during exercise as the time available for expiration shortens, resulting in dynamic hyperinflation. Increased \dot{V}/\dot{Q} mismatch increases the dead space volume and wasted ventilation. Flattening of the diaphragmatic muscles and an increasingly horizontal alignment of the intercostal muscles place the respiratory muscles at a mechanical disadvantage. The work of breathing is therefore markedly increased, first on exercise but, as the disease advances, at rest too.

Emphysema (Fig. 19.24) may be classified by the pattern of the enlarged airspaces: centriacinar, panacinar and periacinar. Bullae form in some individuals. This results in impaired gas exchange and respiratory failure.

Clinical features

COPD should be suspected in any patient over the age of 40 years who presents with symptoms of chronic bronchitis and/or breathlessness. Depending on the presentation, important differential diagnoses include chronic asthma, tuberculosis, bronchiectasis and congestive cardiac failure.

Cough and associated sputum production are usually the first symptoms, often referred to as a 'smoker's cough'. Haemoptysis may complicate exacerbations of COPD but should not be attributed to COPD without thorough investigation.

Breathlessness usually brings about the first presentation to medical attention. The level should be quantified for future reference by documenting the exercise the patient can manage before stopping; the modified Medical Research Council (MRC) dyspnoea scale may also be useful (Box 19.28). In advanced disease, enquiry should be made as to the presence of oedema (which may be seen for the first time during an exacerbation) and morning headaches, which may suggest hypercapnia.

Physical signs (pp. 642–643) are non-specific, correlate poorly with lung function, and are seldom obvious until the disease is advanced. Breath sounds are typically quiet; crackles may accompany infection but if persistent raise the possibility of bronchiectasis. Finger clubbing is not a feature of COPD and should trigger further investigation for lung cancer, bronchiectasis or fibrosis. The presence of

i

19.28 Modified MRC dyspnoea scale

Grade	Degree of breathlessness related to activities
0	No breathlessness except with strenuous exercise
1	Breathlessness when hurrying on the level or walking up a slight hill
2	Walks slower than contemporaries on level ground because of breathlessness or has to stop for breath when walking at own pace
3	Stops for breath after walking about 100 m or after a few minutes on level ground
4	Too breathless to leave the house, or breathless when dressing or undressing

Fig. 19.24 The pathology of emphysema. **A** Normal lung. **B** Emphysematous lung showing gross loss of the normal surface area available for gas exchange.

pitting oedema should be documented but the frequently used term 'cor pulmonale' is actually a misnomer, as the right heart seldom 'fails' in COPD and the occurrence of oedema usually relates to failure of salt and water excretion by the hypoxic, hypercapnic kidney. The body mass index (BMI) is of prognostic significance and should be recorded.

Two classical phenotypes have been described: 'pink puffers' and 'blue bloaters'. The former are typically thin and breathless, and maintain a normal $PaCO_2$ until the late stage of disease. The latter develop (or tolerate) hypercapnia earlier and may develop oedema and secondary polycythaemia. In practice, these phenotypes often overlap.

Investigations

Although there are no reliable radiographic signs that correlate with the severity of airflow limitation, a chest X-ray is essential to identify alternative diagnoses such as cardiac failure, other complications of smoking such as lung cancer, and the presence of bullae. A full blood count is useful to exclude anaemia or document polycythaemia, and in younger patients with predominantly basal emphysema, α_1 -antitrypsin should be assayed.

The diagnosis requires objective demonstration of airflow obstruction by spirometry and is established when the post-bronchodilator FEV_1 is less than 80% of the predicted value and accompanied by $FEV_1/FVC < 70\%$. An $FEV_1/FVC < 70\%$ with an FEV_1 of 80% or more suggests the presence of mild disease, although this may be a normal finding in older patients. The severity of COPD may be defined according to the post-bronchodilator FEV_1 as a percentage of the predicted value for the patient's age (Box 19.29). A low peak flow is consistent with COPD but is non-specific, does not discriminate between obstructive and restrictive disorders, and may underestimate the severity of airflow limitation.

Measurement of lung volumes provides an assessment of hyperinflation. This is generally performed using the helium dilution technique (p. 650); however, in patients with severe COPD, and in particular large bullae, body plethysmography is preferred because the use of helium may underestimate lung volumes. The presence of emphysema is suggested by a low gas transfer factor (p. 650). Exercise tests provide an objective assessment of exercise tolerance and a baseline on which to judge the response to bronchodilator therapy or rehabilitation programmes; they may also be valuable when assessing prognosis. Pulse oximetry may

Fig. 19.25 Gross emphysema. HRCT showing emphysema most evident in the right lower lobe.

EBM 19.30 Smoking cessation and COPD

'Sustained smoking cessation in mild to moderate COPD is accompanied by a reduced decline in FEV_1 compared to persistent smokers.'

• Anthonisen NR, et al. *Am J Respir Crit Care Med* 2002; 166:675–679.

prompt referral for a domiciliary oxygen assessment if less than 93%.

Health status questionnaires provide valuable clinical information but are currently too cumbersome for day-to-day practice.

HRCT is likely to play an increasing role in the assessment of COPD, as it allows the detection, characterisation and quantification of emphysema (Fig. 19.25) and is more sensitive than a chest X-ray at detecting bullae.

Management

The management of COPD (Fig. 19.26) has been the subject of unjustified pessimism. It is usually possible to improve breathlessness, reduce the frequency and severity of exacerbations, and improve health status and the prognosis.

Smoking cessation

Every attempt should be made to highlight the role of smoking in the development and progress of COPD, advising and assisting the patient toward smoking cessation (p. 99). Reducing the number of cigarettes smoked each day has little impact on the course and prognosis of COPD, but complete cessation is accompanied by an improvement in lung function and deceleration in the rate of FEV_1 decline (Fig. 19.27 and Box 19.30). In regions where the indoor burning of biomass fuels is important, the introduction of non-smoking cooking devices or the use of alternative fuels should be encouraged.

Bronchodilators

Bronchodilator therapy is central to the management of breathlessness. The inhaled route is preferred and a number of different agents delivered by a variety of devices are available. Choice should be informed by patient preference and inhaler assessment. Short-acting bronchodilators, such as the β_2 -agonists salbutamol and terbutaline, or the anticholinergic, ipratropium bromide,

19.29 Spirometric classification of COPD severity based on post-bronchodilator FEV_1		
Stage	Severity	FEV_1
I	Mild	$FEV_1/FVC < 0.70$ $FEV_1 \geq 80\%$ predicted
II	Moderate	$FEV_1/FVC < 0.70$ $50\% \leq FEV_1 < 80\%$ predicted
III	Severe	$FEV_1/FVC < 0.70$ $30\% \leq FEV_1 < 50\%$ predicted
IV	Very severe	$FEV_1/FVC < 0.70$ $FEV_1 < 30\%$ predicted or $FEV_1 < 50\%$ predicted plus chronic respiratory failure

I : Mild	II : Moderate	III : Severe	IV : Very severe
<ul style="list-style-type: none"> • $FEV_1/FVC < 0.70$ • $FEV_1 \geq 80\%$ predicted 	<ul style="list-style-type: none"> • $FEV_1/FVC < 0.70$ • $50\% \leq FEV_1 < 80\%$ predicted 	<ul style="list-style-type: none"> • $FEV_1/FVC < 0.70$ • $30\% \leq FEV_1 < 50\%$ predicted 	<ul style="list-style-type: none"> • $FEV_1/FVC < 0.70$ • $FEV_1 < 30\%$ predicted or $FEV_1 < 50\%$ predicted <i>plus</i> chronic respiratory failure
Active reduction of risk factor(s); influenza vaccination			
Add short-acting bronchodilator (when needed)			
		Add regular treatment with one or more long-acting bronchodilators (when needed) Add rehabilitation	
		Add inhaled glucocorticosteroids if repeated exacerbations	
		Add long-term oxygen if chronic respiratory failure Consider surgical treatments	

Fig. 19.26 Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines for treatment of COPD. Post-bronchodilator FEV_1 is recommended for the diagnosis and assessment of severity of COPD.

Fig. 19.27 Model of annual decline in FEV_1 with accelerated decline in susceptible smokers. When smoking is stopped, subsequent loss is similar to that in healthy non-smokers.

may be used for patients with mild disease. Longer-acting bronchodilators, such as the β_2 -agonists salmeterol and formoterol, or the anticholinergic tiotropium bromide, are more appropriate for patients with moderate to severe disease. Significant improvements in breathlessness may be reported despite minimal changes in FEV_1 , probably reflecting improvements in lung emptying that reduce dynamic hyperinflation and ease the work of breathing.

Oral bronchodilator therapy may be contemplated in patients who cannot use inhaled devices efficiently. Theophylline preparations improve breathlessness and quality of life, but their use has been limited by side-effects, unpredictable metabolism and drug interactions. Bambuterol, a pro-drug of terbutaline, is used on occasion. Orally active highly selective phosphodiesterase inhibitors are currently under development.

Corticosteroids

Inhaled corticosteroids (ICS) reduce the frequency and severity of exacerbations; they are currently recommended in patients with severe disease ($FEV_1 < 50\%$)

who report two or more exacerbations requiring antibiotics or oral steroids per year. Regular use is associated with a small improvement in FEV_1 , but they do not alter the natural history of the FEV_1 decline. It is more usual to prescribe a fixed combination of an ICS with a LABA.

Oral corticosteroids are useful during exacerbations but maintenance therapy contributes to osteoporosis and impaired skeletal muscle function and should be avoided. Oral corticosteroid trials assist in the diagnosis of asthma but do not predict response to inhaled steroids in COPD.

Pulmonary rehabilitation

Exercise should be encouraged at all stages and patients should be reassured that breathlessness, whilst distressing, is not dangerous. Multidisciplinary programmes that incorporate physical training, disease education and nutritional counselling reduce symptoms, improve health status and enhance confidence. Most programmes include 2–3 sessions per week, last between 6 and 12 weeks, and are accompanied by demonstrable and sustained improvements in exercise tolerance and health status.

Oxygen therapy

Long-term domiciliary oxygen therapy (LTOT) has been shown to be of significant benefit in specific patients (Boxes 19.31 and 19.32). It is most conveniently provided by an oxygen concentrator and patients should be instructed to use oxygen for a minimum of 15 hours/day; greater benefits are seen in patients who receive > 20 hours/day. The aim of therapy is to increase the PaO_2 to at least 8 kPa (60 mmHg) or SpO_2 to at least 90%. Ambulatory oxygen therapy should be considered in

EBM 19.31 Long-term domiciliary oxygen therapy (LTOT)

'Long-term home oxygen therapy improves survival in selected patients with COPD complicated by severe hypoxaemia (arterial PaO_2 less than 8.0 kPa (55 mmHg)).'

• Cranston JM, et al. (Cochrane Review). Cochrane Library, issue 4, 2005. Oxford: Update Software.

For further information:  www.brit-thoracic.org.uk

19.32 Prescription of long-term oxygen therapy (LTOT) in COPD

Arterial blood gases measured in clinically stable patients on optimal medical therapy on at least two occasions 3 weeks apart:

- $PaO_2 < 7.3$ kPa (55 mmHg) irrespective of $PaCO_2$ and $FEV_1 < 1.5$ L
- PaO_2 7.3–8 kPa (55–60 mmHg) plus pulmonary hypertension, peripheral oedema or nocturnal hypoxaemia
- patient stopped smoking.

Use at least 15 hours/day at 2–4 L/min to achieve a $PaO_2 > 8$ kPa (60 mmHg) without unacceptable rise in $PaCO_2$.

patients who desaturate on exercise and show objective improvement in exercise capacity and/or dyspnoea with oxygen. Oxygen flow rates should be adjusted to maintain SpO_2 above 90%.

Surgical intervention

Some patients with COPD may benefit from surgical intervention. Young patients in whom large bullae compress surrounding normal lung tissue, who otherwise have minimal airflow limitation and a lack of generalised emphysema, may be considered for bullectomy. Patients with predominantly upper lobe emphysema, with preserved gas transference and no evidence of pulmonary hypertension, may benefit from lung volume reduction surgery (LVRS), in which peripheral emphysematous lung tissue is resected with the aim of reducing hyperinflation and decreasing the work of breathing may lead to improvements in FEV_1 , lung volumes, exercise tolerance and quality of life. Both bullectomy and LVRS can be performed thorascopically, minimising morbidity, and endoscopic techniques for lung volume reduction are also under development. Lung transplantation may benefit carefully selected patients with advanced disease but is limited by shortage of donor organs.

Other measures

Patients with COPD should be offered an annual influenza vaccination and, as appropriate, pneumococcal vaccination. Obesity, poor nutrition, depression and social isolation should be identified and, if possible, improved. Mucolytic therapy such as acetylcysteine, or antioxidant agents are occasionally used but with limited evidence.

Palliative care

Addressing end-of-life needs is an important, yet often ignored aspect of care in advanced disease. Morphine preparations may be used for palliation of breathlessness in advanced disease and benzodiazepines in low dose may reduce anxiety. Decisions regarding resuscitation should be addressed in advance of critical illness.

Prognosis

COPD has a variable natural history but is usually progressive. The prognosis is inversely related to age and directly related to the post-bronchodilator FEV_1 . Additional poor prognostic indicators include weight loss and pulmonary hypertension. A recent study has suggested that a composite score (BODE index) comprising the body mass index (B), the degree of airflow obstruction (O), a measurement of dyspnoea (D) and exercise capacity (E), may assist in predicting death from respiratory and other causes (Box 19.33). Respiratory failure, cardiac disease and lung cancer represent common modes of death.

19.33 Calculation of the BODE index

Variable	Points on BODE index			
	0	1	2	3
FEV₁	≥ 65	50–64	36–49	≤ 35
Distance walked in 6 min (m)	≥ 350	250–349	150–249	≤ 149
MRC dyspnoea scale*	0–1	2	3	4
Body mass index	> 21	≤ 21		
A patient with a BODE score of 0–2 has a mortality rate of around 10% at 52 months, whereas a patient with a BODE score of 7–10 has a mortality rate of around 80% at 52 months.				
*See Box 19.28.				

Acute exacerbations of COPD

Acute exacerbations of COPD are characterised by an increase in symptoms and deterioration in lung function and health status. They become more frequent as the disease progresses and are usually triggered by bacteria, viruses or a change in air quality. They may be accompanied by the development of respiratory failure and/or fluid retention and represent an important cause of death.

Many patients can be managed at home with the use of increased bronchodilator therapy, a short course of oral corticosteroids, and if appropriate, antibiotics. The presence of cyanosis, peripheral oedema or an alteration in consciousness should prompt referral to hospital. In other patients, consideration of comorbidity and social circumstances may influence decisions regarding hospital admission.

19.34 Obstructive pulmonary disease in old age

- **Asthma:** may appear de novo in old age so airflow obstruction should not always be assumed to be due to COPD.
- **PEF recordings:** older people with poor vision have difficulty reading PEF meters.
- **Perception of bronchoconstriction:** impaired by age, so an older patient's description of symptoms may not be a reliable indicator of severity.
- **Stopping smoking:** the benefits on the rate of loss of lung function decline with age but remain valuable up to the age of 80.
- **Metered-dose inhalers:** many older people cannot use these because of difficulty coordinating and triggering the device. Even mild cognitive impairment virtually precludes their use. Frequent demonstration and reinstruction in the use of all devices are required.
- **Mortality rates for acute asthma:** higher in old age, partly because patients underestimate the severity of bronchoconstriction and also develop a lower degree of tachycardia and pulsus paradoxus for the same degree of bronchoconstriction.
- **Treatment decisions:** advanced age in itself is not a barrier to intensive care or mechanical ventilation in an acute episode of asthma or COPD, but this decision may be difficult and should be shared with the patient (if possible), the relatives and the GP.

Oxygen therapy

In patients with an exacerbation of severe COPD, high concentrations of oxygen may cause respiratory depression and worsening acidosis (pp. 661–662). Controlled oxygen at 24% or 28% should be used with the aim of maintaining a $PaO_2 > 8$ kPa (60 mmHg) (or an $SaO_2 > 90\%$) without worsening acidosis.

Bronchodilators

Nebulised short-acting β_2 -agonists combined with an anticholinergic agent (e.g. salbutamol with ipratropium) should be administered. With careful supervision, it is usually safe to drive nebulisers with oxygen, but if concern exists regarding oxygen sensitivity, nebulisers may be driven by compressed air and supplemental oxygen delivered by nasal cannula.

Corticosteroids

Oral prednisolone reduces symptoms and improves lung function. Currently, doses of 30 mg for 10 days are recommended but shorter courses may be acceptable. Prophylaxis against osteoporosis should be considered in patients who receive repeated courses of steroids (p. 770).

Antibiotic therapy

The role of bacteria in exacerbations remains controversial and there is little evidence for the routine administration of antibiotics. They are currently recommended for patients reporting an increase in sputum purulence, sputum volume or breathlessness. In most cases, simple regimens are advised, such as an aminopenicillin or a macrolide. Co-amoxiclav is only required in regions where β -lactamase-producing organisms are known to be common.

Non-invasive ventilation

If, despite the above measures, the patient remains tachypnoeic and acidotic ($H^+ \geq 45/pH < 7.35$), then NIV should be commenced (p. 196). Several studies have demonstrated its benefit (Box 19.35). It is not useful in patients who cannot protect their airway. Mechanical ventilation may be contemplated in those with a reversible cause for deterioration (e.g. pneumonia), or when no prior history of respiratory failure has been noted.

Additional therapy

Exacerbations may be accompanied by the development of peripheral oedema; this usually responds to diuretics. There has been a vogue for using an infusion of intravenous aminophylline but evidence for benefit is limited and there are risks of inducing arrhythmias and drug interactions. The use of the respiratory stimulant doxapram has been largely superseded by the develop-

ment of NIV, but it may be useful for a limited period in selected patients with a low respiratory rate.

Discharge

Discharge from hospital may be planned once the patient is clinically stable on his or her usual maintenance medication. The provision of a nurse-led 'hospital at home' team providing short-term nebuliser loan improves discharge rates and provides additional support for the patient.

Bronchiectasis

Bronchiectasis means abnormal dilatation of the bronchi. Chronic suppurative airway infection with sputum production, progressive scarring and lung damage are present, whatever the cause.

Aetiology and pathogenesis

Bronchiectasis may result from a congenital defect affecting airway ion transport or ciliary function, such as cystic fibrosis (p. 678), or be acquired secondary to damage to the airways by a destructive infection, inhaled toxin or foreign body. The result is chronic inflammation and infection in airways. Box 19.36 shows the common causes, of which tuberculosis is the most common world-wide.

Localised bronchiectasis may occur due to the accumulation of pus beyond an obstructing bronchial lesion, such as enlarged tuberculous hilar lymph nodes, a bronchial tumour or an inhaled foreign body (e.g. an aspirated peanut).

Pathology

The bronchiectatic cavities may be lined by granulation tissue, squamous epithelium or normal ciliated epithelium. There may also be inflammatory changes in the deeper layers of the bronchial wall and hypertrophy of the bronchial arteries. Chronic inflammatory and fibrotic changes are usually found in the surrounding lung tissue, resulting in progressive destruction of the normal lung architecture in advanced cases.

19.36 Causes of bronchiectasis**Congenital**

- Cystic fibrosis
- Ciliary dysfunction syndromes
 - Primary ciliary dyskinesia (immotile cilia syndrome)
 - Kartagener's syndrome (sinusitis and transposition of the viscera)
- Primary hypogammaglobulinaemia (p. 881)

Acquired: children

- Pneumonia (complicating whooping cough or measles)
- Primary TB
- Inhaled foreign body

Acquired: adults

- Suppurative pneumonia
- Pulmonary TB
- Allergic bronchopulmonary aspergillosis complicating asthma (p. 696)
- Bronchial tumours

EBM 19.35 Non-invasive ventilation in COPD exacerbations

'Non-invasive ventilation is safe and effective in patients with an acute exacerbation of COPD complicated by mild to moderate respiratory acidosis and should be considered early in the course of respiratory failure to reduce the need for endotracheal intubation, treatment failure and mortality.'

• Ram FS, et al. (Cochrane Review). Cochrane Library, issue 3, 2004. Oxford: Update Software.

Clinical features

The symptoms of bronchiectasis are summarised in Box 19.37.

Physical signs in the chest may be unilateral or bilateral. If the bronchiectatic airways do not contain secretions and there is no associated lobar collapse, there are no abnormal physical signs. When there are large amounts of sputum in the bronchiectatic spaces, numerous coarse crackles may be heard over the affected areas. Collapse with retained secretions blocking a proximal bronchus may lead to locally diminished breath sounds, while advanced disease may lead to scarring and overlying bronchial breathing. Acute haemoptysis is an important complication of bronchiectasis; management is covered on page 657.

19.37 Symptoms of bronchiectasis

Cough

- Chronic productive cough due to accumulation of pus in dilated bronchi; usually worse in mornings and often brought on by changes of posture. Sputum often copious and persistently purulent in advanced disease. Halitosis is a common accompanying feature

Pneumonia and pleurisy

- Due to inflammatory changes in lung and pleura surrounding dilated bronchi when spread of infection occurs: fever, malaise and increased cough and sputum volume, which may be associated with pleurisy. Recurrent pleurisy in the same site often occurs in bronchiectasis

Haemoptysis

- Can be slight or massive and is often recurrent. Usually associated with purulent sputum or an increase in sputum purulence. Can, however, be the only symptom in so-called 'dry bronchiectasis'

Poor general health

- When disease is extensive and sputum persistently purulent, there may be associated weight loss, anorexia, lassitude, low-grade fever, and failure to thrive in children. In these patients, digital clubbing is common

Investigations

Bacteriological and mycological examination of sputum

In addition to common respiratory pathogens, sputum culture may reveal *Pseudomonas aeruginosa*, fungi such as *Aspergillus* and various mycobacteria. Frequent cultures are necessary to ensure appropriate treatment of resistant organisms.

Radiological examination

Bronchiectasis, unless very gross, is not usually apparent on a chest X-ray. In advanced disease, thickened airway walls, cystic bronchiectatic spaces, and associated areas of pneumonic consolidation or collapse may be visible. CT is much more sensitive, and shows thickened dilated airways (Fig. 19.28).

Assessment of ciliary function

A screening test can be performed in patients suspected of having a ciliary dysfunction syndrome by measuring the time taken for a small pellet of saccharin placed in

Fig. 19.28 CT of bronchiectasis. This scan shows extensive dilatation of the bronchi with thickened walls (arrows) in both lower lobes.

the anterior chamber of the nose to reach the pharynx, when the patient can taste it. This time should not exceed 20 minutes but is greatly prolonged in patients with ciliary dysfunction. Ciliary beat frequency may also be assessed using biopsies taken from the nose. Structural abnormalities of cilia can be detected by electron microscopy.

Management

In patients with airflow obstruction, inhaled bronchodilators and corticosteroids should be used to enhance airway patency.

Physiotherapy

Patients should be instructed on how to perform regular daily physiotherapy to assist the drainage of excess bronchial secretions. Efficiently executed, this is of great value both in reducing the amount of cough and sputum and in preventing recurrent episodes of bronchopulmonary infection. Patients should adopt a position in which the lobe to be drained is uppermost. Deep breathing followed by forced expiratory manœuvres (the 'active cycle of breathing' technique) is of help in moving secretions in the dilated bronchi towards the trachea, from which they can be cleared by vigorous coughing. 'Percussion' of the chest wall with cupped hands may help to dislodge sputum, but does not suit all patients. Devices which increase airway pressure, either by a constant amount (positive expiratory pressure mask) or in an oscillatory manner (flutter valve), aid sputum clearance in some patients, and a variety of techniques should be tried to find one that suits the individual. The optimum duration and frequency of physiotherapy depend on the amount of sputum, but 5–10 minutes once or twice daily is a minimum for most patients.

Antibiotic therapy

For most patients with bronchiectasis, the appropriate antibiotics are the same as those used in COPD (p. 676); however, in general, larger doses and longer courses are required, while resolution of symptoms is often incomplete. When secondary infection occurs with staphylococci and Gram-negative bacilli, in particular

Pseudomonas species, antibiotic therapy becomes more challenging and should be guided by the microbiological sensitivities. For *Pseudomonas*, oral ciprofloxacin (250–750 mg 12-hourly) or ceftazidime by intravenous injection or infusion (1–2 g 8-hourly) may be required. Haemoptysis in bronchiectasis often responds to treating the underlying infection, although in severe cases percutaneous embolisation of the bronchial circulation by an interventional radiologist may be necessary.

Surgical treatment

Excision of bronchiectatic areas is only indicated in a small proportion of cases. These are usually young patients in whom the bronchiectasis is unilateral and confined to a single lobe or segment on CT. Unfortunately, many of the patients in whom medical treatment proves unsuccessful are also unsuitable for surgery because of either extensive bronchiectasis or coexisting chronic lung disease. In progressive forms of bronchiectasis, resection of destroyed areas of lung which are acting as a reservoir of infection should only be considered as a last resort.

Prognosis

The disease is progressive when associated with ciliary dysfunction and cystic fibrosis, and eventually causes respiratory failure. In other patients the prognosis can be relatively good if physiotherapy is performed regularly and antibiotics are used aggressively.

Prevention

As bronchiectasis commonly starts in childhood following measles, whooping cough or a primary tuberculous infection, it is essential that these conditions receive adequate prophylaxis and treatment. The early recognition and treatment of bronchial obstruction is also important.

Cystic fibrosis

Genetics, pathogenesis and epidemiology

Cystic fibrosis (CF) is the most common fatal genetic disease in Caucasians, with autosomal recessive inheritance, a carrier rate of 1 in 25 and an incidence of about 1 in 2500 live births (pp. 45 and 50). CF is the result of mutations affecting a gene on the long arm of chromosome 7 which codes for a chloride channel known as cystic fibrosis transmembrane conductance regulator (*CFTR*), that influences salt and water movement across epithelial cell membranes. The most common *CFTR* mutation in northern European and American populations is $\Delta F508$, but over one thousand mutations of this gene have now been identified. The genetic defect causes increased sodium and chloride content in sweat and increased resorption of sodium and water from respiratory epithelium (Fig. 19.29). Relative dehydration of the airway epithelium is thought to predispose to chronic bacterial infection and ciliary dysfunction, leading to bronchiectasis. The gene defect also causes disorders in the gut epithelium, pancreas, liver and reproductive tract (see below).

In the 1960s, few patients with CF survived childhood, yet with aggressive treatment of airway infection and nutritional support, life expectancy has improved dramatically, such that there are now more adults than children with CF in many developed countries. Until recently, the diagnosis was most commonly made from the clinical picture (bowel obstruction, failure to thrive, steatorrhoea and/or chest symptoms in a young child) supported by sweat electrolyte testing and genotyping. Patients with unusual phenotypes were commonly missed, however, and late diagnosis led to poorer outcomes. Neonatal screening for CF using immunoreactive trypsin and genetic testing of newborn blood samples is now routine in the UK, and should reduce delayed diagnosis and

Fig. 19.29 Cystic fibrosis: basic defect in the pulmonary epithelium. **A** The CF gene codes for a chloride channel (1) in the apical (luminal) membrane of epithelial cells in the conducting airways. This is normally controlled by cyclic adenosine monophosphate (cAMP) and indirectly by β -adrenoceptor stimulation, and is one of several apical ion channels which control the quantity and solute content of airway-lining fluid. Normal channels appear to inhibit the adjacent epithelial sodium channels (2). **B** In CF, one of many CF gene defects causes absence or defective function of this chloride channel (3). This leads to reduced chloride secretion and loss of inhibition of sodium channels with excessive sodium resorption (4) and dehydration of the airway lining. The resulting abnormal airway-lining fluid predisposes to infection by mechanisms still to be fully explained

improve outcomes. Prenatal screening by amniocentesis may be offered to those known to be at high risk.

Clinical features

The lungs are macroscopically normal at birth, but bronchiolar inflammation and infections usually lead to bronchiectasis in childhood. At this stage, the lungs are most commonly infected with *Staphylococcus aureus*; however, many patients become colonised with *Pseudomonas aeruginosa* by the time they reach adulthood. Recurrent exacerbations of bronchiectasis, initially in the upper lobes but subsequently throughout both lungs, cause progressive lung damage resulting ultimately in death from respiratory failure. Other clinical manifestations are shown in Box 19.38. Most men with CF are infertile due to failure of development of the vas deferens, but microsurgical sperm aspiration and in vitro fertilisation are now possible. Genotype is a poor predictor of disease severity in individuals; even siblings with matching genotypes may have quite different phenotypes. This suggests that other 'modifier genes', as yet unidentified, influence clinical outcome.

19.38 Complications of cystic fibrosis	
Respiratory	
<ul style="list-style-type: none"> • Infective exacerbations of bronchiectasis • Spontaneous pneumothorax • Haemoptysis • Nasal polyps 	<ul style="list-style-type: none"> • Respiratory failure • Cor pulmonale • Lobar collapse due to secretions
Gastrointestinal	
<ul style="list-style-type: none"> • Malabsorption and steatorrhoea • Distal intestinal obstruction syndrome 	<ul style="list-style-type: none"> • Biliary cirrhosis and portal hypertension • Gallstones
Others	
<ul style="list-style-type: none"> • Diabetes (25% of adults) • Delayed puberty • Male infertility • Stress incontinence due to repeated forced cough 	<ul style="list-style-type: none"> • Psychosocial problems • Osteoporosis • Arthropathy • Cutaneous vasculitis

Management

Treatment of CF lung disease

The management of CF lung disease is that of severe bronchiectasis. All patients with CF who produce sputum should perform regular chest physiotherapy, and should do so more frequently during exacerbations. While infections with *Staph. aureus* can often be managed with oral antibiotics, intravenous treatment (often self-administered at home through a subcutaneous vascular port) is usually needed for *Pseudomonas* species. Regular nebulised antibiotic therapy (colomycin or tobramycin) is used between exacerbations in an attempt to suppress chronic *Pseudomonas* infection.

Unfortunately, the bronchi of many CF patients eventually become colonised with pathogens which are resistant to most antibiotics. Resistant strains of *P. aeruginosa*, *Stenotrophomonas maltophilia* and *Burkholderia cepacia* are the main culprits, and may require prolonged treatment with unusual combinations of antibiotics. *Aspergillus* and

19.39 Treatments that may reduce chest exacerbations and/or improve lung function in CF

Therapy	Patients treated
Nebulised recombinant human DNase 2.5 mg daily	Age \geq 5, FVC > 40% predicted
Nebulised tobramycin 300 mg 12-hourly, given in alternate months	Patients colonised with <i>Pseudomonas aeruginosa</i>
Regular oral azithromycin 500 mg three times/week	Patients colonised with <i>Pseudomonas aeruginosa</i>

'atypical mycobacteria' are also frequently found in the sputum of CF patients, but in most cases these behave as benign 'colonisers' of the bronchiectatic airways and do not require specific therapy. Some patients have coexistent asthma, which is treated with inhaled bronchodilators and corticosteroids; allergic bronchopulmonary aspergillosis (p. 696) also occurs occasionally in CF.

Three maintenance treatments have been shown to cause modest rises in lung function and/or to reduce the frequency of chest exacerbations in CF patients (Box 19.39). Individual responses are variable and should be carefully monitored to avoid burdening patients with treatments that prove ineffective.

For advanced CF lung disease, home oxygen and NIV may be necessary to treat respiratory failure. Ultimately, lung transplantation can produce dramatic improvements but is limited by donor organ availability.

Treatment of non-respiratory manifestations of CF

There is a clear link between good nutrition and prognosis in CF. Malabsorption is treated with oral pancreatic enzyme supplements and vitamins. The increased calorie requirements of CF patients are met by supplemental feeding, including nasogastric or gastrostomy tube feeding if required. Diabetes eventually appears in over 25% of patients and often requires insulin therapy. Osteoporosis secondary to malabsorption and chronic ill health should be sought and treated (p. 1116).

Somatic gene therapy

The discovery of the CF gene and the fact that the lethal defect is located in the respiratory epithelium (which is accessible by inhaled therapy) presents an exciting opportunity for gene therapy. Manufactured normal CF gene can be 'packaged' within a viral or liposome vector and delivered to the respiratory epithelium to correct the genetic defect. Initial trials in the nasal and bronchial epithelium have shown some effect, and further trials of nebulised bronchial delivery are planned. Improved gene transfer efficiency is needed before this will become a practical clinical treatment.

INFECTIONS OF THE RESPIRATORY SYSTEM

Infections of the upper and lower respiratory tract are a major cause of morbidity and mortality throughout the world; patients at the extremes of age, and those with pre-existing lung disease or immune suppression are at particular risk.

Upper respiratory tract infection

The causes, clinical features, complications and management of the common and most important upper respiratory tract infections are summarised in Boxes 19.40 and 19.41. The vast majority of these illnesses are caused by viruses (Box 19.40), of which acute coryza (common cold) is by far the most common. Immunity is short-lived and virus-specific. Bacterial infection is the usual cause of acute tonsillitis, otitis media and epiglottitis.

Acute epiglottitis represents a medical emergency because of the risk of asphyxia, requiring prompt diagnosis and treatment, but those with other upper respiratory tract infections recover rapidly and specific investigation is rarely warranted. Viruses can be isolated from exfoliated cells collected on throat swabs, and may be identified retrospectively by serological tests. Throat swabs may also be helpful if streptococcal pharyngitis is suspected, and a blood film and serological testing (p. 316) will identify infectious mononucleosis. X-rays of the sinuses may be required if an underlying chronic sinusitis is suspected.

19.40 Respiratory infections caused by viruses

Clinical syndrome	Usual cause (other causes in parentheses)
Epidemic influenza	Influenza A and B
'Influenza-like' illness	Adenoviruses, rhinoviruses (enteroviruses)
Pharyngitis	Adenoviruses (enteroviruses, parainfluenza viruses, influenza A and B in partially immune)
Common cold (coryza)	Rhinoviruses (coronaviruses, enteroviruses, adenoviruses, respiratory syncytial virus)
'Feverish' cold	Rhinoviruses, enteroviruses (influenza A and B, parainfluenza viruses, respiratory syncytial virus)
Croup	Parainfluenza 1, 2, 3 (rhinoviruses, enteroviruses)
Bronchitis	Rhinoviruses, adenoviruses (influenza A and B)
Bronchiolitis	Respiratory syncytial virus (parainfluenza 3)
Pneumonia	Influenza A and B, chickenpox (respiratory syncytial virus, parainfluenza, measles and adenoviruses)

Pneumonia

Pneumonia is defined as an acute respiratory illness associated with recently developed radiological pulmonary shadowing which may be segmental, lobar or multilobar. The context in which pneumonia develops is highly suggestive of the likely organism(s) involved;

therefore, pneumonias are usually classified as community- or hospital-acquired, or those occurring in immunocompromised hosts. 'Lobar pneumonia' is a radiological and pathological term referring to homogeneous consolidation of one or more lung lobes, often with associated pleural inflammation; bronchopneumonia refers to more patchy alveolar consolidation associated with bronchial and bronchiolar inflammation often affecting both lower lobes.

Community-acquired pneumonia (CAP)

UK figures suggest that an estimated 5–11/1000 adults suffer from CAP each year, accounting for around 5–12% of all lower respiratory tract infections. The incidence varies with age, being much higher in the very young and very old, in whom the mortality rates are also much higher. World-wide, CAP continues to kill more children than any other illness.

Most cases are spread by droplet infection and occur in previously healthy individuals but several factors may impair the effectiveness of local defences and predispose to CAP (Box 19.42). *Strep. pneumoniae* (Fig. 19.30) remains the most common infecting agent, and thereafter, the likelihood that other organisms may be involved depends on the age of the patient and the clinical context. Viral infections are an important cause of CAP in children, and their contribution to adult CAP is increasingly recognised. The common causative organisms are shown in Box 19.43.

Clinical features

Pneumonia usually presents as an acute illness in which systemic features such as fever, rigors, shivering and vomiting predominate (see Box 19.43). The appetite is usually lost and headache is common. Pulmonary symptoms include breathlessness and cough, which at first is characteristically short, painful and dry, but later accompanied by the expectoration of mucopurulent sputum. Rust-coloured sputum may be seen in patients with *Strep. pneumoniae* infection, and the occasional patient may report haemoptysis. Pleuritic chest pain may be a presenting feature and on occasion may be referred to the shoulder or anterior abdominal wall. Upper abdominal tenderness is sometimes apparent in patients with lower lobe pneumonia or if there is associated hepatitis. Less typical presentations may be seen at the extremes of

Fig. 19.30 Gram stain of sputum showing Gram-positive diplococci characteristic of *Strep. pneumoniae* (arrows).

19.41 Common upper respiratory tract infections

Infection	Clinical features	Complications	Management
Acute coryza (common cold)	Rapid onset. Sneezing. Sore throat. Watery nasal discharge. Cough (Similar features in nasal allergy)	Sinusitis, bronchitis, pneumonia. Hearing impairment, otitis media due to blockage of Eustachian tubes	Treatment not usually required. Paracetamol 0.5–1 g 4–6-hourly. Nasal decongestant. Antibiotics not necessary if uncomplicated
Acute pharyngitis	More severe sore throat. Hoarse voice or loss of voice with pain on speaking. Painful and unproductive cough. Stridor in children, caused by inflammatory oedema leading to partial obstruction of a small larynx	Rare. Chronic laryngitis, tracheitis, bronchitis or pneumonia	Rest voice. Paracetamol 0.5–1 g 4–6-hourly for relief of discomfort and pyrexia. Steam inhalations may help. Antibiotics not necessary if uncomplicated
Sinusitis	Fever. Severe unilateral pain over maxillary or other sinus. Purulent nasal discharge. Commonly viral, but bacterial (e.g. <i>Strep. pneumoniae</i> , <i>H. influenzae</i>) likely if persists 7–10 days	CNS or orbital spread of infection	Steam inhalation and nasal decongestants. Co-amoxiclav if bacterial cause suspected.
Acute laryngo-tracheobronchitis (croup)*	Sudden paroxysms of cough accompanied by stridor and breathlessness. Contraction of accessory muscles and indrawing of intercostal spaces. Cyanosis and asphyxia in small children	Death from asphyxia. Superinfection with bacteria, especially <i>Strep. pneumoniae</i> and <i>Staph. aureus</i> . Viscid secretions may occlude bronchi	Steam inhalations and humidified air/high concentrations of oxygen. Endotracheal intubation or tracheostomy may be required to relieve laryngeal obstruction and allow clearing of bronchial secretions. Intravenous co-amoxiclav or erythromycin for serious illness. Maintain adequate hydration
Acute epiglottitis	Mostly affects young children. Fever and sore throat, progressing to stridor and dysphagia caused by swelling of epiglottis and surrounding structures. Due to <i>H. influenzae</i> type b	Death from asphyxia, which may be precipitated by attempts to examine the throat— <i>avoid using a tongue depressor or any instrument</i> unless facilities for endotracheal intubation or tracheostomy are immediately available	I.v. co-amoxiclav or chloramphenicol therapy essential. Urgent endotracheal intubation or tracheostomy may be necessary. Routine immunisation has reduced incidence in the UK
Acute bronchitis and tracheitis	Often follows acute coryza. Initial dry, painful cough with retrosternal discomfort in tracheitis. Chest tightness, wheeze and breathlessness if bronchitis develops. Sputum is initially scanty or mucoid, then becomes mucopurulent, more copious and, in tracheitis, often blood-stained. Acute bronchitis may be associated with a pyrexia of 38–39°C. Spontaneous recovery occurs over a few days	Bronchopneumonia. Exacerbation of asthma or COPD which, if severe, may result in type II respiratory failure	Specific treatment rarely necessary in previously healthy individuals. Amoxicillin 250 mg 8-hourly should be given to those developing bronchopneumonia. Cough may be eased by pholcodine 5–10 mg 6–8-hourly. In COPD and asthma, aggressive treatment of exacerbations may be required (pp. 675 and 668)
Influenza	Range from mild to rapidly fatal. Sudden onset of pyrexia with generalised aching, headache, anorexia, nausea and vomiting, and harsh unproductive cough. Most recover within 3–5 days, but may be followed by 'post-viral syndrome' with debility that persists for weeks. During epidemics, diagnosis is usually obvious. Sporadic cases diagnosed by virus isolation, fluorescent antibody techniques or serological tests for specific antibodies	Tracheitis, bronchitis, bronchiolitis and bronchopneumonia. Secondary bacterial invasion by <i>Strep. pneumoniae</i> , <i>H. influenzae</i> and <i>Staph. aureus</i> may occur. Rarely, toxic cardiomyopathy (may cause sudden death), encephalitis, demyelinating encephalopathy and peripheral neuropathy	Bed rest. Paracetamol 0.5–1 g 4–6-hourly. Pholcodine 5–10 mg 6–8-hourly for cough. Specific treatment for pneumonia may be necessary. Antiviral agents (e.g. zanamivir) reduce the rate of viral replication and may be effective when used as an adjunct to vaccination. Antiviral resistance is a potential problem

*Whooping cough (caused by *Bordetella pertussis*) is often considered a disease of non-immunised children but it also occurs in sporadic 'epidemics' in middle life when immunisation effectiveness has waned. After a short febrile tracheobronchitis (which is responsive to antibiotics), severe episodic paroxysmal coughing bouts, associated with laryngospasm and post-tussive vomiting, often lead to intercostal muscle tears or fractured ribs, and may persist for many weeks.

19.42 Factors that predispose to pneumonia

- Cigarette smoking
- Upper respiratory tract infections
- Alcohol
- Corticosteroid therapy
- Old age
- Recent influenza infection
- Pre-existing lung disease
- HIV
- Indoor air pollution

age. Clinical signs reflect the nature of the inflammatory response. Proteinaceous fluid and inflammatory cells congest the airspaces, leading to consolidation of lung tissue (which takes on the appearance of liver on a cut surface: phases of red, then grey hepatisation). This improves the conductivity of sound to the chest wall and the clinician may hear bronchial breathing and whispering pectoriloquy (p. 642). Crackles are often also detected.

Investigations

The objectives are to exclude other conditions that mimic pneumonia (Box 19.44), assess the severity, and identify the development of complications.

A chest X-ray usually provides confirmation of the diagnosis. In lobar pneumonia, a homogeneous opacity localised to the affected lobe or segment usually appears within 12–18 hours of the onset of the illness (Fig. 19.31). Radiological examination is helpful if a complication such as parapneumonic effusion, intrapulmonary abscess formation or empyema is suspected.

Many cases of CAP can be managed successfully without identification of the organism, particularly if there are no features indicating severe disease. A full range of microbiological tests should be performed on patients with severe CAP (Box 19.45). The identification of *Legionella pneumophila* has important public health

19.43 Common clinical features of community-acquired pneumonia (CAP)

Organism	Clinical features
<i>Streptococcus pneumoniae</i>	Most common cause. Affects all age groups, particularly young to middle-aged. Characteristically rapid onset, high fever and pleuritic chest pain; may be accompanied by herpes labialis and 'rusty' sputum. Bacteraemia more common in women and those with diabetes or COPD
<i>Mycoplasma pneumoniae</i>	Children and young adults. Epidemics occur every 3–4 years, usually in autumn. Rare complications include haemolytic anaemia, Stevens–Johnson syndrome, erythema nodosum, myocarditis, pericarditis, meningoencephalitis, Guillain–Barré syndrome
<i>Legionella pneumophila</i>	Middle to old age. Local epidemics around contaminated source, e.g. cooling systems in hotels, hospitals. Person-to-person spread unusual. Some features more common, e.g. headache, confusion, malaise, myalgia, high fever and vomiting and diarrhoea. Laboratory abnormalities include hyponatraemia, elevated liver enzymes, hypoalbuminaemia and elevated creatine kinase. Smoking, corticosteroids, diabetes, chronic kidney disease increase risk
<i>Chlamydia pneumoniae</i>	Young to middle-aged. Large-scale epidemics or sporadic; often mild, self-limiting disease. Headaches and a longer duration of symptoms before hospital admission. Usually diagnosed on serology
<i>Haemophilus influenzae</i>	More common in old age and those with underlying lung disease (COPD, bronchiectasis)
<i>Staphylococcus aureus</i>	Associated with debilitating illness and often preceded by influenza. Radiographic features include multilobar shadowing, cavitation, pneumatoceles and abscesses. Dissemination to other organs may cause osteomyelitis, endocarditis or brain abscesses. Mortality up to 30%
<i>Chlamydia psittaci</i>	Consider in those in contact with birds, especially recently imported and exotic. Malaise, low-grade fever, protracted illness, hepatosplenomegaly and occasionally headache with meningism
<i>Coxiella burnetii</i> (Q fever, 'query' fever)	Consider in workers in dairy farms, abattoirs and hide factories (as amniotic fluid and placenta carry high risk). Risk of infection increases with age and male sex. Acute illness characterised by severe headache, high fever, hepatitis, myalgia, conjunctivitis. Chronic disease causes endocarditis, hepatomegaly
<i>Klebsiella pneumoniae</i> (Freidländer's bacillus)	More common in men, alcoholics, diabetics, elderly, hospitalised patients, and those with poor dental hygiene. Predilection for upper lobes and particularly liable to suppurate and form abscesses. May progress to pulmonary gangrene
<i>Actinomyces israelii</i>	Mouth commensal. Cervicofacial, abdominal or pulmonary infection, empyema, chest wall sinuses, pus with sulphur granules
Primary viral pneumonias	
Influenza, parainfluenza, measles	May cause pneumonia commonly complicated by secondary bacterial infection
Herpes simplex	May cause tracheobronchitis or pneumonia in the immunosuppressed
Varicella	May cause severe pneumonia. Heals with small nodules that calcify and become visible on chest X-ray
Adenovirus	Pneumonia reported in malnourished children and immunocompromised adults
Cytomegalovirus (CMV)	Pneumonia may be a major problem in transplant recipients (particularly bone marrow) and those with AIDS
Coronavirus (Urbani SARS-associated coronavirus)	SARS (severe acute respiratory distress syndrome) should be suspected if a high fever (> 38°C), malaise, muscle aches, a dry cough and breathlessness follow within 10 days of travel to an area affected by an epidemic

19.44 Differential diagnosis of pneumonia

- Pulmonary infarction
- Pulmonary/pleural TB
- Pulmonary oedema (can be unilateral)
- Pulmonary eosinophilia (p. 715)
- Malignancy: bronchoalveolar cell carcinoma
- Rare disorders: cryptogenic organising pneumonia/bronchiolitis obliterans organising pneumonia (COP/BOOP)

implications and requires notification. In patients who do not respond to initial therapy, microbiological results may allow its appropriate modification. Microbiology also provides useful epidemiological information.

Pulse oximetry provides a non-invasive method of measuring arterial oxygen saturation (SaO_2) and monitoring response to oxygen therapy. An arterial blood gas is important in those with $SaO_2 < 93\%$ or with features of severe pneumonia, to identify ventilatory failure or acidosis.

The white cell count may be normal or only marginally raised in pneumonia caused by atypical organisms, whereas a neutrophil leucocytosis of more than $15 \times 10^9/L$ favours a bacterial aetiology. A very high ($> 20 \times 10^9/L$) or low ($< 4 \times 10^9/L$) white cell count may be seen in severe pneumonia. Urea and electrolytes and liver function tests should also be checked. The C-reactive protein (CRP) is typically elevated.

Assessment of disease severity

This is best assessed by an experienced clinician; however, the CURB-65 scoring system helps guide antibiotic and admission policies, and gives useful prognostic information (Fig. 19.32).

Management

The most important aspects of management include oxygenation, fluid balance and antibiotic therapy. In severe or prolonged illness, nutritional support may be required.

19.45 Microbiological investigations in patients with CAP

All patients

- Sputum: direct smear by Gram (see Fig. 19.30) and Ziehl–Neelsen stains. Culture and antimicrobial sensitivity testing
- Blood culture: frequently positive in pneumococcal pneumonia
- Serology: acute and convalescent titres for *Mycoplasma*, *Chlamydia*, *Legionella*, and viral infections. Pneumococcal antigen detection in serum or urine
- PCR: *Mycoplasma* can be detected from swab of oropharynx

Severe community-acquired pneumonia

The above tests *plus* consider:

- Tracheal aspirate, induced sputum, bronchoalveolar lavage, protected brush specimen or percutaneous needle aspiration. Direct fluorescent antibody stain for *Legionella* and viruses
- Serology: *Legionella* antigen in urine. Pneumococcal antigen in sputum and blood. Immediate IgM for *Mycoplasma*
- Cold agglutinins: positive in 50% of patients with *Mycoplasma*

Selected patients

- Throat/nasopharyngeal swabs: helpful in children or during influenza epidemic
- Pleural fluid: should always be sampled when present in more than trivial amounts, preferably with ultrasound guidance

Oxygen

Oxygen should be administered to all patients with tachypnoea, hypoxaemia, hypotension or acidosis with the aim of maintaining the $PaO_2 \geq 8$ kPa (60 mmHg) or $SaO_2 \geq 92\%$. High concentrations ($\geq 35\%$), preferably humidified, should be used in all patients who do not have hypercapnia associated with COPD. Assisted ventilation should be considered at an early stage in those who remain hypoxaemic despite adequate oxygen therapy. NIV (p. 194) may have a limited role but early recourse to mechanical ventilation is often more appropriate (Box 19.46).

Fig. 19.31 Pneumonia of the right middle lobe. **A** PA view: consolidation in the right middle lobe with characteristic opacification beneath the horizontal fissure and loss of normal contrast between the right heart border and lung. **B** Lateral view: consolidation confined to the anteriorly situated middle lobe.

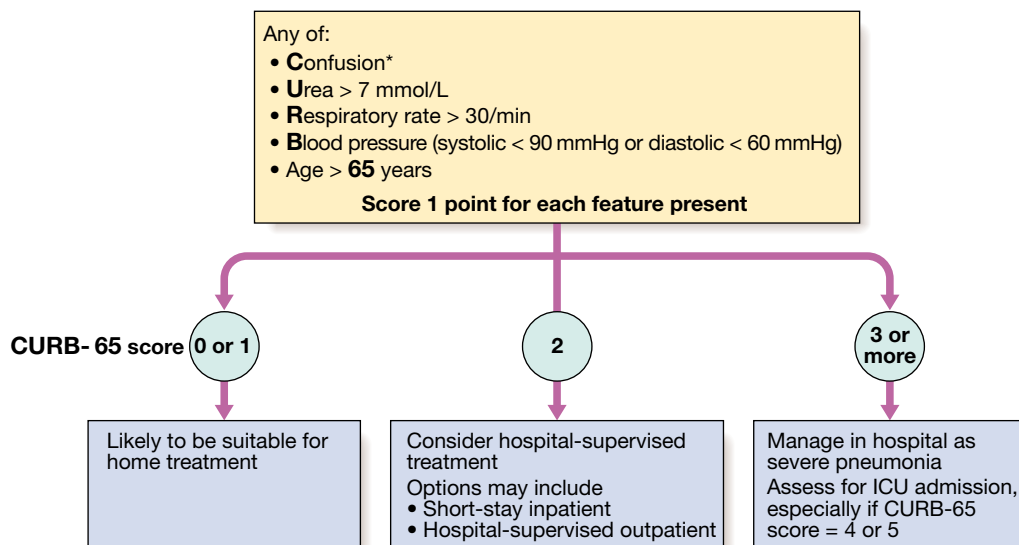

Fig. 19.32 Hospital CURB-65. *Defined as a Mental Test Score of 8 or less, or new disorientation in person, place or time. (A urea of 7 mmol/L \approx 20 mg/dL.)

19.46 Indications for referral to ITU

- CURB score 4–5 failing to respond rapidly to initial management
- Persisting hypoxia (PaO_2 < 8 kPa (60 mmHg)) despite high concentrations of oxygen
- Progressive hypercapnia
- Severe acidosis
- Circulatory shock
- Reduced conscious level

Fluid balance

Intravenous fluids should be considered in those with severe illness, in older patients and in those with vomiting. Otherwise, an adequate oral intake of fluid should be encouraged. Inotropic support may be required in patients with circulatory shock (p. 193).

Antibiotic treatment

Prompt administration of antibiotics improves outcome. The initial choice of antibiotic is guided by clinical context, severity assessment, local knowledge of antibiotic resistance patterns, and at times epidemiological information, e.g. during a mycoplasma epidemic (Box 19.47). In most patients with uncomplicated pneumonia a 7–10-day course is adequate, although treatment is usually required for longer in patients with *Legionella*, staphylococcal or *Klebsiella* pneumonia. Oral antibiotics are usually adequate unless the patient has severe illness, impaired consciousness, loss of swallowing reflex or malabsorption.

Treatment of pleural pain

It is important to relieve pleural pain, in order to allow the patient to breathe normally and cough efficiently. For the majority, simple analgesia with paracetamol, co-codamol or NSAIDs is sufficient. In some patients, opiates may be required but these must be used with extreme caution in patients with poor respiratory function.

Physiotherapy

Physiotherapy may be helpful to assist expectoration in patients who suppress cough because of pleural pain or when mucus plugging leads to bronchial collapse.

Prognosis

Most patients respond promptly to antibiotic therapy. However, fever may persist for several days and the chest X-ray often takes several weeks or even months to resolve, especially in old age. Delayed recovery suggests either that a complication has occurred (Box 19.48) or that the diagnosis is incorrect (see Box 19.44). Alternatively, the pneumonia may be secondary to a proximal bron-

19.47 Antibiotic treatment for CAP*

Uncomplicated CAP

- Amoxicillin 500 mg 8-hourly orally

If patient is allergic to penicillin

- Clarithromycin 500 mg 12-hourly orally *or*
Erythromycin 500 mg 6-hourly orally

If *Staphylococcus* is cultured or suspected

- Flucloxacillin 1–2 g 6-hourly i.v. *plus*
• Clarithromycin 500 mg 12-hourly i.v.

If *Mycoplasma* or *Legionella* is suspected

- Clarithromycin 500 mg 12-hourly orally or i.v. *or*
Erythromycin 500 mg 6-hourly orally or i.v. *plus*
• Rifampicin 600 mg 12-hourly i.v. in severe cases

Severe CAP

- Clarithromycin 500 mg 12-hourly i.v. *or*
Erythromycin 500 mg 6-hourly i.v. *plus*
• Co-amoxiclav 1.2 g 8-hourly i.v. *or*
Ceftriaxone 1–2 g daily i.v. *or*
Cefuroxime 1.5 g 8-hourly i.v. *or*
Amoxicillin 1 g 6-hourly i.v. *plus* flucloxacillin 2 g 6-hourly i.v.

*Adapted from British Thoracic Society Guidelines.

19.48 Complications of pneumonia

- Para-pneumonic effusion—common
- Empyema (p. 725)
- Retention of sputum causing lobar collapse
- DVT and pulmonary embolism
- Pneumothorax, particularly with *Staph. aureus*
- Suppurative pneumonia/lung abscess
- ARDS, renal failure, multi-organ failure
- Ectopic abscess formation (*Staph. aureus*)
- Hepatitis, pericarditis, myocarditis, meningoenzephalitis
- Pyrexia due to drug hypersensitivity

chial obstruction or recurrent aspiration. The mortality rate in adults managed at home is very low (< 1%); hospital death rates are typically between 5 and 10%, but may be as high as 50% in severe illness.

Discharge and follow-up

The decision to discharge a patient depends on home circumstances and the likelihood of complications. A chest X-ray need not be repeated before discharge in those making a satisfactory clinical recovery. Clinical review should be arranged around 6 weeks later and a chest X-ray obtained if there are persistent symptoms, physical signs or reasons to suspect underlying malignancy.

Prevention

The risk of further pneumonia is increased by smoking, so current smokers should be advised to stop. Influenza and pneumococcal vaccination should be considered in selected patients (Box 19.49 and p. 146). Because of the mode of spread (see Box 19.43), *Legionella pneumophila* has important public health implications and usually requires notification to the appropriate health authority. In developing countries, tackling malnourishment and indoor air pollution, and encouraging immunisation against measles, pertussis and *Haemophilus influenzae* type b are particularly important in children.

EBM 19.49 Influenza and pneumococcal vaccines in old age

'Influenza vaccine reduces the risk of influenza and death in elderly people.'

'Polysaccharide pneumococcal vaccines do not appear to reduce the incidence of pneumonia or death but may reduce the incidence of invasive pneumococcal disease.'

- Andrew R, et al. (Cochrane Review). Cochrane Library, issue 4, 2003. Oxford: Update Software.

Hospital-acquired pneumonia

Hospital-acquired or nosocomial pneumonia refers to a new episode of pneumonia occurring at least 2 days after admission to hospital. It is the second most common hospital-acquired infection (HAI) and the leading cause of HAI-associated death. Older people are particularly at risk, as are patients in intensive care units, especially when mechanically ventilated, in which case the term ventilator-associated pneumonia (VAP) is applied. Health care-associated pneumonia (HCAP) refers to the development of pneumonia in a person who has spent at least

2 days in hospital within the last 90 days, attended a haemodialysis unit, received intravenous antibiotics, or been resident in a nursing home or other long-term care facility.

Aetiology

When HAP occurs within 4–5 days of admission (early-onset), the organisms involved are similar to those involved in CAP; however, late-onset HAP is more often attributable to Gram-negative bacteria (e.g. *Escherichia*, *Pseudomonas* and *Klebsiella* species), *Staph. aureus* (including methicillin-resistant *Staph. aureus* (MRSA)) and anaerobes. The factors predisposing to the development of HAP are listed in Box 19.50.

19.50 Factors predisposing to hospital-acquired pneumonia

Reduced host defences against bacteria

- Reduced immune defences (e.g. corticosteroid treatment, diabetes, malignancy)
- Reduced cough reflex (e.g. post-operative)
- Disordered mucociliary clearance (e.g. anaesthetic agents)
- Bulbar or vocal cord palsy

Aspiration of nasopharyngeal or gastric secretions

- Immobility or reduced conscious level
- Vomiting, dysphagia, achalasia or severe reflux
- Nasogastric intubation

Bacteria introduced into lower respiratory tract

- Endotracheal intubation/tracheostomy
- Infected ventilators/nebulisers/bronchoscopes
- Dental or sinus infection

Bacteraemia

- Abdominal sepsis
- I.v. cannula infection
- Infected emboli

Clinical features and investigations

Universally agreed diagnostic criteria are lacking; however, HAP should be considered in any hospitalised or ventilated patient who develops purulent sputum (or endotracheal secretions), new radiological infiltrates, an otherwise unexplained increase in oxygen requirement, a core temperature > 38.3°C, and a leucocytosis or leucopenia. Circulating biomarkers may assist with the diagnosis but are currently non-specific. Appropriate investigations are similar to those outlined for CAP, although whenever possible, microbiological confirmation should be sought. In mechanically ventilated patients, bronchoscopy-directed protected brush specimens or bronchoalveolar lavage (BAL) may be performed. Endotracheal aspirates are easy to obtain but less reliable.

Management

The choice of empirical antibiotic therapy should be based on local knowledge of pathogens and drug resistance patterns, and variables such as length of hospital stay, recent antibiotics and comorbidity. Adequate Gram-negative cover is usually provided by:

- a third-generation cephalosporin (e.g. cefotaxime) with an aminoglycoside (e.g. gentamicin)

- meropenem or
- a monocyclic β -lactam (e.g. aztreonam) and flucloxacillin.

MRSA is treated with intravenous vancomycin, but when appropriate, oral therapy may be considered with doxycycline, rifampicin or linezolid.

The nature and severity of most HAPs dictate that these antibiotics are all given intravenously, at least initially. Physiotherapy is important in those who are immobile or old. Adequate oxygen therapy, fluid support and monitoring are essential.

Prevention

Despite appropriate management, the mortality from HAP is high at approximately 30%, emphasising the importance of prevention. Good hygiene is paramount, including both hand washing and equipment. Steps should be taken to minimise the chances of aspiration and limit the use of stress ulcer prophylaxis with proton pump inhibitors. Oral antiseptic (chlorhexidine 2%) may be used to decontaminate the upper airway and some intensive care units use selective decontamination of the digestive tract when the anticipated requirement for ventilation will exceed 48 hours.

Suppurative pneumonia, aspiration pneumonia and pulmonary abscess

These conditions are considered together, as their aetiology and clinical features overlap. Suppurative pneumonia is characterised by destruction of the lung parenchyma by the inflammatory process and, although microabscess formation is a characteristic histological feature, 'pulmonary abscess' is usually taken to refer to lesions in which there is a large localised collection of pus, or a cavity lined by chronic inflammatory tissue, from which pus has escaped by rupture into a bronchus.

Suppurative pneumonia and pulmonary abscess often develop after the inhalation of septic material dur-

ing operations on the nose, mouth or throat, under general anaesthesia, or of vomitus during anaesthesia or coma, particularly if oral hygiene is poor. Additional risk factors for aspiration pneumonia include bulbar or vocal cord palsy, stroke, achalasia or oesophageal reflux, and alcoholism. Aspiration tends to localise to dependent areas of the lung such as the apical segment of the lower lobe in a supine patient. Suppurative pneumonia and abscess may also complicate local bronchial obstruction from a neoplasm or foreign body.

Infections are usually due to a mixture of anaerobes and aerobes in common with the typical flora encountered in the mouth and upper respiratory tract, and isolates of *Bacteroides melaninogenicus*, *Fusobacterium necrophorum*, anaerobic or microaerophilic cocci, and *Bacteroides fragilis* may be identified. When suppurative pneumonia or pulmonary abscess occurs in a previously healthy lung, the most likely infecting organisms are *Staph. aureus* or *Klebsiella pneumoniae*.

Bacterial infection of a pulmonary infarct or a collapsed lobe may also produce a suppurative pneumonia or lung abscess. The organism(s) isolated from the sputum include *Strep. pneumoniae*, *Staph. aureus*, *Strep. pyogenes*, *H. influenzae* and, in some cases, anaerobic bacteria. In many cases, however, no pathogen can be isolated, particularly when antibiotics have been given.

Recently, cases of community-acquired MRSA (CA-MRSA) have been reported. This organism is distinct from MRSA but produces the toxin Panton-Valentine leukocidin, which causes a rapidly progressive severe necrotising pneumonia.

Lemierre's syndrome is a rare cause of pulmonary abscesses. The usual causative agent is the anaerobe, *Fusobacterium necrophorum*. It typically commences as a sore throat, painful swollen neck, fever, rigor, haemoptysis and dyspnoea, and bacterial spread into the jugular veins leads to thrombosis and metastatic spread of the organisms.

Injecting drug-users are at particular risk of developing haematogenous lung abscess, often in association with endocarditis affecting the pulmonary and tricuspid valves.

The clinical features of a suppurative pneumonia are summarised in Box 19.52. A non-infective form of aspiration pneumonia—exogenous lipid pneumonia—may follow the aspiration of animal, vegetable or mineral oils.

Investigations

Radiological features of suppurative pneumonia include homogeneous lobar or segmental opacity consistent with consolidation or collapse. Abscesses are characterised by cavitation and fluid level. Occasionally, a pre-existing emphysematous bulla becomes infected and appears as a cavity containing an air-fluid level. Sputum and blood should be sent for culture.

Management

Oral treatment with amoxicillin 500 mg 6-hourly is effective in many patients. Aspiration pneumonia can be treated with co-amoxiclav 1.2 g 8-hourly. If an anaerobic bacterial infection is suspected (e.g. from fetor of the sputum), oral metronidazole 400 mg 8-hourly should be added. Further modification of antibiotics should be informed by clinical response and the microbiological

19.51 Respiratory infection in old age

- **Increased risk of and from respiratory infection:** because of reduced immune responses, increased closing volumes, reduced respiratory muscle strength and endurance, altered mucus layer, poor nutritional status and the increased prevalence of chronic lung disease.
- **Predisposing factors:** other medical conditions may predispose to infection, e.g. swallowing difficulties due to stroke increase the risk of aspiration pneumonia.
- **Atypical presentation:** older patients often present with, for example, confusion, rather than breathlessness or cough.
- **Mortality:** the vast majority of deaths from pneumonia in developed countries occur in older people.
- **Influenza:** has a much higher complication rate, morbidity and mortality. Vaccination significantly reduces morbidity and mortality in old age but uptake is poor.
- **Tuberculosis:** most cases in old age represent reactivation of previous, often unrecognised disease and may be precipitated by steroid therapy, diabetes mellitus and the factors above. Cryptic miliary TB is an occasional alternative presentation. Older people more commonly suffer adverse effects from antituberculous chemotherapy and require close monitoring.

19.52 Clinical features of suppurative pneumonia

Symptoms

- Cough productive of large amounts of sputum which is sometimes fetid and blood-stained
- Pleural pain common
- Sudden expectoration of copious amounts of foul sputum occurs if abscess ruptures into a bronchus

Clinical signs

- High remittent pyrexia
- Profound systemic upset
- Digital clubbing may develop quickly (10–14 days)
- Chest examination usually reveals signs of consolidation; signs of cavitation rarely found
- Pleural rub common
- Rapid deterioration in general health with marked weight loss can occur if disease not adequately treated

results. CA-MRSA is usually susceptible to a variety of oral non- β -lactam antibiotics, such as trimethoprim/sulfamethoxazole, clindamycin, tetracyclines and linezolid. Parenteral therapy with vancomycin or daptomycin can also be considered. *Fusobacterium necrophorum* is highly susceptible to β -lactam antibiotics and to metronidazole, clindamycin and third-generation cephalosporins. Prolonged treatment for 4–6 weeks may be required in some patients with lung abscess.

Physiotherapy is of great value, especially when supuration is present in the lower lobes or when a large abscess cavity has formed. In most patients, there is a good response to treatment, and although residual fibrosis and bronchiectasis are common sequelae, these seldom give rise to serious morbidity. Surgery should be contemplated if no improvement occurs despite optimal medical therapy. Removal or treatment of any obstructing endobronchial lesion is essential.

Pneumonia in the immunocompromised patient

Patients immunocompromised by drugs or disease (particularly HIV; pp. 395–397) are at high risk of pulmonary infection. The majority of infections are caused by the same pathogens that cause pneumonia in non-immunocompromised individuals, but in patients with more profound immunosuppression, unusual organisms, or those normally considered to be of low virulence or non-pathogenic, may become 'opportunistic' pathogens (Box 19.53). In addition to the more common agents, the possibility of Gram-negative bacteria, especially *Pseudomonas aeruginosa*, viral agents, fungi, mycobacteria, and less common organisms such as *Nocardia asteroides*, must be considered. Infection is often due to more than one organism.

Clinical features

These typically include fever, cough and breathlessness, but are less specific with more profound degrees of immunosuppression. In general, the onset of symptoms tends to be less rapid when caused by opportunistic organisms such as *Pneumocystis jirovecii* and in mycobacterial infections, than with bacterial infections

19.53 Causes of immune suppression-associated lung infection

	Causes	Infecting organisms
Defective phagocytic function	Acute leukaemia Cytotoxic drugs Agranulocytosis	Gram-positive bacteria, including <i>Staph. aureus</i> Gram-negative bacteria Fungi, e.g. <i>Candida albicans</i> and <i>Aspergillus fumigatus</i>
Defects in cell-mediated immunity	Immunosuppressive drugs Cytotoxic chemotherapy Lymphoma Thymic aplasia	Viruses Cytomegalovirus Herpesvirus Adenovirus Influenza Fungi <i>Pneumocystis jirovecii</i> (formerly <i>carinii</i>) <i>Candida albicans</i> <i>Aspergillus fumigatus</i>
Defects in antibody production	Multiple myeloma Chronic lymphocytic leukaemia	<i>Haemophilus influenzae</i> <i>Mycoplasma pneumoniae</i>

(p. 395). In *P. jirovecii* pneumonia, symptoms of cough and breathlessness can be present several days or weeks before the onset of systemic symptoms or the appearance of radiographic abnormality. The clinical features of invasive pulmonary aspergillosis are described on page 697.

Diagnosis

The approach to investigation is informed by the clinical context and severity of the illness. Invasive investigations such as bronchoscopy, BAL, transbronchial biopsy or surgical lung biopsy are often impractical, as many patients are too ill to undergo these safely. However, 'induced sputum' (p. 649) may offer a relatively safe method of obtaining microbiological samples. HRCT is useful in differentiating the likely cause:

- Focal unilateral airspace opacification favours bacterial infection, mycobacteria or nocardia.
- Bilateral opacification favours *P. jirovecii* pneumonia, fungi, viruses and unusual bacteria, e.g. nocardia.
- Cavitation may be seen with *N. asteroides*, mycobacteria and fungi.
- The presence of a 'halo sign' may suggest *Aspergillus* (see Fig. 19.40, p. 696).
- Pleural effusions suggest a pyogenic bacterial infection and are uncommon in *P. jirovecii* pneumonia.

Management

In theory, treatment should be based on an established aetiological diagnosis; in practice, the causative agent is frequently unknown and broad-spectrum antibiotic therapy is required, such as:

- a third-generation cephalosporin, or a quinolone, plus an antistaphylococcal antibiotic, or
- an antipseudomonal penicillin plus an aminoglycoside.

Thereafter treatment may be tailored according to the results of investigations and the clinical response.

Depending on the clinical context and response to treatment, antifungal or antiviral therapies may be added. The management of *P. jirovecii* infection is detailed on page 395 and of invasive aspergillosis on page 697.

Mechanical ventilation increases the risk of nosocomial pneumonia and is associated with a greater mortality rate. It may be avoided by the early use of NIV. The delivery of NIV via a hood (p. 194) is as effective as a face mask and allows the patient to expectorate, communicate and feed.

Tuberculosis

Epidemiology

Tuberculosis (TB) is caused by infection with *Mycobacterium tuberculosis* (MTB), which is part of a complex of organisms including *M. bovis* (reservoir cattle) and *M. africanum* (reservoir human). The impact of TB on world health is significant; in 2006, there were an estimated 9.2 million new cases, 14.4 million prevalent cases and 1.5 million deaths attributable to TB. Furthermore, it is estimated that around one-third of the world's population has latent TB. The majority of cases occur in the world's poorest nations, who struggle to cover the costs associated with management and control programmes (Fig. 19.33). The resurgence of TB has been largely driven in Africa by HIV disease, and in the former Soviet Union and Baltic states by lack of appropriate health care exacerbated by social and political upheaval.

Pathology and pathogenesis

M. bovis infection arises from drinking non-sterilised milk from infected cows. *M. tuberculosis* is spread by the inhalation of aerosolised droplet nuclei from other infected patients. Once inhaled, the organisms lodge in the alveoli and initiate the recruitment of macrophages and lymphocytes. Macrophages undergo transformation into epithelioid and Langhans cells which aggregate with the lymphocytes to form the classical tuberculous granuloma (Fig. 19.34). Numerous granulomas aggregate to form a primary lesion or 'Ghon focus'

Fig. 19.34 Tuberculous granuloma. The normal lung tissue is lost and replaced by a mass of fibrous tissue with granulomatous inflammation characterised by the presence of large numbers of macrophages and multinucleate giant cells (small arrow). The central area of this focus of granulomatous inflammation shows caseous degeneration (large arrow).

(a pale yellow, caseous nodule, usually a few mm to 1–2 cm in diameter), which is characteristically situated in the periphery of the lung. Spread of organisms to the hilar lymph nodes is followed by a similar pathological reaction; the combination of a primary lesion and regional lymph nodes is referred to as the 'primary complex of Ranke'. Reparative processes encase the primary complex in a fibrous capsule limiting the spread of bacilli: so-called latent TB. If no further complications ensue, this lesion eventually calcifies and is clearly seen on a chest X-ray. However, lymphatic or haematogenous spread may occur before immunity is established, seeding secondary foci in other organs including lymph nodes, serous membranes, meninges, bones, liver, kidneys and lungs, which may lie dormant for years. The only clue that infection has occurred may be the appearance of a cell-mediated, delayed-type hypersensitivity reaction to tuberculin, demonstrated by tuberculin skin testing. If these reparative processes fail, primary progressive disease ensues (Fig. 19.35). The estimated

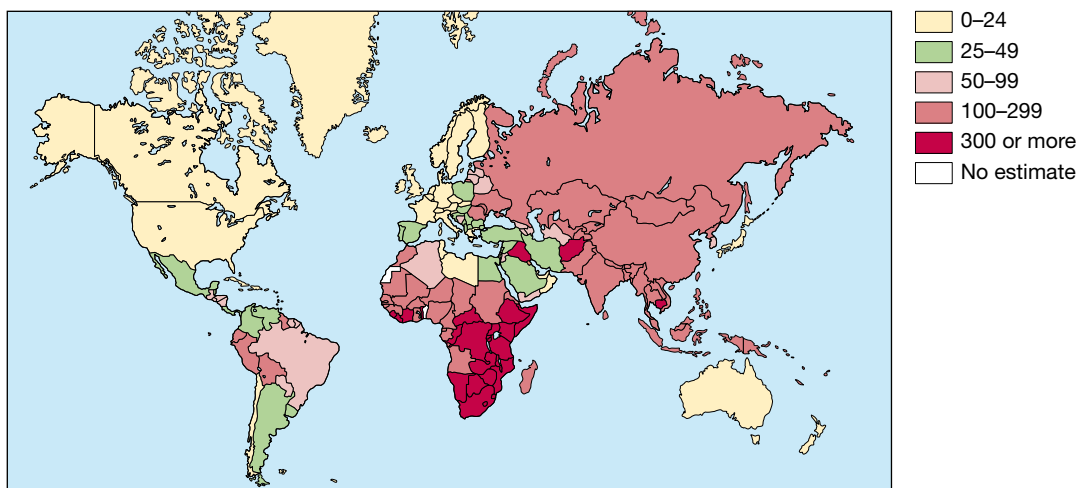

Fig. 19.33 World-wide incidence of tuberculosis. Estimated new cases (all forms) per 100 000 population (WHO).

Fig. 19.35 Primary pulmonary TB. (1) Spread from the primary focus to hilar and mediastinal lymph glands to form the 'primary complex', which in most cases heals spontaneously. (2) Direct extension of the primary focus—progressive pulmonary TB. (3) Spread to the pleura—tuberculous pleurisy and pleural effusion. (4) Blood-borne spread: *few bacilli*—pulmonary, skeletal, renal, genitourinary infection often months or years later; *massive spread*—miliary TB and meningitis.

lifetime risk of developing disease after primary infection is 10%, with roughly half of this risk occurring in the first 2 years after infection. Box 19.54 lists factors predisposing to TB and Box 19.55 shows the timetable of disease progression.

Clinical features: pulmonary disease

Primary pulmonary TB

Primary TB refers to the infection of a previously uninfected (tuberculin-negative) individual. A few patients develop a self-limiting febrile illness but clinical disease only occurs if there is a hypersensitivity reaction or progressive infection (Box 19.56). Progressive primary dis-

19.54 Factors increasing the risk of TB

Patient-related

- Age (children > young adults < elderly)
- First-generation immigrants from high-prevalence countries
- Close contacts of patients with smear-positive pulmonary TB
- Overcrowding (prisons, collective dormitories); homelessness (doss houses and hostels)
- Chest radiographic evidence of self-healed TB
- Primary infection < 1 year previously
- Smoking: cigarettes and bidis (Indian cigarettes made of tobacco wrapped in temburini leaves)

Associated diseases

- Immunosuppression: HIV, anti-TNF therapy, high-dose corticosteroids, cytotoxic agents
- Malignancy (especially lymphoma and leukaemia)
- Type 1 diabetes mellitus
- Chronic renal failure
- Silicosis
- Gastrointestinal disease associated with malnutrition (gastrectomy, jejuno-ileal bypass, cancer of the pancreas, malabsorption)
- Deficiency of vitamin D or A
- Recent measles: increases risk of child contracting TB

19.55 Timetable of TB

Time from infection	Manifestations
3–8 weeks	Primary complex, positive tuberculin skin test
3–6 months	Meningeal, miliary and pleural disease
Up to 3 years	Gastrointestinal, bone and joint, and lymph node disease
Around 8 years	Renal tract disease
From 3 years onwards	Post-primary disease due to reactivation or reinfection

19.56 Features of primary TB

Infection (4–8 weeks)	
<ul style="list-style-type: none"> • Influenza-like illness • Skin test conversion 	<ul style="list-style-type: none"> • Primary complex
Disease	
<ul style="list-style-type: none"> • Lymphadenopathy: hilar (often unilateral), paratracheal or mediastinal • Collapse (especially right middle lobe) • Consolidation (especially right middle lobe) 	<ul style="list-style-type: none"> • Obstructive emphysema • Cavitation (rare) • Pleural effusion • Endobronchial • Miliary • Meningitis • Pericarditis
Hypersensitivity	
<ul style="list-style-type: none"> • Erythema nodosum • Phlyctenular conjunctivitis 	<ul style="list-style-type: none"> • Dactylitis

ease may appear during the course of the initial illness or after a latent period of weeks or months.

Miliary TB

Blood-borne dissemination gives rise to miliary TB, which may present acutely but more frequently is characterised by 2–3 weeks of fever, night sweats, anorexia, weight loss and a dry cough. Hepatosplenomegaly may develop and the presence of a headache may indicate coexistent tuberculous meningitis. Auscultation of the chest is frequently normal, although with more advanced disease widespread crackles are evident. Fundoscopy may show choroidal tubercles. The classical appearances on chest X-ray are of fine 1–2 mm lesions ('millet seed') distributed throughout the lung fields, although occasionally the appearances are coarser. Anaemia and leucopenia reflect bone marrow involvement. 'Cryptic' miliary TB is an unusual presentation sometimes seen in old age (Box 19.57).

Post-primary pulmonary TB

Post-primary disease refers to exogenous ('new' infection) or endogenous (reactivation of a dormant primary lesion) infection in a person who has been sensitised by earlier exposure. It is most frequently pulmonary and characteristically occurs in the apex of an upper lobe where the oxygen tension favours survival of the strictly aerobic organism. The onset is usually insidious, developing slowly over several weeks. Systemic symptoms include fever, night sweats, malaise, and loss of appetite

19.57 Cryptic TB

- Age over 60 years
- Intermittent low-grade pyrexia of unknown origin
- Unexplained weight loss, general debility (hepatosplenomegaly in 25–50%)
- Normal chest X-ray
- Blood dyscrasias; leukaemoid reaction, pancytopenia
- Negative tuberculin skin test
- Confirmation by biopsy (granulomas and/or acid-fast bacilli demonstrated) of liver or bone marrow

19.58 Clinical presentations of pulmonary TB

- Chronic cough, often with haemoptysis
- Pyrexia of unknown origin
- Unresolved pneumonia
- Exudative pleural effusion
- Asymptomatic (diagnosis on chest X-ray)
- Weight loss, general debility
- Spontaneous pneumothorax

and weight, and are accompanied by progressive pulmonary symptoms (Box 19.58). Very occasionally, this form of TB may present with one of the complications listed in Box 19.59. Radiological changes include ill-defined opacification in one or both of the upper lobes, and as progression occurs, consolidation, collapse and cavitation develop to varying degrees (Fig. 19.36). It is often difficult to distinguish active from quiescent disease on radiological criteria alone, but the presence of a miliary pattern or cavitation favours active disease. In extensive disease, collapse may be marked and result in significant displacement of the trachea and mediastinum. Occasionally, a caseous lymph node may drain into an adjoining bronchus resulting in tuberculous pneumonia.

Clinical features: extrapulmonary disease

Extrapulmonary tuberculosis (Fig. 19.37) accounts for about 20% of cases in those who are HIV-negative but is more prevalent in HIV-positive individuals.

19.59 Chronic complications of pulmonary TB

Pulmonary

- | | |

Fig. 19.36 Chest X-ray: major manifestations and differential diagnosis of pulmonary TB. Less common manifestations include pneumothorax, ARDS (p. 187), cor pulmonale and localised emphysema.

Lymphadenitis

Lymph nodes are the most common extrapulmonary site of disease. Cervical and mediastinal glands are affected most frequently, followed by axillary and inguinal; more than one region may be involved. Disease may represent primary infection, spread from contiguous sites or reactivation. Supraclavicular lymphadenopathy is often the result of spread from mediastinal disease. The nodes are usually painless and initially mobile but become matted together with time. When caseation and liquefaction occur, the swelling becomes fluctuant and may discharge through the skin with the formation of a 'collar-stud' abscess and sinus formation. Approximately half of cases fail to show any constitutional features such as fevers or night sweats. The tuberculin test is usually strongly positive. During or after treatment, paradoxical enlargement, development of new nodes and suppuration may all occur but without evidence of continued infection; rarely, surgical excision is necessary. In non-immigrant children in the UK, most mycobacterial lymphadenitis is caused by opportunistic mycobacteria, especially of the *M. avium* complex.

Gastrointestinal disease

TB can affect any part of the bowel and patients may present with a wide range of symptoms and signs (see Fig. 19.37). Upper gastrointestinal tract involvement is rare and is usually an unexpected histological finding in an endoscopic or laparotomy specimen. Ileocaecal disease accounts for approximately half of abdominal TB

Fig. 19.37 Systemic presentations of extrapulmonary TB.

cases. Fever, night sweats, anorexia and weight loss are usually prominent and a right iliac fossa mass may be palpable. Up to 30% of cases present with an acute abdomen. Ultrasound or CT may reveal thickened bowel wall, abdominal lymphadenopathy, mesenteric thickening or ascites. Barium enema and small bowel enema reveal narrowing, shortening and distortion of the bowel with caecal involvement predominating. Diagnosis rests on obtaining histology by either colonoscopy or mini-laparotomy. The main differential diagnosis is Crohn's disease (p. 895). Tuberculous peritonitis is characterised by abdominal distension, pain and constitutional symptoms. The ascitic fluid is exudative and cellular with a predominance of lymphocytes. Laparoscopy reveals multiple white 'tubercles' over the peritoneal and omental surfaces. Low-grade hepatic dysfunction is common in miliary disease when biopsy reveals granulomas. Occasionally, patients may be frankly icteric with a mixed hepatic/cholestatic picture.

Pericardial disease

Disease occurs in two forms: pericardial effusion and constrictive pericarditis (p. 639). Fever and night sweats are rarely prominent and the presentation is usually insidious with breathlessness and abdominal swelling. Coexistent pulmonary disease is very rare, with the exception of pleural effusion. Pulsus paradoxus, a raised JVP, hepatomegaly, prominent ascites and peripheral oedema are common to both types. Pericardial effusion is associated with increased pericardial dullness and a

globular enlarged heart on chest X-ray. Constriction is associated with a raised JVP, an early third heart sound and, occasionally, atrial fibrillation; pericardial calcification occurs in around 25% of cases. Diagnosis is on clinical, radiological and echocardiographic grounds (p. 639). The effusion is frequently blood-stained. Open pericardial biopsy can be performed where there is diagnostic uncertainty. The addition of corticosteroids to antituberculosis treatment has been shown to be beneficial for both forms of pericardial disease.

Central nervous system disease

Meningeal disease represents the most important form of central nervous system TB (see Fig. 19.37). Unrecognised and untreated, it is rapidly fatal. Even when appropriate treatment is prescribed, mortality rates of 30% have been reported and survivors may be left with neurological sequelae. Clinical features, investigations and management are described on page 1208.

Bone and joint disease

The spine is the most common site for bony TB (Pott's disease), which usually presents with chronic back pain and typically involves the lower thoracic and lumbar spine (see Fig. 19.37). The infection starts as a discitis and then spreads along the spinal ligaments to involve the adjacent anterior vertebral bodies, causing angulation of the vertebrae with subsequent kyphosis. Paravertebral and psoas abscess formation is common and the disease may present with a large (cold) abscess in the inguinal

region. CT and/or MRI are valuable in gauging the extent of disease, the amount of cord compression, and the site for needle biopsy or open exploration if required. The major differential diagnosis is malignancy, which tends to affect the vertebral body and leave the disc intact. Important complications include spinal instability or cord compression.

TB can affect any joint, but most frequently involves the hip or knee. Presentation is usually insidious with pain and swelling; fever and night sweats are uncommon. Radiological changes are often non-specific, but as disease progresses, reduction in joint space and erosions appear. Poncet's arthropathy refers to an immunologically mediated polyarthritides that usually resolves within 2 months of starting treatment.

Genitourinary disease

Fever and night sweats are rare with renal tract TB and patients are often only mildly symptomatic for many years. Haematuria, frequency and dysuria are often present, with sterile pyuria found on urine microscopy and culture. In women, infertility from endometritis, or pelvic pain and swelling from salpingitis or a tubo-ovarian abscess occur occasionally. In men, genitourinary TB may present as epididymitis or prostatitis.

Diagnosis

The presence of an otherwise unexplained cough for more than 2–3 weeks, particularly in an area where TB is highly prevalent, or typical chest X-ray changes should prompt further investigation (Box 19.60). Direct microscopy of sputum is the most important first step. The probability of detecting acid-fast bacilli is proportional

Fig. 19.38 Positive Ziehl–Neelsen stain. Mycobacteria retain the red carbol fuchsin stain despite washing with acid and alcohol.

to the bacillary burden in the sputum (typically positive when 5000–10 000 organisms are present). By virtue of their substantial lipid-rich wall, tuberculous bacilli are difficult to stain. The most effective techniques are the Ziehl–Neelsen and rhodamine–auramine (Fig. 19.38) stains. The latter causes the tuberculous bacilli to fluoresce against a dark background and is easier to use when numerous specimens need to be examined; however, it is more complex and expensive, limiting applicability in resource-poor regions.

A positive smear is sufficient for the presumptive diagnosis of TB but definitive diagnosis requires culture. Smear-negative sputum should also be cultured, as only 10–100 viable organisms are required for sputum to be culture-positive. A diagnosis of smear-negative TB may be made in advance of culture if the chest X-ray appearances are typical of TB and there is no response to a broad-spectrum antibiotic.

MTB grows slowly and may take between 4 and 6 weeks to appear on solid medium such as Löwenstein–Jensen or Middlebrook. Faster growth (1–3 weeks) occurs in liquid media such as the radioactive BACTEC system or the non-radiometric mycobacteria growth indicator tube (MGIT). The BACTEC method is commonly used in developed nations and detects mycobacterial growth by measuring the liberation of $^{14}\text{CO}_2$, following metabolism of ^{14}C -labelled substrate present in the medium. New strategies for the rapid confirmation of TB at low cost are being developed; these include the nucleic acid amplification test (NAT), designed to amplify nucleic acid regions specific to MTB such as IS6110, and the MPB64 skin patch test, in which immunogenic antigen detects active but not latent TB, and has the potential to provide a simple, non-invasive test which does not require a laboratory or highly skilled personnel.

Drug sensitivity testing is particularly important in those with a previous history of TB, treatment failure or chronic disease, those who are resident in or have visited an area of high prevalence of resistance, or those who are HIV-positive. The detection of rifampicin resistance, using molecular tools to test for the presence of the *rpo* gene currently associated with around 95% of rifampicin-resistant cases, is important as the drug forms the cornerstone of 6-month chemotherapy. Rapid tests for other forms of drug resistance are under development. If a cluster of cases suggests a common source, confirmation may be sought by fingerprinting of isolates

 19.60 Diagnosis of TB
Specimens required
Pulmonary <ul style="list-style-type: none"> • Sputum* (induced with nebulised hypertonic saline if not expectorating) • Bronchoscopy with washings or BAL • Gastric washing* (mainly used for children)
Extrapulmonary <ul style="list-style-type: none"> • Fluid examination (cerebrospinal, ascitic, pleural, pericardial, joint): yield classically very low • Tissue biopsy (from affected site); also bone marrow/liver may be diagnostic in patients with disseminated disease
Diagnostic tests
<ul style="list-style-type: none"> • Circumstantial (ESR, CRP, anaemia etc.) • Tuberculin skin test (low sensitivity/specificity; useful only in primary or deep-seated infection) • Stain <ul style="list-style-type: none"> • Ziehl–Neelsen • Auramine fluorescence • Nucleic acid amplification • Culture <ul style="list-style-type: none"> • Solid media (Löwenstein–Jensen, Middlebrook) • Liquid media (e.g. BACTEC or MGIT) • Response to empirical antituberculous drugs (usually seen after 5–10 days)
<p>*At least 2 but preferably 3, including an early morning sample. (MGIT = mycobacteria growth indicator tube)</p>

with restriction-fragment length polymorphism (RFLP) or DNA amplification.

The diagnosis of extrapulmonary TB can be more challenging. There are generally fewer organisms (particularly in meningeal or pleural fluid), so culture or histopathological examination of tissue is more important. In the presence of HIV, however, examination of sputum may still be useful, as subclinical pulmonary disease is common.

Management

Chemotherapy

A variety of highly effective short-course regimens are available; choice depends on local health resources and infrastructure (Box 19.61). They are based on the principle of an initial intensive phase (which rapidly reduces the bacterial population), followed by a continuation phase to destroy any remaining bacteria. Treatment should be commenced immediately in any patient who is smear-positive, or who is smear-negative but with typical chest X-ray changes and no response to standard antibiotics.

Quadruple therapy has become standard in the UK, although ethambutol may be omitted under certain circumstances. Fixed-dose tablets combining two or three drugs are generally favoured: for example, Rifater (rifampicin, isoniazid and pyrazinamide) daily for 2 months, followed by 4 months of Rifinah (rifampicin and isoniazid). Streptomycin is rarely used in the UK, but is an important component of short-course treatment regimens in developing nations. Six months of therapy is appropriate for all patients with new-onset, uncomplicated pulmonary disease. However, 9–12 months of therapy should be considered if the patient is HIV-positive, or if drug intolerance occurs and a second-line agent is substituted. Meningitis should be treated for a minimum of 12 months. Pyridoxine should be prescribed in pregnant women and malnourished patients to reduce the risk of peripheral neuropathy with isoniazid. Where drug resistance is not anticipated, patients can be assumed to be non-infectious after 2 weeks of appropriate therapy.

Most patients can be treated at home. Admission to a hospital unit with appropriate isolation facilities should be considered where there is uncertainty about the diagnosis, intolerance of medication, questionable compliance, adverse social conditions or a significant risk of multidrug-resistant TB (MDR-TB: culture-positive after 2 months on treatment, or contact with known MDR-TB).

In choosing a suitable drug regimen, underlying comorbidity (renal and hepatic dysfunction, eye disease, peripheral neuropathy and HIV status), as well as the potential for drug interactions, must be considered. Baseline liver function and regular monitoring are important for patients treated with standard therapy including rifampicin, isoniazid and pyrazinamide, as all of these agents are potentially hepatotoxic. Mild asymptomatic increases in transaminases are common but serious liver damage is rare. Patients treated with rifampicin should be advised that their urine, tears and other secretions will develop a bright orange/red coloration, and women taking the oral contraceptive pill must be warned that its efficacy will be reduced and alternative contraception may be necessary. Ethambutol should be used with caution in patients with renal failure, with appropriate dose reduction and monitoring of drug levels. Adverse drug reactions occur in about 10% of patients, but are significantly more common in the presence of HIV co-infection (Box 19.62).

Corticosteroids reduce inflammation and limit tissue damage, and are currently recommended when treating pericardial or meningeal disease, and in children with endobronchial disease. They may confer benefit in TB of the ureter, pleural effusions and extensive pulmonary disease, and can suppress hypersensitivity drug reactions. Surgery is still occasionally required (e.g. for massive haemoptysis, loculated empyema, constrictive pericarditis, lymph node suppuration, spinal disease with cord compression), but usually only after a full course of antituberculosis treatment.

19.61 Treatment of TB (World Health Organization recommendations)

	Category of TB	Initial phase*	Continuation phase
1	New cases of smear-positive pulmonary TB Severe extrapulmonary TB Severe smear-negative pulmonary TB Severe concomitant HIV disease	2 months H ₃ R ₃ Z ₃ E ₃ or 2 months H ₃ R ₃ Z ₃ S ₃ 2 months HRZE or 2 months HRZS	4 months H ₃ R ₃ 4 months HR 6 months HE†
2§	Previously treated smear-positive pulmonary TB Relapse Treatment failure Treatment after default	2 months H ₃ R ₃ Z ₃ E ₃ or 1 month H ₃ R ₃ Z ₃ E 2 months HRZES or 1 month HRZE	5 months H ₃ R ₃ E ₃ 5 months HRE
3‡	New cases of smear-negative pulmonary TB Less severe extrapulmonary TB	2 months H ₃ R ₃ Z ₃ E ₃ 2 months HRZE	4 months H ₃ R ₃ 4 months HR 6 months HE†

*The subscript after the letter refers to the number of doses per week; daily has no subscript. (H = isoniazid; R = rifampicin; Z = pyrazinamide; E = ethambutol; S = streptomycin)

†A continuation phase of 6 months HE has a higher failure and relapse rate than a continuation phase of 4 months of HR but can be used for mobile patients and those with a limited access to health services; the HE regimen can also be used concomitantly with anti-retroviral treatment of HIV-infected patients.

§Treatment should be guided by sensitivity testing.

‡Ethambutol may be omitted in the initial phase of category 3 patients if disease is non-cavitary, smear-negative pulmonary TB, or if patients are known to have a drug-susceptible organism, or for young children with primary TB.

19.62 Main adverse reactions of first-line antituberculous drugs

	Isoniazid	Rifampicin	Pyrazinamide	Streptomycin	Ethambutol
Mode of action	Cell wall synthesis	DNA transcription	Unknown	Protein synthesis	Cell wall synthesis
Major adverse reactions	Peripheral neuropathy ¹ Hepatitis ² Rash	Febrile reactions Hepatitis Rash Gastrointestinal disturbance	Hepatitis Gastrointestinal disturbance Hyperuricaemia	8th nerve damage Rash	Retrobulbar neuritis ³ Arthralgia
Less common adverse reactions	Lupoid reactions Seizures Psychoses	Interstitial nephritis Thrombocytopenia Haemolytic anaemia	Rash Photosensitisation Gout	Nephrotoxicity Agranulocytosis	Peripheral neuropathy Rash

¹The risk of peripheral neuropathy may be reduced by prescribing pyridoxine.
²Hepatitis is more common in patients with a slow acetylator status and in alcoholics.
³Reduced visual acuity and colour vision may be reported with higher doses and are usually reversible.

The effectiveness of therapy for pulmonary TB may be judged by a further sputum smear at 2 months and at 5 months. A positive sputum smear at 5 months defines treatment failure. Extrapulmonary TB must be assessed clinically or radiographically as appropriate.

Control and prevention

The WHO is committed to reducing the incidence of TB by 2015. Important components of this goal include supporting the development of laboratory and health-care services to improve detection and treatment of active and latent TB.

Detection of latent TB

Contact tracing is a legal requirement in many countries. It has the potential to identify the probable index case, other cases infected by the same index patient (with or without evidence of disease), and close contacts who should receive BCG vaccination (see below) or chemotherapy. Approximately 10–20% of close contacts of patients with smear-positive pulmonary TB and 2–5% of those with smear-negative, culture-positive disease have evidence of TB infection.

Cases are commonly identified using the tuberculin skin test (Box 19.63 and Fig. 19.39). An otherwise asymptomatic contact with a positive tuberculin skin test but a normal chest X-ray may be treated with chemoprophylaxis to prevent infection progressing to clinical disease. Chemoprophylaxis is also recommended for children aged less than 16 years identified during contact tracing to have a strongly positive tuberculin test, children aged less than 2 years in close contact with smear-positive pulmonary disease, those in whom recent tuberculin conversion has been confirmed, and babies of mothers with pulmonary TB. It should also be considered for HIV-infected close contacts of a patient with smear-positive disease. Rifampicin plus isoniazid for 3 months or isoniazid for 6 months is effective.

Tuberculin skin testing may be associated with false-positive reactions in those who have had a BCG vaccination and in areas where exposure to non-tuberculous mycobacteria is high. These limitations may be overcome by employing interferon-gamma release assays (IGRAs). These tests measure the release of IFN- γ from sensitised T cells in response to antigens such as early secreted

19.63 Skin testing in TB: tests using purified protein derivative (PPD)

Heaf test

- Read at 3–7 days
- Multipuncture method
 - Grade 1: 4–6 papules
 - Grade 2: Confluent papules forming ring
 - Grade 3: Central induration
 - Grade 4: > 10 mm induration

Mantoux test

- Read at 2–4 days
- Using 10 tuberculin units
 - Positive when induration 5–14 mm (equivalent to Heaf grade 2) and > 15 mm (Heaf grade 3–4)

False negatives

- Severe TB (25% of cases negative)
- Newborn and elderly
- HIV (if CD4 count < 200 cells/mL)
- Malnutrition
- Recent infection (e.g. measles) or immunisation
- Immunosuppressive drugs
- Malignancy
- Sarcoidosis

antigenic target (ESAT)-6 or culture filtrate protein (CFP)-10 that are encoded by genes specific to the MTB and are not shared with BCG or opportunistic mycobacteria. The greater specificity of these tests, combined with the logistical convenience of one blood test, as opposed to two visits for skin testing, suggests that IGRAs will replace the tuberculin skin test in low-incidence, high-income countries.

Directly observed therapy (DOT)

Poor adherence to therapy is a major factor in prolonged infectious illness, risk of relapse and the emergence of drug resistance. DOT involves the supervised administration of therapy thrice weekly and improves adherence. It has become an important control strategy in resource-poor nations. In the UK, it is currently only recommended for patients thought unlikely to be adherent to therapy: those who are homeless, alcohol or drug users, drifters, those with serious mental illness and those with a history of non-compliance.

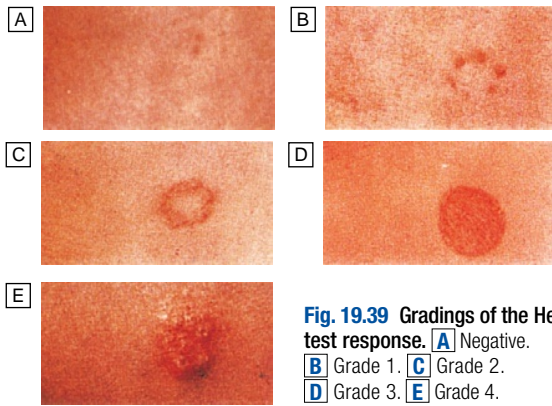

Fig. 19.39 Grading of the Heat test response. **A** Negative. **B** Grade 1. **C** Grade 2. **D** Grade 3. **E** Grade 4.

TB and HIV/AIDS

The close links between HIV and TB, particularly in sub-Saharan Africa, and the potential for both diseases to overwhelm health-care funding in resource-poor nations have been recognised with the promotion of programmes that link detection and treatment of TB with detection and treatment of HIV. It is recommended that all patients with TB should be counselled and tested for HIV disease. Mortality is high and TB is a leading cause of death in HIV patients. Full discussion of its presentation and management is given on pages 396–397.

Drug-resistant TB

Drug-resistant TB is defined by the presence of resistance to any first-line agent. Multidrug-resistant (MDR) TB is defined by resistance to at least rifampicin and isoniazid, with or without other drug resistance. Extensively drug-resistant (XDR) TB is defined by resistance to at least rifampicin and isoniazid, in addition to any quinolone and at least one injectable second-line agent. The prevalence of MDR-TB is rising, particularly in the former Soviet Union, Central Asia and Africa. It is more common in those with a prior history of TB, particularly if treatment has been inadequate, and those with HIV infection (Box 19.64). Diagnosis is challenging, especially in developing countries, and although cure may be possible, it requires prolonged treatment with less effective, more toxic and more expensive therapies. Mortality rate from MDR-TB is high and that from XDR-TB higher still.

Vaccines

BCG (the Calmette-Guérin bacillus), a live attenuated vaccine derived from *M. bovis*, is the most established TB vaccine. It is administered by intradermal injection and is highly immunogenic. BCG appears to be effective in preventing disseminated disease, including tuberculous meningitis, in children, but its efficacy in adults is incon-

sistent and new vaccines are urgently needed. Current vaccination policies vary world-wide according to incidence and health-care resources, but usually target children and other high-risk individuals. BCG is very safe with the occasional complication of local abscess formation. It should not be administered to those who are immunocompromised (e.g. by HIV) or pregnant.

Prognosis

Following successful completion of chemotherapy, cure should be anticipated in the majority of patients. There is a small (< 5%) and unavoidable risk of relapse, which usually occurs within 5 months and has the same drug susceptibility. In the absence of treatment, a patient with smear-positive TB will remain infectious for an average of 2 years; in 1 year, 25% of untreated cases will die. Death is more likely in those who are smear-positive and those who smoke. A few patients die unexpectedly soon after commencing therapy and it is possible that some have subclinical hypoadrenalism that is unmasked by a rifampicin-induced increase in steroid metabolism. HIV-positive patients have higher mortality rates and a modestly increased risk of relapse.

Opportunistic mycobacterial infection

Other species of environmental mycobacteria (termed 'atypical') may cause human disease (Box 19.65). The sites commonly involved are the lungs, lymph nodes, skin and soft tissues. The most widely recognised *M. avium* complex (MAC) is well described in severe HIV disease (CD4 count < 50 cells/mL; p. 396); however, several others (including MAC) colonise and/or infect apparently immunocompetent patients with chronic lung diseases such as COPD, bronchiectasis, pneumoconiosis, old TB, or cystic fibrosis. The clinical presentation varies from a relatively indolent course in some, to an aggressive course characterised by cavitary or nodular disease in others. Radiological appearances may be similar to classical TB, but in patients with bronchiectasis, opportunistic infection may present

19.65 Site-specific opportunistic mycobacterial disease

• MAC (HIV-associated)	• <i>M. fortuitum</i>
• <i>M. haemophilum</i>	• <i>M. chelonae</i>
• <i>M. genavense</i>	• BCG

(MAC = Mycobacterium avium complex—*M. scrofulaceum*, *M. intracellulare* and *M. avium*)

19.64 Factors contributing to emergence of drug-resistant TB

- Drug shortages
- Poor-quality drugs
- Lack of appropriate supervision
- Transmission of drug-resistant strains
- Prior anti-tuberculosis treatment
- Treatment failure (smear-positive at 5 months)

with lower zone nodules. The most commonly reported organisms include *M. kansasii*, *M. malmoense*, *M. xenopi* and *M. abscessus*, but geographical variation is marked. *M. abscessus* and *M. fortuitum* grow rapidly, but the majority grow slowly. More rapid discriminating systems are under development, including DNA probes, high-performance liquid chromatography (HPLC), PCR restriction enzyme analysis (PRA) and 16S rRNA gene sequence analysis. With the exception of *M. kansasii*, drug sensitivity testing is usually unhelpful in predicting treatment response. There is no requirement for notification as the organisms are not normally communicable.

Respiratory diseases caused by fungi

The majority of fungi encountered by humans are harmless saprophytes, but in certain circumstances (Box 19.66) some species may infect human tissue, promoting damaging allergic reactions or producing toxins. 'Mycosis' is the term used to describe disease caused by fungal infection.

Aspergillus spp

Most cases of bronchopulmonary aspergillosis are caused by *Aspergillus fumigatus*, but other members of the genus (*A. terreus*, *A. flavus* and *A. niger*) occasionally cause disease. The conditions associated with *Aspergillus* species are listed in Box 19.67.

Allergic bronchopulmonary aspergillosis (ABPA)

ABPA is a hypersensitivity reaction to germinating fungal spores, which may complicate asthma and cystic fibrosis. It is a recognised cause of pulmonary eosinophilia (p. 715). The prevalence of ABPA is approximately 1–2% in asthma and 5–10% in CF. A variety of HLA antigens convey either an increased or a decreased risk of developing the condition, suggesting that genetic susceptibility is important.

19.66 Factors predisposing to fungal disease

Systemic factors

- Metabolic disorders: diabetes mellitus
- Chronic alcoholism
- HIV and AIDS
- Corticosteroids and other immunosuppressant medication
- Radiotherapy

Local factors

- Tissue damage by suppurative or necrosis
- Alteration of normal bacterial flora by antibiotic therapy

19.67 Classification of bronchopulmonary aspergillosis

- Allergic bronchopulmonary aspergillosis (asthmatic pulmonary eosinophilia)
- Extrinsic allergic alveolitis (*Aspergillus clavatus*)
- Intracavitary aspergilloma
- Invasive pulmonary aspergillosis
- Chronic and subacute pulmonary aspergillosis

19.68 Features of allergic bronchopulmonary aspergillosis

- Asthma (in the majority of cases)
- Proximal bronchiectasis (inner two-thirds of chest CT field)
- Positive skin test to an extract of *A. fumigatus*
- Elevated total serum IgE > 417 KU/L or 1000 ng/mL
- Elevated serum IgE (*A. fumigatus*) or IgG (*A. fumigatus*)
- Peripheral blood eosinophilia > $0.5 \times 10^9/L$
- Presence or history of chest X-ray abnormalities
- Fungal hyphae of *A. fumigatus* on microscopic examination of sputum

Clinical features and investigations

Clinical features depend on the stage of disease. Common early manifestations include fever, breathlessness, cough productive of bronchial casts and worsening of asthmatic symptoms. The appearance of radiographic infiltrates may cause ABPA to be mistaken for pneumonia, but the diagnosis may also be suggested by abnormalities such as segmented or lobar collapse on chest X-rays of patients whose asthmatic symptoms are stable. Diagnostic features are shown in Box 19.68. If bronchiectasis develops, its symptoms and complications often overshadow those of asthma.

Management

ABPA is generally an indication for regular low-dose oral corticosteroids (prednisolone 7.5–10 mg daily) to suppress the immunopathological responses and prevent progress to tissue damage. In some patients, itraconazole (400 mg/day) allows a reduction in oral steroids; a 4-month trial is usually recommended to assess its efficacy. The use of specific anti-IgE monoclonal antibodies is under consideration. Exacerbations, particularly when associated with new chest X-ray changes, should be treated promptly with prednisolone 40–60 mg daily and physiotherapy. If persistent lobar collapse occurs, bronchoscopy (usually under general anaesthetic) should be performed to remove impacted mucus and ensure prompt reinflation.

Aspergilloma

Inhaled *Aspergillus* may lodge and germinate in areas of damaged lung tissue forming a fungal ball or aspergilloma. The upper lobes are most frequently involved, and fungal balls readily form in tuberculous cavities (Fig. 19.40). Less common causes include damage from a lung abscess cavity, a bronchiectatic space, pulmonary infarct,

Fig. 19.40 CT of aspergilloma in the left upper lobe. The rounded fungal ball is separated from the wall of the cavity by a 'halo' of air.

sarcoid, ankylosing spondylitis or a cavitated tumour. The presence of multiple aspergilloma cavities in a diseased area of lung has been termed 'complex aspergilloma' (see below).

Clinical features and diagnosis

Simple aspergillomas are often asymptomatic, and are identified incidentally on chest X-ray. However, they may cause recurrent haemoptysis which can be severe and life-threatening.

The fungal ball produces a tumour-like opacity on X-ray, but can be distinguished from a carcinoma by the presence of a crescent of air between the fungal ball and the upper wall of the cavity. HRCT is more sensitive (see Fig. 19.40). Elevated serum precipitins to *A. fumigatus* are found in virtually all patients. Sputum microscopy typically demonstrates scanty hyphal fragments, and is usually positive on culture. Less than half exhibit skin hypersensitivity to extracts of *A. fumigatus*. Rarely, other filamentous fungi can cause intracavitary mycetoma and are identified by culture; antibody tests are unavailable.

Management

Asymptomatic cases do not require treatment. Specific antifungal therapy is of no value and steroids may predispose to invasion. Aspergillomas complicated by haemoptysis should be excised surgically. In those unfit for surgery, palliative procedures range from local instillation of amphotericin B to bronchial artery embolisation. The latter has also been used to control haemoptysis as a prelude to definitive surgery.

Invasive pulmonary aspergillosis (IPA)

IPA is most commonly a complication of profound neutropenia caused by drugs (especially immunosuppressants) and/or disease (Box 19.69).

Clinical features and diagnosis

Acute IPA causes a severe necrotising pneumonia, and must be considered in any immunocompromised patient who develops fever, new respiratory symptoms (particularly pleural pain or haemoptysis) or a pleural rub. Invasion of pulmonary vessels causes thrombosis and infarction, and systemic spread may occur to the brain, heart, kidneys and other organs. Tracheobronchial aspergillosis complicates lung transplant and presents with large airway invasion, fungal plaques and ulceration.

HRCT characteristically shows macronodules (usually ≥ 1 cm), which may be surrounded by a 'halo' of low attenuation if captured early (< 5 days). Culture or histopathological evidence of *Aspergillus* in diseased

tissue gives a definitive diagnosis, but the majority of patients are too ill for invasive tests such as bronchoscopy or lung biopsy. Other investigations include detection of *Aspergillus* cell wall components (galactomannan and β -1,3-glucan) in blood or BAL fluid, and *Aspergillus* DNA by PCR. Diagnosis is most often inferred from a combination of features (Box 19.70).

Management and prevention

IPA carries a high mortality rate, especially if treatment is delayed. The treatment of choice is voriconazole. Second-line agents include lipid-associated amphotericin, caspofungin or posaconazole. Response is assessed both clinically and radiologically. Recovery is dependent on immune reconstitution, which may be accompanied by enlargement and/or cavitation of pulmonary nodules.

Patients at risk of *Aspergillus* (and other fungal infections) should be nursed in rooms with high-efficiency particulate air (HEPA) filters and laminar airflow. In

19.70 Criteria for the diagnosis of probable invasive pulmonary aspergillosis¹

Host factors

- Recent history of neutropenia ($< 0.5 \times 10^9/L$ for ≥ 10 days) temporally related to the onset of fungal disease
- Recipient of allogeneic stem cell transplant
- Prolonged use of corticosteroids (average minimum 0.3 mg/kg/day prednisolone or equivalent) for > 3 weeks (excludes ABPA)
- Treatment with other recognised T-cell immune suppressants such as ciclosporin, TNF- α blockers, specific monoclonal antibodies (e.g. alemtuzumab) or nucleoside analogues during the last 90 days
- Inherited severe immune deficiency, e.g. chronic granulomatous disease or severe combined immune deficiency (p. 79)

Clinical criteria²

- The presence of one of the following three imaging signs on CT:
 1. Dense, well-circumscribed lesion(s) with or without a halo sign
 2. Air crescent sign
 3. Cavity

Tracheobronchitis

- Tracheobronchial ulceration, nodule, pseudomembrane, plaque or eschar seen on bronchoscopy

Mycological criteria

- Mould in sputum, BAL fluid or bronchial brush, indicated by one of the following:
 1. Recovery of fungal elements indicating a mould of *Aspergillus*
 2. Recovery by culture of a mould of *Aspergillus*
- Indirect tests (detection of antigen or cell wall constituents)
 1. Galactomannan antigen in plasma, serum or BAL fluid
 2. β -1,3-glucan detected in serum (detects other species of fungi as well as *Aspergillus*)³

¹Adapted from European Organisation for Research and Treatment of Cancer/ Mycoses Study Group.

²Must be consistent with the mycological findings, if any, and temporally related to current episode.

³May be useful as a preliminary screening tool for invasive aspergillosis.

19.69 Risk factors for invasive aspergillosis

- Neutropenia: risk related to duration and degree
- Solid organ or allogeneic stem cell transplantation
- Prolonged high dose corticosteroid therapy
- Leukaemia and other haematological malignancies
- Cytotoxic chemotherapy
- Advanced HIV disease
- Severe COPD
- Critically ill patients on intensive care units
- Chronic granulomatous disease

areas with high spore counts, patients may be advised to wear a mask if venturing outside their hospital room. Posaconazole (200 mg 8-hourly) or itraconazole (200 mg/day) may be prescribed for primary prophylaxis, and patients with a history of definite or probable IPA should be considered for secondary prophylaxis before further immunosuppression.

Chronic and subacute pulmonary aspergillosis

Chronic pulmonary aspergillosis (CPA) is an indolent, non-invasive complication of chronic lung disease such as COPD, tuberculosis/non-tuberculous mycobacterial disease or fibrotic conditions; it may be associated with malnutrition, diabetes or liver disease, and co-infection with non-tuberculous mycobacteria. CPA may mimic TB, resulting in its delayed diagnosis. Features include cough (with or without haemoptysis), weight loss, anorexia and fatigue over months or years, with associated fever, night sweats, and an elevated CRP and ESR. Radiological features include thick-walled cavities (predominantly apical), pulmonary infiltrates, pleural thickening and, later, fibrosis. The terms chronic necrotising (CNPA), cavitary ('complex aspergilloma') and fibrosing pulmonary aspergillosis have been applied, depending on predominant features. There is overlap between CNPA, 'subacute' and 'semi-invasive' aspergillosis. Subacute aspergillosis/CNPA is an increasingly recognised complication in patients in intensive care, especially in the presence of pre-existing COPD. Diagnosis is achieved by a combination of radiological examination, histopathology, isolation of the fungus in sputum and detection of *Aspergillus* IgG in serum. Disease is usually treated with prolonged/indefinite courses of itraconazole or voriconazole, but cure is unusual. The most frequent pattern is chronic relapse/remission with gradual, inexorable deterioration. Surgical intervention is fraught with complications and should be avoided.

Other fungal infections

Pulmonary mucormycosis and endemic mycoses

Mucormycosis (p. 379) may present with a pulmonary syndrome indistinguishable clinically from acute IPA. Diagnosis relies on histopathology (where available) and/or culture of the organism from diseased tissue. The principles of treatment are as for other forms of mucormycosis: correction of predisposing factors, antifungal therapy with high-dose lipid-amphotericin B or posaconazole, and surgical débridement.

Histoplasmosis, coccidioidomycosis, blastomycosis and cryptococcosis

These are discussed on pages 379–381.

TUMOURS OF THE BRONCHUS AND LUNG

Lung cancer is the most common cause of death from cancer world-wide, causing 1.4 million deaths per year. Tobacco use is the major preventable cause; however,

19.71 The burden of lung cancer

- Strikes 900 000 men and 330 000 women each year
- Accounts for 18% of all cancer deaths
- More than a threefold increase in deaths since 1950
- Rates rising in women: female lung cancer deaths outnumber male in some Nordic countries
- Has overtaken breast cancer in several countries, making it the most common cause of cancer death in men and women

just as tobacco use and cancer rates are falling in some developed countries, both smoking and lung cancer are rising in Eastern Europe and in many developing countries (Box 19.71). The great majority of tumours in the lung are primary bronchial carcinomas, and in contrast to many other tumours, the prognosis remains poor, with fewer than 30% of patients surviving at 1 year and 6–8 % at 5 years. Carcinomas of many other organs, as well as osteogenic and other sarcomas, may cause metastatic pulmonary deposits.

Primary tumours of the lung

Aetiology

Cigarette smoking is by far the most important cause of lung cancer. It is thought to be directly responsible for at least 90% of lung carcinomas, the risk being proportional to the amount smoked and to the tar content of cigarettes. The death rate from the disease in heavy smokers is 40 times that in non-smokers. Risk falls slowly after smoking cessation, but remains above that in non-smokers for many years. It is estimated that 1 in 2 smokers dies from a smoking-related disease, about half in middle age. The effect of 'passive' smoking is more difficult to quantify but is currently thought to be a factor in 5% of all lung cancer deaths. Exposure to naturally occurring radon is another risk. The incidence of lung cancer is slightly higher in urban than in rural dwellers, which may reflect differences in atmospheric pollution (including tobacco smoke) or occupation, since a number of industrial materials (e.g. asbestos, silica, beryllium, cadmium and chromium) are associated with lung cancer. In recent years, the strong link between smoking and ill health has led many Western governments to legislate against smoking in public places, and smoking prevalence and some smoking-related diseases are already declining in these countries (pp. 98–99).

Bronchial carcinoma

The incidence of bronchial carcinoma increased dramatically during the 20th century as a direct result of the tobacco epidemic (Fig. 19.41). In women, smoking prevalence and deaths from lung cancer continue to increase, and more women now die of lung cancer than breast cancer in the USA and the UK.

Pathology

Bronchial carcinomas arise from the bronchial epithelium or mucous glands. The common cell types are listed in Box 19.72. When the tumour occurs in a large bronchus, symptoms arise early, but tumours originating in a peripheral bronchus can grow very large

Males

Rate per 100 000

**Females**

Rate per 100 000

Fig. 19.41 Mortality trends from lung cancer in England and Wales, 1950–2004 by age and year of death. **A** Males. **B** Females. Note the decline in mortality from lung cancer in men towards the end of this period, reflecting a change in smoking habit.

i**19.72 Common cell types in bronchial carcinoma**

Cell type	%
Squamous	35
Adenocarcinoma	30
Small-cell	20
Large-cell	15

without producing symptoms, resulting in delayed diagnosis. Peripheral squamous tumours may undergo central necrosis and cavitation, and may resemble a lung abscess on X-ray (Fig. 19.42). Bronchial carcinoma may involve the pleura either directly or by lymphatic spread and may extend into the chest wall, invading the intercostal nerves or the brachial plexus and causing pain. Lymphatic spread to mediastinal and supraclavicular lymph nodes frequently occurs prior to diagnosis. Blood-borne metastases occur most commonly in liver, bone, brain, adrenals and skin. Even a small primary tumour may cause widespread metastatic deposits and this is a particular characteristic of small-cell lung cancers.

Clinical features

Lung cancer presents in many different ways, reflecting local, metastatic or paraneoplastic tumour effects.

- **Cough.** The most common early symptom, cough is often dry; however, secondary infection may cause purulent sputum. A change in the character of a smoker's cough, particularly if associated with other new symptoms, should always raise suspicion of bronchial carcinoma.
- **Haemoptysis.** This is common, especially with central bronchial tumours. Although it frequently

Fig. 19.42 Large cavitated bronchial carcinoma in left lower lobe.

accompanies bronchitic infection and may be benign, haemoptysis in a smoker should always be investigated to exclude a bronchial carcinoma. Occasionally, central tumours invade large vessels, causing sudden massive haemoptysis which may be fatal.

- **Bronchial obstruction.** This is another common presentation, and the clinical and radiological manifestations (Figs 19.43 and 19.44; Box 19.73) depend on the site and extent of the obstruction, any secondary infection, and the extent of coexisting lung disease. Complete obstruction causes collapse

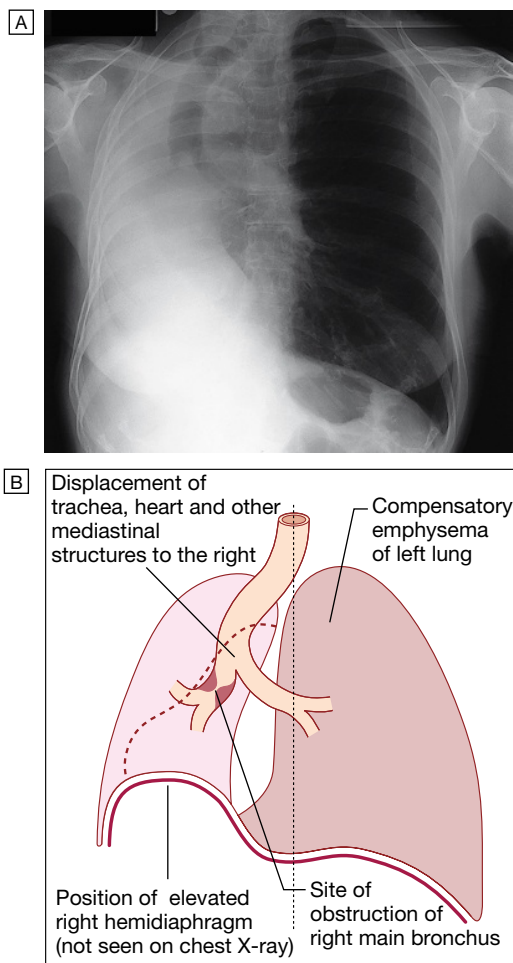

Fig. 19.43 Collapse of the right lung: effects on neighbouring structures. **A** Chest X-ray. **B** Abnormalities highlighted.

of a lobe or lung, with breathlessness, mediastinal displacement and dullness to percussion with reduced breath sounds. Partial bronchial obstruction may cause a monophonic, unilateral wheeze that fails to clear with coughing and may also impair the drainage of secretions sufficiently to cause pneumonia or lung abscess as a presenting problem. Pneumonia that recurs at the same site or responds slowly to treatment, particularly in a smoker, should always suggest an underlying bronchial carcinoma. Stridor (a harsh inspiratory noise) occurs when the lower trachea, carina or main bronchi are narrowed by the primary tumour or by compression from malignant enlargement of the subcarinal and paratracheal lymph nodes.

- **Breathlessness.** This may be caused by collapse or pneumonia, or by tumour causing a large pleural effusion or compressing a phrenic nerve causing diaphragmatic paralysis.
- **Pain and nerve entrapment.** Pleural pain usually indicates malignant pleural invasion, although it can occur with distal infection. Intercostal nerve involvement causes pain in the distribution of a thoracic dermatome. Carcinoma in the lung apex may cause Horner's syndrome (ipsilateral partial

Fig. 19.44 Radiological features of lobar collapse caused by bronchial obstruction. The dotted line in the drawings represents the normal position of the diaphragm.

19.73 Causes of large bronchus obstruction

Common

- Bronchial carcinoma or adenoma
- Enlarged tracheobronchial lymph nodes (malignant or tuberculous)
- Inhaled foreign bodies (especially right lung and in children)
- Bronchial casts or plugs consisting of inspissated mucus or blood clot (especially asthma, cystic fibrosis, haemoptysis, debility)
- Collections of mucus or mucopus retained in the bronchi as a result of ineffective expectoration (especially post-operative following abdominal surgery)

Rare

- Aortic aneurysm
- Giant left atrium
- Pericardial effusion
- Congenital bronchial atresia
- Fibrous bronchial stricture (e.g. following TB or bronchial surgery/lung transplant)

ptosis, enophthalmos, miosis and hypohidrosis of the face – p. 1166) due to involvement of the sympathetic chain at or above the stellate ganglion. Pancoast's syndrome (pain in the shoulder and inner aspect of the arm, sometimes with small muscle wasting in the hand) indicates malignant destruction of the T1 and C8 roots in lower part of the brachial plexus by an apical lung tumour.

- *Mediastinal spread.* Involvement of the oesophagus may cause dysphagia. If the pericardium is invaded, arrhythmia or pericardial effusion may occur. Superior vena cava obstruction by malignant nodes causes suffusion and swelling of the neck and face, conjunctival oedema, headache and dilated veins on the chest wall, and is most commonly due to bronchial carcinoma. Involvement of the left recurrent laryngeal nerve by tumours at the left hilum causes vocal cord paralysis, voice alteration and a 'bovine' cough (lacking the normal explosive character). Supraclavicular lymph nodes may be palpably enlarged; if so, a needle aspirate may provide a simple means of cytological diagnosis.
- *Metastatic spread.* This may lead to focal neurological defects, epileptic seizures, personality change, jaundice, bone pain or skin nodules. Lassitude, anorexia and weight loss usually indicate metastatic spread.
- *Digital clubbing.* Overgrowth of the soft tissue of the terminal phalanx leading to increased nail curvature is often seen (p. 642). This may be associated with hypertrophic pulmonary osteoarthropathy (HPOA), characterised by periostitis of the long bones, most commonly the distal tibia, fibula, radius and ulna. This causes pain and tenderness over the affected bones and often pitting oedema over the anterior aspect of the shin. X-rays reveal subperiosteal new bone formation. While most frequently associated with bronchial carcinoma, HPOA can occur with other tumours.
- *Non-metastatic extrapulmonary effects* (Box 19.74). Syndrome of inappropriate antidiuretic hormone secretion (SIADH, p. 436) and ectopic

19.74 Non-metastatic extrapulmonary manifestations of bronchial carcinoma

Endocrine (Ch. 20)

- Inappropriate antidiuretic hormone secretion causing hyponatraemia
- Ectopic adrenocorticotrophic hormone secretion
- Hypercalcaemia due to secretion of parathyroid hormone-related peptides
- Carcinoid syndrome (p. 887)
- Gynaecomastia

Neurological (Ch. 26)

- Polyneuropathy
- Myelopathy
- Cerebellar degeneration
- Myasthenia (Lambert–Eaton syndrome, p. 1219)

Other

- Digital clubbing
- Hypertrophic pulmonary osteoarthropathy
- Nephrotic syndrome
- Polymyositis and dermatomyositis
- Eosinophilia

adrenocorticotrophic hormone secretion (p. 774) are usually associated with small-cell lung cancer. Hypercalcaemia is usually caused by squamous cell carcinoma. Associated neurological syndromes may occur with any type of bronchial carcinoma.

Investigations

The main aims of investigation are to confirm the diagnosis, establish the histological cell type and define the extent of the disease.

Imaging

The features of bronchial carcinoma on plain X-rays are illustrated in Figures 19.44 and 19.45 and Box 19.75. CT is usually performed early, as it may reveal mediastinal or metastatic spread, and helps to direct histological sampling procedures. Imaging also indicates whether a tumour is likely to be accessible by bronchoscopy.

Histological characterisation

Around three-quarters of primary lung tumours can be visualised and sampled directly by biopsy and brushing using a flexible bronchoscope. Bronchoscopy also allows an assessment of operability, from the proximity of central tumours to the main carina (Fig. 19.46).

For tumours which are too peripheral to be accessible by bronchoscope, the yield of 'blind' bronchoscopic washings and brushings from the radiologically affected area is low, and percutaneous needle biopsy under CT or ultrasound guidance is a more reliable way to obtain a histological diagnosis. There is a small risk of iatrogenic pneumothorax, which may preclude the procedure if there is extensive coexisting COPD in the remaining lung. In patients who are not fit enough for invasive investigation, at least three sputum samples should be obtained for cytology, which may confirm the diagnosis non-invasively (Fig. 19.47).

In patients with pleural effusions, pleural aspiration and biopsy is the preferred investigation. Where facilities exist, thoracoscopy increases yield by allowing targeted biopsies under direct vision. In patients with

Fig. 19.45 Common radiological presentations of bronchial carcinoma.

 19.75 Common radiological presentations of bronchial carcinoma
1 Unilateral hilar enlargement
<ul style="list-style-type: none"> Central tumour. Hilar glandular involvement. However, a peripheral tumour in the apical segment of a lower lobe can look like an enlarged hilar shadow on the PA X-ray
2 Peripheral pulmonary opacity (p. 657)
<ul style="list-style-type: none"> Usually irregular but well circumscribed, and may contain irregular cavitation. Can be very large
3 Lung, lobe or segmental collapse
<ul style="list-style-type: none"> Usually caused by tumour within the bronchus leading to occlusion. Lung collapse may be due to compression of the main bronchus by enlarged lymph glands
4 Pleural effusion
<ul style="list-style-type: none"> Usually indicates tumour invasion of pleural space; very rarely, a manifestation of infection in collapsed lung tissue distal to a bronchial carcinoma
5-7 Broadening of mediastinum, enlarged cardiac shadow, elevation of a hemidiaphragm
<ul style="list-style-type: none"> Paratracheal lymphadenopathy may cause widening of the upper mediastinum. A malignant pericardial effusion will cause enlargement of the cardiac shadow. If a raised hemidiaphragm is caused by phrenic nerve palsy, screening will show it to move paradoxically upwards when patient sniffs
8 Rib destruction
<ul style="list-style-type: none"> Direct invasion of the chest wall or blood-borne metastatic spread can cause osteolytic lesions of the ribs

metastatic disease, the diagnosis can often be confirmed by needle aspiration or biopsy of affected lymph nodes, skin lesions, liver or bone marrow.

Staging to guide treatment

The propensity of small-cell lung cancer to metastasise early dictates that patients with this tumour type are usually not suitable for surgical intervention. In patients with other cell types, subsequent investigations should focus on determining whether the tumour is operable, because complete resection may be curative. While CT may show obvious spread of disease, for many patients the results are equivocal and further investiga-

Fig. 19.46 Bronchoscopic view of a bronchogenic carcinoma. There is distortion of mucosal folds, partial occlusion of the airway lumen and abnormal tumour tissue.

tion is required before deciding whether curative surgery is feasible. Enlarged upper mediastinal nodes may be sampled by using a bronchoscope equipped with endobronchial ultrasound (EBUS) or by mediastinoscopy. Nodes in the lower mediastinum can be sampled through the oesophageal wall using endoscopic ultrasound. Combined CT and PET imaging (see Fig. 19.5, p. 648) is used increasingly to detect metabolically active tumour metastases. Head CT, radionuclide bone scanning, liver ultrasound and bone marrow biopsy are generally reserved for patients with clinical, haematological or biochemical evidence of tumour spread to such sites.

Finally, detailed physiological testing is required to ensure that the patient's respiratory and cardiac function is sufficient to allow surgical treatment (Box 19.76).

Fig. 19.47 Sputum sample showing a cluster of carcinoma cells. There is keratinisation, showing orangeophilia of the cytoplasm, and non-keratinised forms are also seen. The nuclei are large and 'coal-black' in density. These are the features of squamous cell bronchogenic carcinoma.

19.76 Contraindications to surgical resection in bronchial carcinoma

- Distant metastasis (M1)
- Invasion of central mediastinal structures including heart, great vessels, trachea and oesophagus (T4)
- Malignant pleural effusion (T4)
- Contralateral mediastinal nodes (N3)
- $FEV_1 < 0.8$ L
- Severe or unstable cardiac or other medical condition

N.B. In otherwise fit individuals, direct extension of tumour into the chest wall, diaphragm, mediastinal pleura or pericardium or to within 2 cm of the main carina does not exclude surgery. Though surgically resectable, patients with N2 (ipsilateral mediastinal) nodes may require neoadjuvant or adjuvant therapy.

Management

Surgical resection carries the best hope of long-term survival; however, some patients treated with radical radiotherapy and chemotherapy also achieve prolonged remission or cure. Unfortunately, in over 75% of cases, treatment with curative intent is not possible, or is inappropriate due to extensive spread or comorbidity. Such patients can only be offered palliative therapy and best supportive care. Radiotherapy, and in some cases chemotherapy, can relieve distressing symptoms.

Surgical treatment

Accurate pre-operative staging, coupled with improvements in surgical and post-operative care, now offers 5-year survival rates of over 75% in stage I disease (N0, tumour confined within visceral pleura) and 55% in stage II disease, which includes resection in patients with ipsilateral peribronchial or hilar node involvement.

Radiotherapy

While much less effective than surgery, radical radiotherapy can offer long-term survival in selected patients with localised disease in whom comorbidity precludes surgery. Continuous hyper-fractionated accelerated radiotherapy (CHART), in which a similar total dose is given in smaller but more frequent fractions, may offer better survival prospects than conventional schedules. The greatest value of radiotherapy, however, is in the palliation of distressing complications such as superior vena cava obstruction, recurrent haemoptysis, and pain caused by chest wall invasion or by skeletal metastatic deposits. Obstruction of the trachea and main bronchi can also be relieved temporarily. Radiotherapy can be used in conjunction with chemotherapy in the treatment of small-cell carcinoma, and is particularly efficient at preventing the development of brain metastases in patients who have had a complete response to chemotherapy (p. 272).

Chemotherapy

The treatment of small-cell carcinoma with combinations of cytotoxic drugs, sometimes in combination with radiotherapy, can increase the median survival from 3 months to well over a year. Combination chemotherapy leads to better outcomes than single-agent treatment. In particular, oral etoposide leads to more toxicity and worse survival than standard combination chemotherapy. Regular cycles of therapy, including combinations of i.v. cyclophosphamide, doxorubicin and vincristine or i.v. cisplatin and etoposide, are

commonly used. Nausea and vomiting are common side-effects and are best treated with 5-HT₃ receptor antagonists (p. 285).

The use of combinations of chemotherapeutic drugs requires considerable skill and should be overseen by teams of expert clinicians and nurses. In general, chemotherapy is less effective in non-small-cell bronchial cancers. However, studies in such patients using platinum-based chemotherapy regimens have shown a 30% response rate associated with a small increase in survival.

Neoadjuvant and adjuvant chemotherapy

In non-small-cell carcinoma, there is some evidence that chemotherapy given before surgery may increase survival and can effectively 'down-stage' disease with limited nodal spread. Post-operative chemotherapy is now proven to improve survival rates when operative samples show nodal involvement by tumour.

Laser therapy and stenting

Palliation of symptoms caused by major airway obstruction can be achieved in selected patients using bronchoscopic laser treatment to clear tumour tissue and allow re-aeration of collapsed lung. The best results are achieved in tumours of the main bronchi. Endobronchial stents can be used to maintain airway patency in the face of extrinsic compression by malignant nodes.

General aspects of management

The best outcomes are obtained when lung cancer is managed in specialist centres by multidisciplinary teams including oncologists, thoracic surgeons, respiratory physicians and specialist nurses; effective communication, pain relief and attention to diet are important. Lung tumours can cause clinically significant depression and anxiety, and these may need specific therapy. The management of non-metastatic endocrine manifestations is described in Chapter 20. When a malignant pleural effusion is present, an attempt should be made to drain the pleural cavity using an intercostal drain; provided the lung fully re-expands, pleurodesis with a sclerosing agent such as talc should be performed.

Prognosis

The overall prognosis in bronchial carcinoma is very poor, with around 70% of patients dying within a year of diagnosis and only 6–8% of patients surviving 5 years after diagnosis. The best prognosis is with well-differentiated squamous cell tumours that have not metastasised and are amenable to surgical resection. The clinical features and prognosis of some less common benign and malignant lung tumours are given in Box 19.77.

Secondary tumours of the lung

Blood-borne metastatic deposits in the lungs may be derived from many primary tumours, in particular the breast, kidney, uterus, ovary, testes and thyroid. The secondary deposits are usually multiple and bilateral. Often there are no respiratory symptoms and the diagnosis is made on radiological examination. Breathlessness may occur if a considerable amount of lung tissue has been replaced by metastatic tumour. Endobronchial deposits are uncommon but can cause haemoptysis and lobar collapse.

19.77 Rare types of lung tumour

Tumour	Status	Histology	Typical presentation	Prognosis
Adenosquamous carcinoma	Malignant	Tumours with areas of unequivocal squamous and adeno-differentiation	Peripheral or central lung mass	Stage-dependent
Carcinoid tumour (p. 887)	Low-grade malignant	Neuroendocrine differentiation	Bronchial obstruction, cough	95% 5-year survival with resection
Bronchial gland adenoma	Benign	Salivary gland differentiation	Tracheobronchial irritation/obstruction	Local resection curative
Bronchial gland carcinoma	Low-grade malignant	Salivary gland differentiation	Tracheobronchial irritation/obstruction	Local recurrence occurs
Hamartoma	Benign	Mesenchymal cells, cartilage	Peripheral lung nodule	Local resection curative
Bronchoalveolar carcinoma	Malignant	Tumour cells line alveolar spaces	Alveolar shadowing, productive cough	Variable, worse if multifocal

Lymphangitic spread of carcinoma in the lung

Lymphatic infiltration may develop in patients with carcinoma of the breast, stomach, bowel, pancreas or bronchus. This grave condition causes severe and rapidly progressive breathlessness associated with marked hypoxaemia. The chest X-ray shows diffuse pulmonary shadowing radiating from the hilar regions, often associated with septal lines, and CT scans show characteristic polygonal thickened interlobular septa. Palliation of breathlessness with opiates may help (p. 285).

Tumours of the mediastinum

The mediastinum can be divided into four major compartments with reference to the lateral chest X-ray (Fig. 19.48):

- superior mediastinum: above a line drawn between the lower border of the 4th thoracic vertebra and the upper end of the body of the sternum
- anterior mediastinum: in front of the heart

- middle mediastinum: between the anterior and posterior compartments
- posterior mediastinum: behind the heart.

A variety of conditions can present radiologically as a mediastinal mass (Box 19.78).

Benign tumours and cysts arising within the mediastinum are frequently diagnosed when radiological examination of the chest is undertaken for some other reason. In general, they do not invade vital structures but may cause symptoms by compressing the trachea or occasionally the superior vena cava. A dermoid cyst may very occasionally rupture into a bronchus.

Malignant mediastinal tumours are distinguished by their power to invade as well as compress surrounding structures. As a result, even a small malignant tumour can produce symptoms, although more commonly the tumour has attained a considerable size before this happens (Box 19.79). The most common cause is mediastinal lymph node metastases from bronchogenic carcinoma, but lymphomas, leukaemia, malignant thymic tumours and germ-cell tumours can cause similar features. Aortic and innominate aneurysms have destructive features resembling those of malignant mediastinal tumours.

Fig. 19.48 The divisions of the mediastinum. (1) Superior mediastinum. (2) Anterior mediastinum. (3) Middle mediastinum. (4) Posterior mediastinum. Sites of the more common mediastinal tumours are also illustrated.

19.78 Causes of a mediastinal mass

Superior mediastinum

- Retrosternal goitre
- Persistent left superior vena cava
- Prominent left subclavian artery
- Thymic tumour
- Dermoid cyst
- Lymphoma
- Aortic aneurysm

Anterior mediastinum

- Retrosternal goitre
- Dermoid cyst
- Thymic tumour
- Lymphoma
- Aortic aneurysm
- Germ cell tumour
- Pericardial cyst
- Hiatus hernia through the diaphragmatic foramen of Morgagni

Posterior mediastinum

- Neurogenic tumour
- Paravertebral abscess
- Oesophageal lesion
- Aortic aneurysm
- Foregut duplication

Middle mediastinum

- Bronchial carcinoma
- Lymphoma
- Sarcoidosis
- Bronchogenic cyst
- Hiatus hernia

19.79 Clinical presentations with malignant invasion of the structures of the mediastinum

Trachea and main bronchi

- Stridor, breathlessness, cough, pulmonary collapse

Oesophagus

- Dysphagia, oesophageal displacement or obstruction on barium swallow examination

Phrenic nerve

- Diaphragmatic paralysis

Left recurrent laryngeal nerve

- Paralysis of left vocal cord giving rise to hoarseness and 'bovine' cough

Sympathetic trunk

- Horner's syndrome

Superior vena cava

- SVC obstruction results in non-pulsatile distension of neck veins, subconjunctival oedema, and oedema and cyanosis of head, neck, hands and arms. Dilated anastomotic veins on chest wall

Pericardium

- Pericarditis and/or pericardial effusion

Fig. 19.49 Large mass (intrathoracic goitre—arrows) extending from right upper mediastinum.

Endoscopic investigation

Bronchoscopy may reveal a primary bronchial carcinoma causing mediastinal tumour by secondary lymphatic spread. EBUS may be used to image and guide sampling of peribronchial masses. The posterior mediastinum can be imaged via the oesophagus using EUS, which also facilitates needle biopsies of tumours or lymph node masses (p. 650).

Surgical exploration

Mediastinoscopy under general anaesthetic can be used to visualise and biopsy masses in the superior and anterior mediastinum; however, surgical exploration of the chest with removal of part or all of the tumour is often required to obtain a histological diagnosis.

Management

Benign mediastinal tumours should be removed surgically because most produce symptoms sooner or later. Some of them, particularly cysts, may become infected, while others, especially neural tumours, have the potential to undergo malignant transformation. The operative mortality is low provided there is no relative contraindication to surgical treatment, such as coexisting cardiovascular disease, COPD or extreme age.

Investigations

Radiological examination

A benign mediastinal tumour generally appears as a sharply circumscribed opacity situated in the mediastinum but encroaching on one or both lung fields (Fig. 19.49). CT (or MRI) is the investigation of choice for mediastinal tumours (e.g. see Fig. 20.12B, p. 750). A malignant mediastinal tumour seldom has a clearly defined margin and often presents as a general broadening of the mediastinal shadow.

INTERSTITIAL AND INFILTRATIVE PULMONARY DISEASES

Diffuse parenchymal lung disease

The diffuse parenchymal lung diseases (DPLDs) are a heterogeneous group of conditions affecting the pulmonary interstitium and/or alveolar lumen. The presentation and natural history of these may differ widely, but they are frequently considered collectively as they

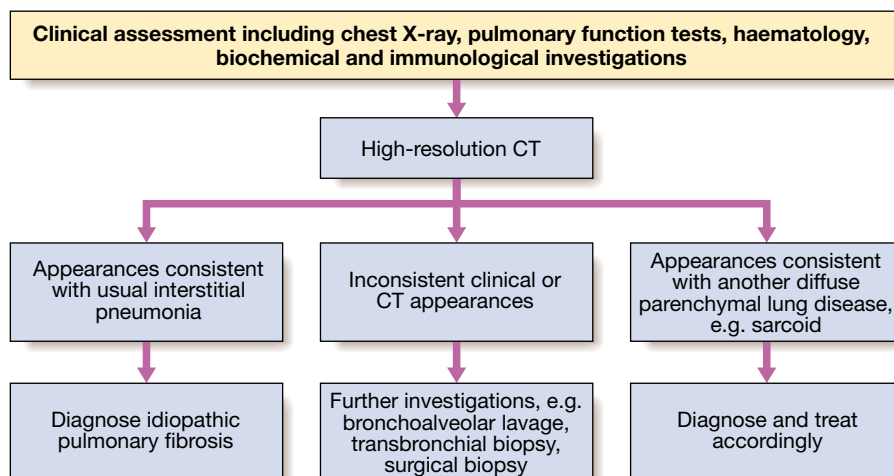

Fig. 19.50 Algorithm for the investigation of patients with interstitial lung disease following initial clinical and chest X-ray examination.

share similar symptoms, physical signs, pulmonary function abnormalities and radiological changes. HRCT has become the critical first step in the investigation of DPLD, indicating the diagnosis or directing further investigation (Fig. 19.50). The classification of DPLD is shown in Figure 19.51. A range of conditions may mimic interstitial lung disease (Box 19.80).

Idiopathic interstitial pneumonias

The idiopathic interstitial pneumonias (IIPs) are characterised by varying patterns of inflammation and fibrosis in the lung parenchyma, and comprise a number of clinicopathological entities that are sufficiently different from one another to be considered as separate diseases

19.80 Conditions which mimic interstitial lung diseases

Infection

- Viral pneumonia
- *Pneumocystis jirovecii*
- *Mycoplasma pneumoniae*
- TB
- Parasites, e.g. filariasis
- Fungal infection

Malignancy

- Leukaemia and lymphoma
- Lymphatic carcinomatosis
- Multiple metastases
- Bronchoalveolar carcinoma

Pulmonary oedema

Aspiration pneumonitis

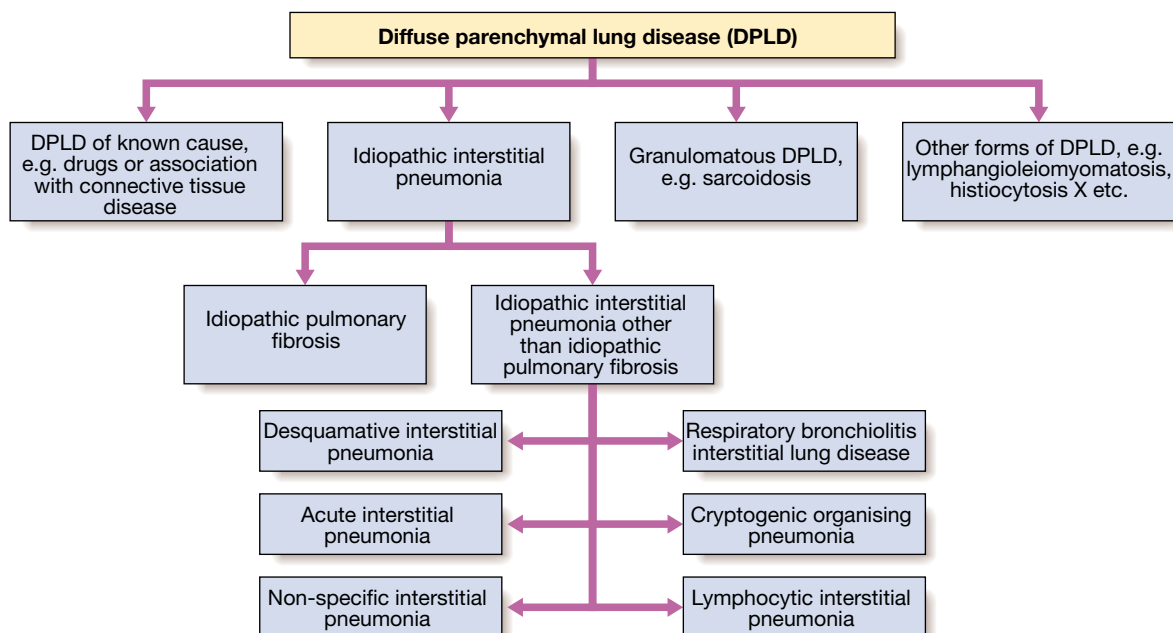

Fig. 19.51 Classification of diffuse parenchymal lung disease (see Box 19.81).

19.81 Differential diagnoses of the interstitial pneumonias

Clinical diagnosis	Notes
Usual interstitial pneumonia (UIP)	Idiopathic pulmonary fibrosis
Non-specific interstitial pneumonia (NSIP)	See page 708
Respiratory bronchiolitis-interstitial lung disease	More common in men and smokers. Usually presents in those aged 40–60. Smoking cessation may lead to improvement. Natural history unclear
Acute interstitial pneumonia	Often preceded by viral upper respiratory tract infection. Severe exertional dyspnoea, widespread pneumonic consolidation and diffuse alveolar damage on biopsy. Prognosis is often poor
Desquamative interstitial pneumonia (DIP)	More common in men and smokers. Presents in those aged 40–60. Insidious onset of dyspnoea. Clubbing in 50%. Biopsy shows increased macrophages in the alveolar space, septal thickening and type II pneumocyte hyperplasia. Prognosis is generally good
Cryptogenic organising pneumonia ('bronchiolitis obliterans organising pneumonia'—BOOP)	Presents as clinical and radiological pneumonia. Systemic features and markedly raised ESR common. Finger clubbing is absent. Biopsy shows a florid proliferation of immature collagen (Masson bodies) and fibrous tissue. Response to corticosteroids is classically excellent
Lymphocytic interstitial pneumonia (LIP)	More common in women, slow onset over years. Investigate for associations with connective tissue disease or HIV. Unclear whether corticosteroids helpful

(Box 19.81). The most common and important of these is idiopathic pulmonary fibrosis (IPF), which accounts for over 85% of new cases.

Idiopathic pulmonary fibrosis

Idiopathic pulmonary fibrosis refers to a specific form of DPLD characterised by pathological (or HRCT) evidence of 'usual interstitial pneumonia' (UIP). The histological features are suggestive of repeated episodes of focal damage to the alveolar epithelium consistent with an autoimmune process, but the aetiology remains elusive; putative factors include viruses (e.g. Epstein-Barr virus), occupational dusts (metal or wood), drugs (antidepressants) or chronic gastro-oesophageal reflux. Familial cases are rare but genetic factors that control the inflammatory and fibrotic response are likely to be important. There is a strong association with cigarette smoking.

Clinical features

IPF is uncommon before the age of 50 years. It usually presents with insidiously progressive breathlessness and a non-productive cough. Constitutional symptoms are unusual. Clinical findings include finger clubbing and the presence of bi-basal fine late inspiratory crackles likened to the unfastening of Velcro. The natural history is usually one of steady decline, but some patients are prone to exacerbations which are accompanied by an acute deterioration in breathlessness, disturbed gas exchange, and new ground glass changes or consolidation on HRCT. In advanced disease, central cyanosis is detectable and patients may develop features of right heart failure.

Investigations (Box 19.82)

There is no circulating marker for IPF. Non-specific findings include hypergammaglobulinaemia, positive rheumatoid factor or antinuclear factor (p. 1063), and an elevated LDH which may reflect active pneumonitis. Pulmonary function tests classically show a restric-

tive defect with reduced lung volumes and gas transfer. However, lung volumes may be paradoxically preserved in patients with concomitant emphysema. Dynamic tests are useful to document exercise tolerance and demonstrate exercise-induced arterial hypoxaemia, but as IPF advances, arterial hypoxaemia and hypocapnia are

19.82 Investigations in DPLD

Laboratory investigations

- Full blood count: lymphopenia in sarcoid; eosinophilia in pulmonary eosinophilias and drug reactions; neutrophilia in hypersensitivity pneumonitis
- Ca^{2+} : may be elevated in sarcoid
- Lactate dehydrogenase (LDH): may provide non-specific indicator of disease activity in DPLD
- Serum ACE: non-specific indicator of disease activity in sarcoid
- ESR and CRP may be non-specifically raised
- Autoimmune screen, rheumatoid factor and anti-CCP antibodies may suggest connective tissue disease

Radiology

- Chest X-ray
- HRCT

Pulmonary function

- Spirometry, lung volumes, gas transfer, exercise tests

Bronchoscopy

- Bronchoalveolar lavage: infection, differential cell counts
- Bronchial biopsy may be useful in sarcoid

Lung biopsy (in selected cases)

- Transbronchial biopsy useful in sarcoid and differential of malignancy or infection
- Video-assisted thoracoscopy (VATS)

Others

- Liver biopsy may be useful in sarcoidosis
- Urinary calcium excretion may be useful in sarcoidosis

present at rest. Virtually all patients have an abnormal chest X-ray at presentation with lower zone bi-basal reticular and reticulonodular opacities. A 'honeycomb' appearance may be seen in advanced disease but is non-specific (Fig. 19.52A). HRCT typically demonstrates a patchy, predominantly peripheral, subpleural and basal reticular pattern with subpleural cysts (honeycombing) and/or traction bronchiectasis (Fig. 19.52B). A lung biopsy is not usually required in those with typical clinical features and HRCT appearances, particularly if other known causes of interstitial lung disease have been excluded, but should be considered in cases of diagnostic uncertainty or with atypical features.

Management

Treatment is challenging. Prednisolone therapy (0.5 mg/kg) combined with azathioprine (2–3 mg/kg) is advocated for patients who are highly symptomatic or have rapidly progressive disease, have a predominantly 'ground glass' appearance on CT or a sustained fall of > 15% in their FVC or gas transfer over a 3–6-month period. However, response rates are notoriously poor, side-effects are guaranteed, and there is little evidence that this therapy impacts on the natural history of the disease. If objective evidence of improvement can be demonstrated, the prednisolone dose may be gradually reduced to a maintenance dose of 10–12.5 mg daily. The potential of therapies such as warfarin, N-acetyl-

cysteine, IFN- γ 1b, pirfenidone, bosentan or etanercept is being explored but cannot be recommended outside clinical trials at present. Lung transplantation should be considered in young patients with advanced disease. Oxygen may be provided for palliation of breathlessness but opiates may be required for relief of severe dyspnoea. The optimum treatment for acute exacerbations is unknown.

Prognosis

A median survival of 3 years is widely quoted; however, the rate of disease progression varies considerably from death within a few months to survival with minimal symptoms for many years. Serial lung function testing may provide useful prognostic information, with relative preservation of lung function suggesting longer survival and desaturation on exercise heralding a poorer prognosis. The finding of high numbers of fibroblastic foci on biopsy suggests a more rapid deterioration. IPF is associated with an increased risk of carcinoma of the lung.

Non-specific interstitial pneumonia

The clinical picture of fibrotic NSIP is similar to that of IPF, although patients tend to be women and younger in age. The aetiology is unknown but recognised associations occur with connective tissue disease, certain drugs and chronic hypersensitivity pneumonitis. HRCT findings are less specific than with IPF and lung biopsy may be required. NSIP is more likely to respond to immunosuppressive therapy than IPF; accordingly, the prognosis is significantly better, particularly in the cellular form of the condition, and the 5-year mortality rate is typically less than 15%.

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder of unknown aetiology that is characterised by the presence of non-caseating granulomas (Fig. 19.53). The condition is more frequently described in colder parts of northern Europe. It also appears to be more common and more severe in those from a West Indian or Asian background; Eskimos, Arabs and Chinese are rarely affected. The tendency for sarcoid to present in the spring and summer has led to speculation as to the role of infective agents,

Fig. 19.52 Idiopathic pulmonary fibrosis. [A] Chest X-ray showing bilateral, predominantly lower zone and peripheral coarse reticulonodular shadowing and small lungs. [B] The CT scan shows honeycombing and scarring which is most marked peripherally.

Fig. 19.53 Sarcoidosis of the lung. Histology showing non-caseating granulomas (arrows).

including mycobacteria, propionibacteria and viruses, but the cause remains elusive. Genetic susceptibility is supported by familial clustering; a range of class II HLA alleles confer protection from or susceptibility to the condition. Sarcoidosis occurs less frequently in smokers.

Clinical features

Sarcoidosis is considered with other DPLD as over 90% of cases affect the lungs, but the condition can affect almost any organ (Fig. 19.54 and Box 19.83). Löfgren's syndrome—an acute illness characterised by erythema nodosum, peripheral arthropathy, uveitis, bilateral hilar lymphadenopathy (BHL), lethargy and occasionally fever—is often seen in young adults. Alternatively, BHL may be detected in an otherwise asymptomatic individual undergoing a chest X-ray for other purposes. Pulmonary disease may also present in a more insidious manner with cough, exertional breathlessness and radiographic infiltrates; chest auscultation is often surprisingly unremarkable. Fibrosis occurs in around 20% of cases of pulmonary sarcoidosis and may cause a silent loss of lung function. Pleural disease is uncommon and finger clubbing is not a feature. Complications such as bronchiectasis, aspergilloma, pneumothorax, pulmonary hypertension and cor pulmonale have been reported but are rare.

19.83 Presentation of sarcoidosis

- Asymptomatic: abnormal routine chest X-ray (~30%) or abnormal liver function tests
- Respiratory and constitutional symptoms (20–30%)
- Erythema nodosum and arthralgia (20–30%)
- Ocular symptoms (5–10%)
- Skin sarcoid (including lupus pernio) (5%)
- Superficial lymphadenopathy (5%)
- Other (1%), e.g. hypercalcaemia, diabetes insipidus, cranial nerve palsies, cardiac arrhythmias, nephrocalcinosis

Investigations

Lymphopenia is characteristic and liver function tests may be mildly deranged. Hypercalcaemia may be present (reflecting increased formation of calcitriol—1,25-dihydroxyvitamin D₃—by alveolar macrophages), particularly if the patient has been exposed to strong sunlight. Hypercalciuria may also be seen and may lead to nephrocalcinosis. Serum angiotensin-converting enzyme (ACE) is a non-specific marker of disease activity and can assist in monitoring the clinical course. Chest radiography has been used to stage sarcoid (Box 19.84).

Fig. 19.54 Possible systemic involvement in sarcoidosis.

19.84 Chest X-ray changes in sarcoidosis

Stage I: BHL (usually symmetrical); paratracheal nodes often enlarged

- Often asymptomatic, but may be associated with erythema nodosum and arthralgia. The majority of cases resolve spontaneously within 1 year

Stage II: BHL and parenchymal infiltrates

- Patients may present with breathlessness or cough. The majority of cases resolve spontaneously

Stage III: parenchymal infiltrates without BHL

- Disease less likely to resolve spontaneously

Stage IV: pulmonary fibrosis

- Can cause progression to ventilatory failure, pulmonary hypertension and cor pulmonale

In patients with pulmonary infiltrates, pulmonary function testing may show a restrictive defect accompanied by impaired gas exchange. Exercise tests may reveal oxygen desaturation. Transbronchial (and bronchial) biopsies show non-caseating granulomas (see Fig. 19.53) and the mucosa may have a 'cobblestone' appearance at bronchoscopy. The BAL fluid typically contains an increased CD4:CD8 T-cell ratio. Characteristic HRCT appearances include reticulonodular opacities that follow a perilymphatic distribution centred on bronchovascular bundles and the subpleural areas.

The occurrence of erythema nodosum with BHL on chest X-ray is often sufficient for a confident diagnosis, without recourse to a tissue biopsy. Similarly, a typical presentation with classical HRCT features may also be accepted. However, in other instances the diagnosis should be confirmed by histological examination of the involved organ. The presence of anergy (e.g. to tuberculin skin tests) may support the diagnosis.

Management

Patients who present with acute illness and erythema nodosum should receive NSAIDs and, if symptoms are severe, a short course of corticosteroids. The majority of patients enjoy spontaneous remission and so if there is no evidence of organ damage, systemic corticosteroid therapy can be withheld for 6 months. However, prednisolone (at a starting dose of 20–40 mg/day) should be commenced immediately in the presence of hypercalcaemia, pulmonary impairment, renal impairment and uveitis (Box 19.85). Topical steroids may be useful in cases of mild uveitis, and inhaled corticosteroids have been used to shorten the duration of systemic corticosteroid use in asymptomatic parenchymal sarcoid. Patients should be

EBM 19.85 Systemic corticosteroids in pulmonary sarcoidosis

'Oral glucocorticoids administered for 6–24 months improve chest X-ray appearances and symptoms but there is little evidence of an improvement in lung function and there are no data from follow-up beyond 2 years.'

- Paramathayan NS, et al. (Cochrane Review). Cochrane Library, issue 2, 2005. Oxford: Update Software.

warned that strong sunlight may precipitate hypercalcaemia and endanger renal function.

Features suggesting a less favourable outlook include age > 40 years, Afro-Caribbean ethnicity, persistent symptoms for more than 6 months, the involvement of more than three organs, lupus pernio and a stage III/IV chest X-ray. In patients with severe disease methotrexate (10–20 mg/week), azathioprine (50–150 mg/day) and specific TNF- α inhibitors (p. 1080) have been effective. Chloroquine, hydroxychloroquine and low-dose thalidomide may be useful in cutaneous sarcoid with limited pulmonary involvement. Selected patients may be referred for consideration of single lung transplantation. The overall mortality is low (1–5%) and usually reflects cardiac involvement or pulmonary fibrosis.

Lung diseases due to organic dusts

A wide range of organic agents may cause respiratory disorders (Box 19.86). Disease results from a local immune response to animal proteins (e.g. bird fancier's lung) or fungal antigens in mouldy vegetable matter. Hypersensitivity pneumonitis is the most common of these conditions.

Hypersensitivity pneumonitis (HP)

Hypersensitivity pneumonitis (also called extrinsic allergic alveolitis) results from the inhalation of a wide variety of organic antigens which give rise to a diffuse immune complex reaction in the walls of the alveoli and bronchioles. Common causes include farm worker's lung and bird fancier's lung.

Pathogenesis and pathology

The pathology of HP is consistent with both type III and type IV immunological mechanisms (p. 86). Precipitating IgG antibodies may be detected in the serum and a type III Arthus reaction is believed to occur in the lung, where the precipitation of immune complexes results in

19.86 Examples of lung diseases caused by organic dusts

Disorder	Source	Antigen/agent
Farmer's lung*	Mouldy hay, straw, grain	<i>Micropolyspora faeni</i> <i>Aspergillus fumigatus</i>
Bird fancier's lung*	Avian excreta, proteins and feathers	Avian serum proteins
Malt worker's lung*	Mouldy maltings	<i>Aspergillus clavatus</i>
Byssinosis (p. 671)	Textile industries	Cotton, flax, hemp dust
Inhalation ('humidifier') fever	Contamination of air conditioning	Thermophilic actinomycetes
Cheese worker's lung*	Mouldy cheese	<i>Aspergillus clavatus</i> <i>Penicillium casei</i>
Maple bark stripper's lung*	Bark from stored maple	<i>Cryptostroma corticale</i>

*Denotes lung disease presenting as hypersensitivity pneumonitis.

activation of complement and an inflammatory response in the alveolar walls, characterised by the influx of mononuclear cells and foamy histiocytes. The presence of poorly formed non-caseating granulomas in the alveolar walls suggests that type IV responses are also important. The distribution of the inflammatory infiltrate is predominantly peribronchiolar, which helps to distinguish the appearances from non-specific or lymphocytic interstitial pneumonias which display a more diffuse distribution. Chronic forms of the disease may be accompanied by fibrosis. For reasons that remain uncertain, there is a lower incidence of HP in smokers compared to non-smokers.

Clinical features

The acute form of the disease should be suspected when anyone who is exposed to organic dust complains, within a few hours of re-exposure to the same dust, of influenza-like symptoms such as headache, myalgia, malaise, pyrexia, dry cough and breathlessness. Chest auscultation reveals widespread end-inspiratory crackles and squeaks. In cases attributable to chronic low-level exposure (as may be the case with an indoor pet bird), the presentation is more often insidious and established fibrosis may be present by the time the disease is recognised. If unchecked, HP may progress to cause severe respiratory disability, hypoxaemia, pulmonary hypertension, cor pulmonale and eventually death.

Investigations

The classical chest X-ray shows upper zone diffuse micronodular shadowing. HRCT is more sensitive and the appearances may provide information on the stage of disease. Acute forms are characterised by ground glass shadowing and areas of consolidation superimposed on small centrilobar nodular opacities; the distribution is typically bilateral with upper and middle lobe predominance. In more chronic disease, features of fibrosis such as volume loss, linear opacities and architectural distortion appear. Pulmonary function tests show a restrictive ventilatory defect with reduced lung volumes and impaired gas transfer, dynamic tests may detect oxygen desaturation and, in more advanced disease, type I respiratory failure is present at rest.

Diagnosis

The diagnosis of HP is usually based on the characteristic clinical and radiological features, together with the identification of a potential source of antigen at the patient's home or place of work (Box 19.87). It may be supported by a positive precipitin test or by more

sensitive serological tests based on the enzyme-linked immunosorbent assay (ELISA) technique. However, the great majority of farmers with positive precipitins do not have farmer's lung, and up to 15% of pigeon breeders may have positive serum precipitins yet remain healthy.

Where HP is suspected but the cause is not readily apparent, a visit to the patient's home or workplace should be arranged. Occasionally, such as when an agent not previously recognised as causing HP is suspected, provocation testing may be necessary to prove the diagnosis; inhalation of the relevant antigen is followed by pyrexia and a reduction in VC and gas transfer factor after 3–6 hours, if positive. BAL fluid usually shows an increase in the number of CD8⁺ T lymphocytes. Transbronchial biopsy can occasionally provide sufficient tissue for a confident diagnosis, but open lung biopsy may be necessary.

Management

Whenever possible, the patient should cease exposure to the inciting agent. However, in some cases this may be difficult to achieve, because of either implications for livelihood (e.g. farmers) or addiction to hobbies (e.g. pigeon breeders). Dust masks with appropriate filters may minimise exposure and may be combined with methods of reducing levels of antigen (e.g. drying hay before storage). In acute cases prednisolone should be given for 3–4 weeks, starting with an oral dose of 40 mg per day. Severely hypoxaemic patients may require high-concentration oxygen therapy initially. Most patients recover completely, but the development of interstitial fibrosis is usually accompanied by permanent disability.

Inhalation ('humidifier') fever

Inhalation fever shares similarities with HP. It occurs as a result of contaminated humidifiers or air-conditioning units that release a fine spray of microorganisms into the atmosphere. The illness is characterised by self-limiting fever and breathlessness; permanent sequelae are unusual. An identical syndrome can also develop after disturbing an accumulation of mouldy hay, compost or mulch. So-called 'hot tub lung' appears to be attributable to *M. avium*. Outbreaks of HP in workers using metalworking fluids appear linked to *Acinetobacter* or *Ochrobactrum*.

Lung diseases due to inorganic dusts

In certain occupations, the inhalation of inorganic dusts, fumes or other noxious substances leads to specific pathological changes in the lungs. Industrial inorganic gases and fumes can cause acute respiratory diseases including pulmonary oedema and asthma (Box 19.88). In general, prolonged exposure to inorganic dusts (Box 19.89) leads to diffuse pulmonary fibrosis (the pneumoconiosis), although beryllium causes an interstitial granulomatous disease similar to sarcoidosis. The pathological result depends largely on the inflammatory and fibrotic responses: silica is highly fibrogenic whereas iron and tin are almost inert. The most important types of pneumoconiosis are coal worker's pneumoconiosis, silicosis and asbestosis. In many types, a long period of dust

19.87 Predictive factors in the identification of hypersensitivity pneumonitis

- Exposure to a known offending antigen
- Positive precipitating antibodies to offending antigen
- Recurrent episodes of symptoms
- Inspiratory crackles on examination
- Symptoms occurring 4–8 hours after exposure
- Weight loss

19.88 Lung diseases caused by inorganic gases and fumes

Cause	Occupation	Disease
Irritant gases (chlorine, ammonia, phosgene, nitrogen dioxide)	Various (industrial accidents)	Acute lung injury ARDS
Cadmium	Welding and electroplating	COPD
Isocyanates (e.g. epoxy resins, paints)	Plastic, paints; manufacture of epoxy resins and adhesives	Bronchial asthma Eosinophilic pneumonia

19.89 Lung diseases caused by exposure to inorganic dusts

Cause	Occupation	Description	Characteristic pathological features
Coal dust	Coal mining	Coal worker's pneumoconiosis	Focal and interstitial fibrosis, centrilobular emphysema, progressive massive fibrosis
Silica	Mining, quarrying, stone dressing, metal grinding, pottery, boiler scaling	Silicosis	
Asbestos	Demolition, ship breaking, manufacture of fireproof insulating materials, pipe and boiler lagging	Asbestos-related disease	Pleural plaques Diffuse pleural thickening Acute benign pleurisy Carcinoma of lung Interstitial fibrosis Mesothelioma
Iron oxide	Arc welding	Siderosis	Mineral deposition only
Tin oxide	Tin mining	Stannosis	Tin-laden macrophages
Beryllium	Aircraft, atomic energy and electronics industries	Berylliosis	Granulomas, interstitial fibrosis

exposure is required before radiological changes appear, and these may precede clinical symptoms. A detailed occupational history is essential not only to avoid missing a case of occupational lung disease, but also to allow appropriate advice to be given to the patient, and if relevant, the employer and legal advisors. Many countries encourage the registration of cases of occupational lung disease.

Coal worker's pneumoconiosis

Simple coal worker's pneumoconiosis (SCWP) follows prolonged inhalation of coal dust. Dust-laden alveolar macrophages aggregate to form macules in or near the

centre of the secondary pulmonary lobule and a fibrotic reaction ensues, resulting in the appearance of scattered discrete fibrotic lesions. Classification is based on the size and extent of radiographic nodularity.

SCWP is asymptomatic, does not impair lung function, and once exposure ceases will seldom progress. In some cases, SCWP may be 'complicated' by an additional pathology such as progressive massive fibrosis (PMF) or Caplan's syndrome. PMF refers to the formation of large dense masses (mainly in the upper lobes); cavitation may occur, raising important differential diagnoses such as lung cancer, tuberculosis and Wegener's granulomatosis. In contrast to SCWP, PMF is usually associated with cough, sputum that may be black (melanoptysis), and breathlessness. It may progress after coal dust exposure ceases and in extreme cases leads to respiratory failure and right ventricular failure. Caplan's syndrome describes the coexistence of rheumatoid arthritis and pneumoconiosis, with rounded fibrotic nodules 0.5–5 cm in diameter. They show pathological features similar to a rheumatoid nodule including central necrosis, palisading histiocytes, and a peripheral rim of lymphocytes and plasma cells. This syndrome may also occur in other types of pneumoconiosis.

Silicosis

Silicosis results from the inhalation of crystalline or free silica, usually in the form of quartz, by workers cutting, grinding and polishing stone. The clinical presentation reflects the intensity of exposure. Classic silicosis is most common and usually manifests after 10–20 years of continuous silica exposure, during which time the patient remains asymptomatic. Accelerated silicosis is associated with a much shorter duration of dust exposure (typically 5–10 years), may present as early as 1 year of exposure, and as the name suggests, follows a more aggressive course. Typical symptoms include cough, with sputum and breathlessness. Very rarely, intense exposure to very fine crystalline silica dust can cause a more acute disease: silicoproteinosis, similar to alveolar proteinosis (Box 19.94, p. 717).

Radiological features are similar to those of SCWP, with multiple well-circumscribed 3–5 mm nodular opacities predominantly in the mid- and upper zones. As the disease progresses, PMF may develop (Fig. 19.55). Enlargement of the hilar glands with an 'eggshell' pattern of calcification is said to be characteristic, but is uncommon and non-specific.

Silica is highly fibrogenic and the disease is usually progressive, even when exposure ceases. The disease is associated with an increased risk of tuberculosis (silicotuberculosis), lung cancer and COPD; associations with renal and connective tissue disease have also been described.

Asbestosis

The main types of the fibrous mineral asbestos are chrysotile (white asbestos), which accounts for 90% of the world's production, crocidolite (blue asbestos) and amosite (brown asbestos). By virtue of their aerodynamic shape, airborne asbestos fibres can penetrate deep within the lung parenchyma, then lodge in small airways where their inert mineral structure confounds the attempts of pulmonary macrophages to clear them. In the lung, pulmonary fibrosis and bronchial carcinoma

Fig. 19.55 Silicosis. [A] A chest X-ray from a patient with silicosis showing the presence of small rounded nodules predominantly seen in the upper zones. [B] HRCT from the same patient demonstrating conglomeration of nodules with posterior bias.

are the most serious consequences. Exposure occurs in a variety of occupations and is a recognised risk factor for several respiratory diseases (Fig. 19.56). Asbestos-related pleural disease is described on page 728.

Asbestosis is a diffuse interstitial fibrosis of the lungs. The risk of development and severity of the disease increase in relation to the amount of dust inhaled, although individual susceptibility appears to be important. Patients usually present with exertional breathlessness and fine, late inspiratory crackles over the lower zones. Digital clubbing (reported in 40% of patients) is an adverse prognostic feature. The chest X-ray shows bi-basal reticulonodular shadowing and asbestos-related pleural disease is usually (but not invariably) present. HRCT is more sensitive than plain radiography and typically shows bi-basal, subpleural, dot-like opacities, curvilinear subpleural lines, ground glass opacification and interlobular septal thickening. In more advanced disease, honeycombing may be present. Pulmonary function tests typically show a restrictive defect with decreased lung volumes and reduced gas transfer factor.

The diagnosis is usually established by a history of substantial asbestos exposure with the clinical, radiological and pulmonary function abnormalities described above. Asbestos bodies may be identified in sputum or BAL and confirm asbestos exposure. Lung biopsy is rarely necessary but may be required to exclude other causes of interstitial lung disease. Asbestos fibre counts may be performed on lung biopsy material.

Management

No specific treatment is available and asbestosis is usually slowly progressive. In advanced cases, respiratory failure and cor pulmonale may develop. About 40% of patients (who usually smoke) develop carcinoma of the lung and 10% may develop mesothelioma (p. 729). Patients should be provided with appropriate legal advice if asbestos exposure occurred as a result of negligent exposure.

Berylliosis

The presence of cough, progressive breathlessness, night sweats and arthralgia in a worker exposed to dusts, fumes or vapours containing beryllium should

Fig. 19.56 Asbestos exposure. The range of possible effects on the respiratory tract.

raise suspicions of chronic berylliosis. The radiographic appearances are similar in type and distribution to sarcoid and biopsy shows sarcoid-like granulomas.

Lung diseases due to systemic inflammatory disease

Acute respiratory distress syndrome

See page 187.

Respiratory involvement in connective tissue disorders

Pulmonary complications of connective tissue disease are common, affecting the airways, the alveoli, the pulmonary vasculature, the diaphragm and chest wall muscles, and the chest wall itself. In some instances, pulmonary disease may precede the appearance of the connective tissue disorder (Box 19.90). Indirect associations between connective tissue disorders and respiratory complications include those due to disease in other organs, e.g. thrombocytopenia causing haemoptysis, pulmonary toxic effects of drugs used to treat the connective tissue disorder (e.g. gold and methotrexate), and secondary infection due to the disease itself, neutropenia or immunosuppressive drug regimens.

Rheumatoid arthritis

Pulmonary involvement is important, accounting for around 10–20% of the mortality associated with the condition (p. 1088). The majority of cases occur within 5 years of the rheumatological diagnosis but pulmonary manifestations may precede joint involvement in 10–20%. Pulmonary fibrosis is the most common pulmonary manifestation. All forms of interstitial disease have been described but NSIP (see Box 19.81, p. 708) is probably the most common.

Pleural effusion is common, especially in men with seropositive disease. Effusions are usually small and unilateral but can be large and bilateral. Most resolve spontaneously. Biochemical testing reveals an exudate with markedly reduced glucose levels and raised LDH. Effusions that fail to resolve spontaneously may respond

to a short course of oral prednisolone (30–40 mg daily) but some become chronic.

Rheumatoid pulmonary nodules are usually asymptomatic and detected incidentally on imaging. They are usually multiple and subpleural in site (Fig. 19.57). Solitary nodules can mimic primary bronchial carcinoma and, when multiple, the differential diagnoses include pulmonary metastatic disease. Cavitation raises the possibility of tuberculosis and predisposes to pneumothorax. The combination of rheumatoid nodules and pneumoconiosis is known as Caplan's syndrome (p. 712).

Bronchitis and bronchiectasis are both more common in rheumatoid arthritis. Rarely, the potentially fatal condition called obliterative bronchiolitis may develop. Bacterial lower respiratory tract infections are frequent. Treatments given for rheumatoid arthritis may also be relevant; corticosteroid therapy predisposes to infections, methotrexate may cause pulmonary fibrosis, and anti-TNF therapy may precipitate the reactivation of tuberculosis.

Fig. 19.57 Rheumatoid (necrobiotic) nodules. Thoracic CT just below the level of the main carina showing the typical appearance of peripheral, pleural-based nodules. The nodule in the left lower lobe shows characteristic cavitation.

19.90 Respiratory complications of connective tissue disorders

Disorder	Airways	Parenchyma	Pleura	Diaphragm and chest wall
Rheumatoid arthritis	Bronchitis, obliterative bronchiolitis, bronchiectasis, crico-arytenoid arthritis, stridor	Pulmonary fibrosis, nodules, upper lobe fibrosis, infections	Pleurisy, effusion, pneumothorax	Poor healing of intercostal drain sites
Systemic lupus erythematosus	–	Pulmonary fibrosis, 'vasculitic' infarcts	Pleurisy, effusion	Diaphragmatic weakness (shrinking lungs)
Systemic sclerosis	Bronchiectasis	Pulmonary fibrosis, aspiration pneumonia	–	Cutaneous thoracic restriction (hidebound chest)
Dermatomyositis/polymyositis	Bronchial carcinoma	Pulmonary fibrosis	–	Intercostal and diaphragmatic myopathy
Rheumatic fever	–	Pneumonia	Pleurisy, effusion	–

Systemic lupus erythematosus (SLE)

Pleuropulmonary involvement is more common in SLE (p. 1107) than in any other connective tissue disorder and may be a presenting problem, when it is sometimes attributed incorrectly to infection or pulmonary embolism. Up to two-thirds of patients have repeated episodes of pleurisy, with or without effusions. Effusions may be bilateral and may also involve the pericardium.

The most serious manifestation of lupus is an acute alveolitis that may be associated with diffuse alveolar haemorrhage. This condition is life-threatening and requires immunosuppression.

Pulmonary fibrosis is a relatively uncommon manifestation. Some patients present with exertional dyspnoea and orthopnoea but without overt signs of pulmonary fibrosis. The chest X-ray reveals elevated diaphragms, and pulmonary function testing shows reduced lung volumes. This condition has been described as 'shrinking lungs' and attributed to diaphragmatic myopathy.

SLE patients with antiphospholipid antibodies are at increased risk of venous and pulmonary thromboembolism and these patients require life-long anticoagulation.

Systemic sclerosis

Most patients with systemic sclerosis (p. 1109) eventually develop diffuse pulmonary fibrosis; at necropsy more than 90% have evidence of lung fibrosis. In some patients, it is indolent, but when progressive, as in IPF, the median survival time is around 4 years. Pulmonary fibrosis is rare in the CREST variant of progressive systemic sclerosis but pulmonary hypertension is an important complication.

Other pulmonary complications include recurrent aspiration pneumonias secondary to oesophageal disease. Rarely, sclerosis of the skin of the chest wall may be so extensive and cicatrising as to restrict chest wall movement: the so-called 'hidebound chest'.

Pulmonary eosinophilia and vasculitides

Pulmonary eosinophilia refers to the association of radiographic (usually pneumonic) abnormalities and peripheral blood eosinophilia. The term encompasses a group of disorders of different aetiology (Box 19.91). Eosinophils

are the predominant cell recovered in sputum or BAL and their products are likely to be the prime mediators of tissue damage.

Acute eosinophilic pneumonia

Acute eosinophilic pneumonia is an acute febrile illness of less than 5 days' duration, characterised by diffuse pulmonary infiltrates and hypoxic respiratory failure. The pathology is usually that of diffuse alveolar damage. Diagnosis is confirmed by BAL, which characteristically demonstrates > 25% eosinophils. The condition is usually idiopathic but drug reactions should be considered. Corticosteroids invariably induce prompt and complete resolution.

Chronic eosinophilic pneumonia

Chronic eosinophilic pneumonia typically presents in an insidious manner with malaise, fever, weight loss, breathlessness and unproductive cough. It is more common in middle-aged females. The classical chest X-ray appearance has been likened to the photographic negative of pulmonary oedema with bilateral, peripheral and predominantly upper lobe parenchymal shadowing. The peripheral blood eosinophil count is almost always very high, and the ESR and total serum IgE are elevated. BAL reveals a high proportion of eosinophils in the lavage fluid. Response to prednisolone (20–40 mg daily) is usually dramatic. Prednisolone can usually be withdrawn after a few weeks without relapse, but long-term low-dose therapy is occasionally necessary.

Tropical pulmonary eosinophilia

Tropical pulmonary eosinophilia occurs as a result of a mosquito-borne filarial infection with *Wuchereria bancrofti* or *Brugia malayi*. The condition presents with

19.91 Pulmonary eosinophilia

Extrinsic (cause known)

- Helminths: e.g. *Ascaris*, *Toxocara*, *Filaria*
- Drugs: nitrofurantoin, para-aminosalicylic acid (PAS), sulfasalazine, imipramine, chlorpropamide, phenylbutazone
- Fungi: e.g. *Aspergillus fumigatus* causing allergic bronchopulmonary aspergillosis (p. 696)

Intrinsic (cause unknown)

- Cryptogenic eosinophilic pneumonia
- Churg–Strauss syndrome (diagnosed on the basis of four or more of the following features: asthma, peripheral blood eosinophilia > $1.5 \times 10^9/L$ (or > 10% of a total white cell count), mononeuropathy or polyneuropathy, pulmonary infiltrates, paranasal sinus disease or eosinophilic vasculitis on biopsy of an affected site)
- Hypereosinophilic syndrome
- Polyarteritis nodosa (p. 1113; rare)

19.92 Interstitial lung disease in old age

- **Idiopathic pulmonary fibrosis:** the most common interstitial lung disease, with a worse prognosis.
- **Chronic aspiration pneumonitis:** must always be considered in elderly patients presenting with bilateral basal shadowing on a chest X-ray.
- **Wegener's granulomatosis:** a rare condition but more common in old age. Renal involvement is more common at presentation and upper respiratory problems are fewer.
- **Asbestosis:** symptoms may only appear in old age because of the prolonged latent period between exposure and disease.
- **Drug-induced interstitial lung disease:** more common, presumably because of the increased chance of exposure to multiple drugs.
- **Rarer interstitial disease:** sarcoidosis, idiopathic pulmonary haemosiderosis, alveolar proteinosis and eosinophilic pneumonia rarely present.
- **Increased dyspnoea:** coexistent muscle weakness, chest wall deformity (e.g. thoracic kyphosis) and deconditioning may all exacerbate dyspnoea associated with interstitial lung disease.
- **Surgical lung biopsy:** often inappropriate in the very frail. A diagnosis therefore frequently depends on clinical and HRCT findings alone.

fever, weight loss, dyspnoea and asthma-like symptoms. Peripheral blood eosinophilia is marked, as is the elevation of total IgE. High antifilarial antibody titres are seen. The diagnosis may be confirmed by a response to treatment with diethylcarbamazine (6 mg/kg/day for 3 weeks). Important differential diagnoses include infection with *Strongyloides stercoralis* (p. 365), *Ascaris* ('larva migrans', p. 365) and other hookworm infestation (p. 364).

Wegener's granulomatosis

Wegener's granulomatosis is a rare vasculitic and granulomatous condition (p. 1113). The lung is commonly involved in systemic forms of the condition but a limited pulmonary form may also occur. Respiratory symptoms include cough, haemoptysis and chest pain. Associated upper respiratory tract manifestations include nasal discharge and crusting, and otitis media. Fever, weight loss and anaemia are common. Radiological features include multiple nodules and cavitation which may resemble primary or metastatic carcinoma, or a pulmonary abscess. Tissue biopsy confirms the distinctive pattern of necrotising granulomas and necrotising vasculitis. Other respiratory complications include tracheal subglottic stenosis and saddle nose deformity. The differential diagnoses include mycobacterial and fungal infection and other forms of pulmonary vasculitis (p. 1112), including polyarteritis nodosa (pulmonary infarction), microscopic polyangiitis, Churg–Strauss syndrome, necrotising sarcoid, bronchocentric granulomatosis, lymphomatoid granulomatosis and cavitating tumours.

Goodpasture's syndrome

This describes the association of pulmonary haemorrhage and glomerulonephritis, in which IgG antibodies bind to the glomerular or alveolar basement membranes (see Box 17.40, p. 502). Pulmonary disease usually precedes renal involvement and includes radiographic infiltrates and hypoxia with or without haemoptysis. It occurs more commonly in men and almost exclusively in smokers.

Lung diseases due to irradiation and drugs

Radiotherapy

Targeting radiotherapy to certain tumours is inevitably accompanied by irradiation of normal lung tissue. Although delivered in divided doses, the effects are cumulative. Acute radiation pneumonitis is typically seen within 6–12 weeks and presents with cough and dyspnoea. This may resolve spontaneously but responds to corticosteroid treatment. Chronic interstitial fibrosis may present several months later with symptoms of exertional dyspnoea and cough. Changes are often confined to the area irradiated but may be bilateral. Established post-irradiation fibrosis does not usually respond to corticosteroid treatment. The pulmonary effects of radiation (p. 272) are exacerbated by treatment with cytotoxic drugs, and the phenomenon of 'recall pneumonitis' describes the appearance of radiation injury in a previously irradiated area when chemother-

19.93 Drug-induced respiratory disease

Non-cardiogenic pulmonary oedema (ARDS)

- Hydrochlorothiazide
- Thrombolytics (streptokinase)
- I.v. β -adrenoceptor agonists (e.g. for premature labour)
- Aspirin and opiates (in overdose)

Non-eosinophilic alveolitis

- Amiodarone, flecainide, gold, nitrofurantoin, cytotoxic agents—especially bleomycin, busulfan, mitomycin C, methotrexate, sulfasalazine

Pulmonary eosinophilia

- Antimicrobials (nitrofurantoin, penicillin, tetracyclines, sulphonamides, nalidixic acid)
- Antirheumatic agents (gold, aspirin, penicillamine, naproxen)
- Cytotoxic drugs (bleomycin, methotrexate, procarbazine)
- Psychotropic drugs (chlorpromazine, dosulepin, imipramine)
- Anticonvulsants (carbamazepine, phenytoin)
- Others (sulfasalazine, nadolol)

Pleural disease

- Bromocriptine, amiodarone, methotrexate, methysergide
- Induction of SLE—phenytoin, hydralazine, isoniazid

Asthma

- Pharmacological mechanisms (β -blockers, cholinergic agonists, aspirin and NSAIDs)
- Idiosyncratic reactions (tamoxifen, dipyridamole)

apy follows radiotherapy. If the patient survives, there are long-term risks of lung cancer.

Drugs

Drugs may cause a number of parenchymal reactions, including ARDS, eosinophilic reactions and diffuse interstitial inflammation/scarring (Box 19.93). Drugs can also cause other lung disorders, including asthma, haemorrhage (e.g. anticoagulants, penicillamine) and occasionally pleural effusions and pleural thickening. An ARDS-like syndrome of acute non-cardiogenic pulmonary oedema may present with dramatic onset of breathlessness, severe hypoxaemia and signs of alveolar oedema on the chest X-ray.

Pulmonary fibrosis may occur in response to a variety of drugs, but is seen most frequently with bleomycin, methotrexate, amiodarone and nitrofurantoin. The pathogenesis of drug-induced eosinophilic pulmonary reactions may be an immune reaction similar to that in hypersensitivity pneumonitis, which specifically attracts large numbers of eosinophils into the lungs. Patients usually present with breathlessness, cough and fever. The chest X-ray characteristically shows patchy shadowing. Most cases resolve completely on withdrawal of the drug, but if the reaction is severe, rapid resolution can be obtained with corticosteroids.

Rare interstitial lung diseases

See Box 19.94.

<div> <div>i</div> <div>19.94 Rare interstitial lung diseases</div> </div>			
Disease	Presentation	Chest X-ray	Course
Idiopathic pulmonary haemosiderosis	Haemoptysis, breathlessness, anaemia	Bilateral infiltrates often perihilar Diffuse pulmonary fibrosis	Rapidly progressive in children Slow progression or remission in adults Death from massive pulmonary haemorrhage or cor pulmonale and respiratory failure
Alveolar proteinosis	Breathlessness and cough Occasionally fever, chest pain and haemoptysis	Diffuse bilateral shadowing, often more pronounced in the hilar regions Air bronchogram	Spontaneous remission in one-third Whole-lung lavage or granulocyte macrophage-colony stimulating factor (GM-CSF) therapy may be effective
Langerhans cell histiocytosis (histiocytosis X)	Breathlessness, cough, pneumothorax	Diffuse interstitial shadowing progressing to honeycombing	Course unpredictable but may progress to respiratory failure Smoking cessation may be followed by significant improvement Poor response to immunosuppressive treatment
Neurofibromatosis	Breathlessness and cough in a patient with multiple organ involvement with neurofibromas including skin	Bilateral reticulonodular shadowing of diffuse interstitial fibrosis	Slow progression to death from respiratory failure Poor response to corticosteroid therapy
Alveolar microlithiasis	May be asymptomatic Breathlessness and cough	Diffuse calcified micronodular shadowing more pronounced in the lower zones	Slowly progressive to cor pulmonale and respiratory failure May stabilise in some
Lymphangioleiomyomatosis	Haemoptysis, breathlessness, pneumothorax and chylous effusion in females	Diffuse bilateral shadowing CT shows characteristic thin-walled cysts with well-defined walls throughout both lungs	Progressive to death within 10 years Oestrogen ablation and progesterone therapy of doubtful value Consider lung transplantation
Pulmonary tuberous sclerosis	Very similar to lymphangioleiomyomatosis except occasionally occurs in men		

PULMONARY VASCULAR DISEASE

Venous thromboembolism (VTE)

Deep venous thrombosis (DVT, p. 1004) and pulmonary embolism (PE) can be considered under this heading. The majority (79%) of pulmonary emboli arise from the propagation of lower limb DVT. Rare causes include septic emboli (from endocarditis affecting the tricuspid or pulmonary valves), tumour (especially choriocarcinoma), fat, air, amniotic fluid and placenta.

The incidence of VTE in the community is unknown; it occurs in approximately 1% of all patients admitted to hospital and accounts for around 5% of in-hospital deaths. It is a common mode of death in patients with cancer, stroke and pregnancy.

Clinical features

VTE can be difficult to diagnose. It may be helpful to consider the following:

- Is the clinical presentation consistent with PE?
- Does the patient have risk factors for PE?
- Are there any alternative diagnoses that can explain the patient's presentation?

Presentation varies depending on the number, size and distribution of emboli, and the underlying cardiorespiratory reserve (Box 19.95). A recognised risk factor is present in between 80% and 90% of patients (Box 19.96). The presence of one or more risk factors may multiply the risk.

Investigations

Chest radiography

A variety of non-specific appearances have been described (Fig. 19.58) but the chest X-ray is most useful in excluding key differential diagnoses, e.g. pneumonia or pneumothorax. Normal appearances in an acutely breathless and hypoxaemic patient should raise the suspicion of PE, as should bilateral changes in a patient presenting with unilateral pleuritic chest pain.

Electrocardiography

The ECG is often normal but is useful in excluding other important differential diagnoses such as acute myocardial infarction and pericarditis. The most common abnormalities in PE include sinus tachycardia and anterior T-wave inversion but are non-specific; larger emboli may cause right heart strain revealed by an $S_1Q_3T_3$ pattern, ST-segment and T-wave changes, or the appearance of right bundle branch block.

Arterial blood gases

Arterial blood gases typically show a reduced PaO_2 , a normal or low $PaCO_2$, and an increased alveolar-arterial oxygen gradient, but may be normal in a significant minority. A metabolic acidosis may be seen in acute massive PE with cardiovascular collapse.

D-dimer and other circulating markers

D-dimer is a specific degradation product released into the circulation when cross-linked fibrin undergoes

19.95 Features of pulmonary thromboemboli

	Acute massive PE	Acute small/medium PE	Chronic PE
Pathophysiology	Major haemodynamic effects: ↓cardiac output; acute right heart failure	Occlusion of segmental pulmonary artery → infarction ± effusion	Chronic occlusion of pulmonary microvasculature, right heart failure
Symptoms	Faintness or collapse, crushing central chest pain, apprehension, severe dyspnoea	Pleuritic chest pain, restricted breathing, haemoptysis	Exertional dyspnoea. Late symptoms of pulmonary hypertension or right heart failure
Signs	Major circulatory collapse: tachycardia, hypotension, ↑JVP, right ventricular gallop rhythm, loud P ₂ , severe cyanosis, ↓urinary output	Tachycardia, pleural rub, raised hemidiaphragm, crackles, effusion (often blood-stained), low-grade fever	May be minimal early in disease. Later: RV heave, loud P ₂ . Terminal: signs of right heart failure
Chest X-ray	Usually normal. May be subtle oligoemia	Pleuropulmonary opacities, pleural effusion, linear shadows, raised hemidiaphragm	Enlarged pulmonary artery trunk, enlarged heart, prominent RV
ECG	S ₁ Q ₃ T ₃ anterior T-wave inversion, right bundle branch block (RBBB)	Sinus tachycardia	RV hypertrophy and strain
Arterial blood gases	Markedly abnormal with ↓PaO ₂ and ↓PaCO ₂ . Metabolic acidosis	May be normal or ↓PaO ₂ or ↓PaCO ₂	Exertional ↓PaO ₂ or desaturation on formal exercise testing
Alternative diagnoses	Myocardial infarction, pericardial tamponade, aortic dissection	Pneumonia, pneumothorax, musculoskeletal chest pain	Other causes of pulmonary hypertension

19.96 Risk factors for venous thromboembolism

Surgery	
• Major abdominal/pelvic surgery	• Post-operative intensive care
• Hip/knee surgery	
Obstetrics	
• Pregnancy/puerperium	
Cardiorespiratory disease	
• COPD	• Other disabling disease
• Congestive cardiac failure	
Lower limb problems	
• Fracture	• Stroke/spinal cord injury
• Varicose veins

• Abdominal/pelvic	• Concurrent chemotherapy
• Advanced/metastatic	
Miscellaneous	
• Increasing age	• Thrombotic disorders (Ch. 24)
• Previous proven VTE	• Trauma
• Immobility	

endogenous fibrinolysis (p. 992). An elevated D-dimer is of limited value, as it occurs in a number of conditions including PE, myocardial infarction, pneumonia and sepsis. However, low D-dimer levels (< 500 ng/mL measured by ELISA), particularly where clinical risk is low, have a high negative predictive value and further investigation is unnecessary (Fig. 19.59). The D-dimer result should be disregarded in high-risk patients, as further investigation is mandatory even if it is normal. Other circulating markers that reflect right ventricular

micro-infarction, such as troponin I and brain natriuretic peptide, are under investigation.

Imaging

A range of imaging techniques can be used to confirm suspected PE. The choice depends on the clinical probability of VTE, the condition of the patient, local availability, risks from iodinated contrast medium, radiation exposure and the associated costs.

CT pulmonary angiography (CTPA, Fig. 19.60) is the most commonly sought first-line diagnostic test. It has the advantage of visualising the distribution and extent of the emboli, or highlighting alternative diagnoses such as consolidation, pneumothorax or aortic dissection. The sensitivity of CT may be increased by simultaneous visualisation of the femoral and popliteal veins. As contrast may be nephrotoxic, care should be taken in patients with renal impairment and the use of iodinated contrast media should be avoided in those with a history of allergy to it.

Ventilation-perfusion scanning is less commonly used, as its utility is limited in patients with pre-existing chronic cardiopulmonary pathology and the scan is most frequently regarded as indeterminate. It is most useful in patients without significant cardiopulmonary disease and a normal chest X-ray; interpretation should be informed by clinical probability.

Colour Doppler ultrasound of the leg veins remains the investigation of choice in patients with suspected DVT, but may also be applied to patients in whom PE is suspected, particularly if there are clinical signs in a limb, as many will have identifiable proximal thrombus in the leg veins.

Echocardiography

Bedside echocardiography is extremely helpful in the differential diagnosis and assessment of acute circulatory collapse (p. 541). Acute dilatation of the right heart

Fig. 19.58 Features of pulmonary thromboembolism/infarction on chest X-ray.

is usually present in massive PE, and thrombus (embolism in transit) may be visible. Alternative diagnoses, including left ventricular failure, aortic dissection and pericardial tamponade, can also be established.

Pulmonary angiography

Conventional pulmonary angiography has been largely superseded by CTPA but may still be used in selected settings or for delivering catheter-based therapies.

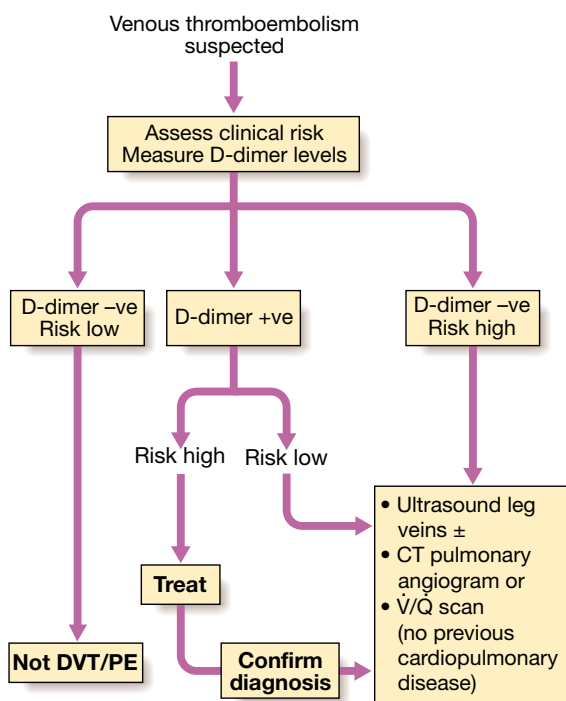

Fig. 19.59 Algorithm for the investigation of patients with suspected pulmonary thromboembolism. Clinical risk is based on the presence of risk factors for VTE and the probability of another diagnosis.

Management

General measures

Prompt recognition and treatment are potentially life-saving. Oxygen should be given to all hypoxaemic patients at a concentration necessary to maintain arterial oxygen saturation above 90%. Circulatory shock should be treated with intravenous fluids or plasma expander, but inotropic agents are of limited value, as the hypoxic dilated right ventricle is near maximally stimulated by endogenous catecholamines. Diuretics and vasodilators should also be avoided, as they will reduce cardiac output. Opiates may be necessary to relieve pain and distress but should be used with caution in the hypotensive patient. Resuscitation by external cardiac massage may be successful in the moribund patient by dislodging and breaking up a large central embolus.

Fig. 19.60 CT pulmonary angiogram. The arrow points to a saddle embolism in the bifurcation of the pulmonary artery.

Anticoagulation

Anticoagulation should be commenced immediately in patients with a high or intermediate probability, but may be safely withheld in patients with low clinical probability pending investigation. Heparin reduces further propagation of clot, the risk of further emboli, and lowers mortality. It is most easily administered as subcutaneous low molecular weight heparin. The dose is based on the patient's weight and there is usually no requirement to monitor tests of coagulation (p. 1005). The duration of LMWH treatment should be at least 5 days, during which time oral warfarin is commenced. LMWH should not be discontinued until the international normalised ratio (INR) is greater than 2.

Patients with a persistent prothrombotic risk or a history of previous emboli should be anticoagulated for life, whereas those with an identifiable and reversible risk factor usually require only 3 months of therapy. If the condition is idiopathic or risk factors are weak, anticoagulation for 6 months is recommended, although the appropriate duration is unclear. Long-term, low-intensity warfarin therapy (target INR 1.5–2.0) appears to be associated with reduced risk of bleeding and may prevent recurrent thromboembolism (p. 1005). The role of D-dimer and right heart function in decision-making on duration of anticoagulation is currently being examined.

Thrombolytic therapy

Thrombolysis is indicated in any patient presenting with acute massive PE accompanied by cardiogenic shock. In the absence of shock, the benefits are less clear but it may be considered in patients presenting with right ventricular dilatation and hypokinesia or severe hypoxaemia. Patients must be screened carefully for haemorrhagic risk, as there is a high risk of intracranial haemorrhage. Surgical pulmonary embolectomy may be considered in selected patients but carries a high mortality risk.

Caval filters

A patient in whom anticoagulation is contraindicated, who has suffered massive haemorrhage on anticoagulation, or recurrent VTE despite anticoagulation, should be considered for an inferior vena caval filter. The introduction of retrievable caval filters has been useful in patients with temporary risk factors.

**19.97 VTE and pregnancy**

- **Maternal mortality:** VTE is the leading cause.
- **CTPA:** may be performed safely with fetal shielding (0.01–0.06 mGy). It is important to consider the risk of radiation to breast tissue (particularly if family history of breast carcinoma) and the risk of iodinated contrast media to mother and fetus (neonatal hypothyroidism).
- **V/Q scanning:** greater radiation dose to fetus (0.11–0.22 mGy) but less to maternal breast tissue.
- **In utero radiation exposure:** estimated incidence of childhood malignancy is about 1 in 16 000 per mGy.
- **Warfarin:** teratogenic, so VTE should be treated with LMWH during pregnancy.

Prognosis

Patients who have suffered symptomatic VTE carry an increased risk of further events, particularly if a persisting risk factor is present. The risk of recurrence is highest in the first 6–12 months after the initial event, and by follow-up at 10 years just under one-third of patients may have suffered a further event. Risks of recurrent VTE are lowest in those with temporary or reversible risk factors.

The immediate mortality is greatest in those with echocardiographic evidence of right ventricular dysfunction or cardiogenic shock. The vast majority of patients attain normal right heart function by 3 weeks but persisting pulmonary hypertension may be present in around 4% of patients by 2 years. A minority progress to overt right ventricular failure.

Pulmonary hypertension

Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure > 25 mmHg at rest or 30 mmHg with exercise. Pulmonary arterial hypertension (PAH) also requires the presence of a pulmonary capillary wedge pressure ≤ 15 mmHg and a pulmonary vascular resistance ≥ 240 dynes/s/cm⁵. The causes of pulmonary hypertension by site of pathology are listed in Box 19.98.

**19.98 Classification of pulmonary hypertension****Pulmonary arterial hypertension**

- Primary pulmonary hypertension: sporadic and familial
- Related to: connective tissue disease (limited cutaneous systemic sclerosis), congenital systemic to pulmonary shunts, portal hypertension, HIV infection, exposure to various drugs or toxins, and persistent pulmonary hypertension of the newborn

Pulmonary venous hypertension

- Left-sided atrial or ventricular heart disease
- Left-sided valvular heart disease
- Pulmonary veno-occlusive disease
- Pulmonary capillary haemangiomatosis

Pulmonary hypertension associated with disorders of the respiratory system and/or hypoxaemia

- COPD
- DPLD
- Sleep-disordered breathing
- Alveolar hypoventilation disorders
- Chronic exposure to high altitude
- Neonatal lung disease
- Alveolar capillary dysplasia
- Severe kyphoscoliosis

Pulmonary hypertension caused by chronic thromboembolic disease

- Thromboembolic obstruction of the proximal pulmonary arteries
- In situ thrombosis
- Sickle cell disease

Miscellaneous

- Inflammatory conditions
- Extrinsic compression of central pulmonary veins

Further classification is based on the degree of functional disturbance according to the New York Heart Association (NYHA) grades I–IV. Although respiratory failure due to intrinsic pulmonary disease is the most common cause of pulmonary hypertension, severe pulmonary hypertension may occur as a primary disorder, as a complication of connective tissue disease (e.g. systemic sclerosis), or as a result of chronic thromboembolic events.

Primary pulmonary hypertension (PPH) is a rare but important disease that affects young people, predominantly women, aged between 20 and 30 years. Familial disease is rarer still, but is known to be associated with mutations in the gene encoding type II bone morphogenetic protein receptor (BMPR2), a member of the TGF- β superfamily. Mutations in this gene have been identified in some patients with sporadic pulmonary hypertension.

Pathological features include hypertrophy of both the media and intima of the vessel wall, and a clonal expansion of endothelial cells which take the appearance of plexiform lesions. There is marked narrowing of the vessel lumen and this together with the frequently observed in situ thrombosis leads to an increase in pulmonary vascular resistance and pulmonary hypertension.

Clinical features

Pulmonary hypertension presents insidiously and is often diagnosed late. Typical symptoms include breathlessness, chest pain, fatigue, palpitation and syncope. Important signs include elevation of the JVP (with a prominent 'a' wave if in sinus rhythm), a parasternal heave (RV hypertrophy), accentuation of the pulmonary component of the second heart sound and a right ventricular third heart sound.

Investigations

Pulmonary hypertension may be suspected if an ECG show a right ventricular 'strain' pattern or a chest X-ray shows enlarged pulmonary arteries, peripheral pruning and right ventricle enlargement. Confirmation is by transthoracic echocardiography; Doppler assessment of the tricuspid regurgitant jet provides a non-invasive estimate of the pulmonary artery pressure. Further assessment should be undertaken in specialist centres that can perform right heart catheterisation to assess pulmonary haemodynamics and measure vasodilator responsiveness, to guide further therapy.

Management

Pulmonary hypertension is incurable but new treatments have delivered significant improvements in exercise performance, symptoms and prognosis. All patients should be anticoagulated with warfarin, and oxygen, diuretics and digoxin prescribed as appropriate. Specific treatment options include high-dose calcium channel blockers, prostaglandins such as epo-prostenol (prostacyclin) or iloprost therapy, the PDE5 inhibitor sildenafil, and the oral endothelin antagonist bosentan. Selected patients can be referred for heart-lung transplantation, and pulmonary thromboendarterectomy may be contemplated in those with chronic proximal pulmonary thromboembolic disease. Atrial septostomy (the creation of a right to left shunt) decompresses the right ventricle and improves haemodynamic performance at the expense of shunting and hypoxaemia.

19.99 Thromboembolic disease in old age

- **Risk:** rises by a factor of 2.5 over the age of 60 years.
- **Prophylaxis for VTE:** should be considered in all older patients who are immobile as a result of acute illness, except when this is due to acute stroke.
- **Association with cancer:** the prevalence of cancer among those with DVT increases with age but the relative risk of malignancy with DVT falls; therefore intensive investigation is not justified if initial assessment reveals no evidence of an underlying neoplasm.
- **Warfarin:** older patients are more sensitive to the anticoagulant effects of warfarin, partly due to the concurrent use of other drugs and the presence of other pathology. Life-threatening or fatal bleeds on warfarin are significantly more common in those aged over 80 years.
- **Chronic immobility:** long-term anticoagulant therapy is not required as there is no associated increase in thromboembolism.

DISEASES OF THE UPPER AIRWAY

Diseases of the nasopharynx

Allergic rhinitis

This is a disorder in which there are episodes of nasal congestion, watery nasal discharge and sneezing. It may be seasonal or perennial.

Aetiology

Allergic rhinitis is due to an immediate hypersensitivity reaction in the nasal mucosa. Seasonal antigens include pollens from grasses, flowers, weeds or trees. Grass pollen is responsible for hay fever, the most common type of seasonal allergic rhinitis in northern Europe, which is at its peak between May and July. This is, however, a world-wide problem, which may be aggravated during harvest seasons.

Perennial allergic rhinitis may be a specific reaction to antigens derived from house dust, fungal spores or animal dander, but similar symptoms can be caused by physical or chemical irritants—for example, pungent odours or fumes, including strong perfumes, cold air and dry atmospheres. The term 'vasomotor rhinitis' is often used in this context, as the term 'allergic' is a misnomer.

Clinical features

In the seasonal type, there are frequent sudden attacks of sneezing, with profuse watery nasal discharge and nasal obstruction. These attacks last for a few hours and are often accompanied by smarting and watering of the eyes and conjunctival infection. In perennial rhinitis, the symptoms are similar but more continuous and generally less severe. Skin hypersensitivity tests with the relevant antigen are usually positive in seasonal allergic rhinitis, but are less useful in perennial rhinitis.

Prevention

In those sensitised to house dust, simple measures such as thorough dust removal from the bed area, leaving a

window open and renewing old pillows are often helpful. Avoidance of pollen and antigens from domestic pets, however desirable and beneficial, is usually impractical.

Management

The following medications, singly or in combination, are usually effective in both seasonal and perennial allergic rhinitis:

- an antihistamine such as loratadine
- sodium cromoglicate nasal spray
- nasal steroid spray, e.g. beclomethasone dipropionate, fluticasone, mometasone or budesonide.

In patients whose symptoms are very severe and seriously interfering with school, business or social activities, systemic corticosteroids are occasionally indicated, but side-effects limit their usefulness. Vasomotor rhinitis is often difficult to treat, but may respond to ipratropium bromide, administered into each nostril 6–8-hourly.

Sleep-disordered breathing

A variety of respiratory disorders affect sleep or are affected by sleep. Cough and wheeze disturbing sleep are characteristic of asthma, while the hypoventilation that accompanies normal sleep can precipitate respiratory failure in patients with disordered ventilation due to kyphoscoliosis, diaphragmatic palsy or muscle disease (e.g. muscular dystrophy).

In contrast, a small but important group of disorders cause problems only during sleep. Patients with these may have normal lungs and daytime respiratory function, but during sleep have either abnormalities of ventilatory drive (central sleep apnoea) or upper airway obstruction (obstructive sleep apnoea). Of these, the obstructive sleep apnoea/hypopnoea syndrome is by far the most common and important. When this coexists with COPD, severe respiratory failure can result even if the COPD is mild.

The sleep apnoea/hypopnoea syndrome

It is now recognised that 2–4% of the middle-aged population suffer from recurrent upper airway obstruction during sleep. The ensuing sleep fragmentation causes daytime sleepiness, especially in monotonous situations, resulting in a threefold increased risk of road traffic accidents and a ninefold increased risk of single-vehicle accidents.

Aetiology

Sleep apnoea results from recurrent occlusion of the pharynx during sleep, usually at the level of the soft palate. Inspiration results in negative pressure within the pharynx. During wakefulness, upper airway dilating muscles, including palatoglossus and genioglossus, contract actively during inspiration to preserve airway patency. During sleep, muscle tone declines, impairing the ability of these muscles to maintain pharyngeal patency. In a minority of people, a combination of an anatomically narrow palatopharynx and underactivity of the dilating muscles during sleep results in inspiratory airway obstruction. Incomplete obstruction causes turbulent flow, resulting in snoring (around 40% of middle-aged

men and 20% of middle-aged women snore). More severe obstruction triggers increased inspiratory effort and transiently wakes the patient, allowing the dilating muscles to re-open the airway. These awakenings are so brief that patients have no recollection of them. After a series of loud deep breaths that may wake their bed partner, the patient rapidly returns to sleep, snores and becomes apnoeic once more. This cycle of apnoea and awakening may repeat itself many hundreds of times per night and results in severe sleep fragmentation and secondary variations in blood pressure, which may predispose over time to sustained hypertension, coronary events and stroke.

Predisposing factors to the sleep apnoea/hypopnoea syndrome include being male, which doubles the risk probably due to a testosterone effect on the upper airway, and obesity, found in about half of patients, because parapharyngeal fat deposits tend to narrow the pharynx. Nasal obstruction or a recessed mandible can further exacerbate the problem. Acromegaly and hypothyroidism also predispose by causing submucosal infiltration and narrowing of the upper airway. Sleep apnoea is often familial, and in these families the maxilla and mandible are back-set, narrowing the upper airway. Alcohol and sedatives predispose to snoring and apnoea by relaxing the upper airway dilating muscles.

Clinical features

Excessive daytime sleepiness is the principal symptom and snoring is virtually universal. The patient usually feels that he or she has been asleep all night but wakes unrefreshed. Bed partners report loud snoring in all body positions and will often have noticed multiple breathing pauses (apnoeas). Difficulty with concentration, impaired cognitive function and work performance, depression, irritability and nocturia are other features.

Investigations

Provided that the sleepiness does not result from inadequate time in bed or from shift work and so on, any person who repeatedly falls asleep during the day when not in bed, who complains that his or her work is impaired by sleepiness, or who is a habitual snorer with multiple witnessed apnoeas should be referred to a respiratory specialist for a sleep assessment. A more quantitative assessment of daytime sleepiness can be obtained by questionnaire (Box 19.100).

Overnight studies of breathing, oxygenation and sleep quality are diagnostic (Fig. 19.61) but the appropriate level of investigations depends on local resources and the probability of the diagnosis. The current threshold for diagnosing the sleep apnoea/hypopnoea syndrome is 15 apnoeas/hypopnoeas per hour of sleep, where an apnoea is a 10-second or longer breathing pause and a hypopnoea a 10-second or longer 50% reduction in breathing.

Differential diagnosis

Several other conditions can cause daytime sleepiness but can usually be excluded by a careful history (Box 19.101). Narcolepsy is a rare cause of sleepiness, occurring in 0.05% of the population (p. 1179). Idiopathic hypersomnolence occurs in younger individuals and is characterised by long nocturnal sleeps.

19.100 Epworth sleepiness scale

How likely are you to doze off or fall asleep in the situations described below? Use the following scale to choose the most appropriate number for each situation:

- 0 = would never doze
- 1 = slight chance of dozing
- 2 = moderate chance of dozing
- 3 = high chance of dozing

- Sitting and reading
- Watching TV
- Sitting, inactive in a public place (e.g. a theatre or a meeting)
- As a passenger in a car for an hour without a break
- Lying down to rest in the afternoon when circumstances permit
- Sitting and talking to someone
- Sitting quietly after a lunch without alcohol
- In a car, while stopped for a few minutes in the traffic

Normal subjects average 5.9 (SD 2.2) and patients with severe obstructive sleep apnoea average 16.0 (SD 4.4).

Management

The major hazard to patients and those around them is traffic accidents, so all drivers must be advised not to drive until treatment has relieved their sleepiness. In a minority, relief of nasal obstruction or the avoidance of alcohol may prevent obstruction. Advice to obese patients to lose weight is often unheeded, and the majority of patients need to use continuous positive airway pressure (CPAP) delivered by a nasal mask every night to splint the upper airway open. When CPAP is tolerated, the effect is often dramatic (see Fig. 19.61), with relief of somnolence and improved daytime performance, quality of life and survival. Unfortunately, 30–50% of patients do not tolerate CPAP. Mandibular advancement devices worn within the mouth are an alternative that is effective in some patients. There is no evidence that palatal surgery is of benefit.

Fig. 19.61 Sleep apnoea/hypopnoea syndrome: overnight oxygen saturation trace. The left-hand panel shows the trace of a 46-year-old patient when he slept without continuous positive airway pressure (CPAP) and had 53 apnoeas plus hypopnoeas/hour, 55 brief awakenings/hour and marked oxygen desaturation. The right-hand panel shows the effect of CPAP of 10 cm H₂O delivered through a tight-fitting nasal mask, which abolished his breathing irregularity and awakenings, and improved his oxygenation.

19.101 Differential diagnosis of persistent sleepiness

Lack of sleep

- Inadequate time in bed
- Extraneous sleep disruption (e.g. babies/children)
- Shift work
- Excessive caffeine intake
- Physical illness (e.g. pain)

Sleep disruption

- Sleep apnoea/hypopnoea syndrome
- Periodic limb movement disorder (recurrent limb movements during non-REM sleep, frequent nocturnal awakenings)

Sleepiness with relatively normal sleep

- Narcolepsy
- Idiopathic hypersomnolence (rare)
- Neurological lesions (e.g. hypothalamic or upper brain-stem infarcts or tumours)
- Drugs

Psychological/psychiatric

- Depression

Laryngeal disorders

Acute infections are described in Box 19.41 (p. 681). Other disorders of the larynx include chronic laryngitis, laryngeal tuberculosis, laryngeal paralysis and laryngeal obstruction. Tumours of the larynx are relatively common, particularly in smokers. For further details, the reader should refer to an otolaryngology text.

Chronic laryngitis

The common causes are listed in Box 19.102. The chief symptoms are hoarseness or loss of voice (aphonia). There is irritation of the throat and a spasmodic cough. The disease pursues a chronic course, frequently uninfluenced by treatment, and the voice may become permanently impaired. The causes of chronic hoarseness are listed in Box 19.103.

In some patients a chest X-ray may bring to light an unsuspected bronchial carcinoma or pulmonary tuberculosis. If no such abnormality is found,

19.102 Causes of chronic laryngitis

- Repeated attacks of acute laryngitis
- Excessive use of the voice, especially in dusty atmospheres
- Heavy tobacco smoking
- Mouth-breathing from nasal obstruction
- Chronic infection of nasal sinuses

19.103 Causes of chronic hoarseness

If hoarseness persists for more than a few days, consider:

- Adverse effect of inhaled corticosteroid treatment
- TB
- Laryngeal paralysis
- Tumour of the larynx

laryngoscopy should be performed, usually by a specialist in otolaryngology.

Management

When no specific treatable cause is found, the voice must be rested completely. This is particularly important in public speakers and singers. Smoking should be avoided. Some benefit may be obtained from frequent inhalations of medicated steam.

Laryngeal paralysis

Interruption of the motor nerve supply of the larynx is nearly always unilateral and, because of the intrathoracic course of the left recurrent laryngeal nerve, usually left-sided. One or both recurrent laryngeal nerves may be damaged at thyroidectomy, by carcinoma of the thyroid or by anterior neck injury. Rarely, the vagal trunk itself is involved by tumour, aneurysm or trauma.

Clinical features

- *Hoarseness* always accompanies laryngeal paralysis, whatever its cause. Paralysis of organic origin is seldom reversible, but when only one vocal cord is affected, hoarseness may improve or even disappear after a few weeks, as the normal cord compensates by crossing the midline to approximate with the paralysed cord on phonation.
- '*Bovine cough*' is a characteristic feature of organic laryngeal paralysis, and has a cow-like quality which lacks the explosive quality of normal coughing because the cords fail to close the glottis. Sputum clearance may also be impaired. A normal cough in patients with partial loss of voice or aphonia virtually excludes laryngeal paralysis.
- *Stridor* is occasionally present but seldom severe, except when laryngeal paralysis is bilateral.

Diagnosis and management

Laryngoscopy is necessary to establish the diagnosis of laryngeal paralysis with certainty. The paralysed cord lies in the so-called 'cadaveric' position, midway between abduction and adduction.

The cause of laryngeal paralysis should be treated if possible. In unilateral paralysis, persistent dysphonia may be improved by the injection of Teflon into the affected vocal cord. In bilateral organic paralysis, tracheal intubation, tracheostomy or plastic surgery on the larynx may be necessary.

Psychogenic hoarseness and aphonia

Psychogenic causes of hoarseness or complete loss of voice may be suggested by associated symptoms in the history (p. 238). However, laryngoscopy may be necessary to exclude a physical cause of the abnormality. In psychogenic aphonia, only the voluntary movement of adduction of the vocal cords is seen to be impaired. Speech therapy may be helpful.

Laryngeal obstruction

Laryngeal obstruction is more liable to occur in children than in adults because of the smaller size of the glottis. Important causes are given in Box 19.104.

19.104 Causes of laryngeal obstruction

- Inflammatory or allergic oedema, or exudate
- Spasm of laryngeal muscles
- Inhaled foreign body
- Inhaled blood clot or vomitus in an unconscious patient
- Tumours of the larynx
- Bilateral vocal cord paralysis
- Fixation of both cords in rheumatoid disease

Clinical features

Sudden complete laryngeal obstruction by a foreign body produces the clinical picture of acute asphyxia: violent but ineffective inspiratory efforts with indrawing of the intercostal spaces and the unsupported lower ribs, accompanied by cyanosis. Unrelieved, the condition progresses rapidly to coma and death within a few minutes. When, as in most cases, the obstruction is incomplete at first, the main clinical features are progressive breathlessness accompanied by stridor and cyanosis. Urgent treatment to prevent complete obstruction is needed.

Management

Transient laryngeal obstruction due to exudate and spasm, which may occur with acute pharyngitis in children (p. 681) and with whooping cough, is potentially dangerous but can usually be relieved by steam inhalation. Laryngeal obstruction from all other causes carries a high mortality and demands prompt treatment.

Relief of obstruction

When a foreign body causes laryngeal obstruction in children, it can often be dislodged by turning the patient head downwards and squeezing the chest vigorously. In adults, a sudden forceful compression of the upper abdomen (Heimlich manoeuvre) may be effective. Otherwise, the cause of the obstruction should be investigated by direct laryngoscopy, which may also permit the removal of an unsuspected foreign body or the insertion of a tube past the obstruction into the trachea. Tracheostomy must be performed without delay if these procedures fail to relieve obstruction, but except in dire emergencies this should be performed in theatre by a surgeon.

Treatment of the cause

In diphtheria, antitoxin should be administered, and for other infections the appropriate antibiotic should be given. In angioedema, complete laryngeal occlusion can usually be prevented by treatment with adrenaline (epinephrine) 0.5–1 mg (0.5–1 mL of 1:1000) i.m., chlorphenamine maleate (10–20 mg by slow i.v. injection) and intravenous hydrocortisone sodium succinate (200 mg).

Tracheal disorders

Acute tracheitis

See Box 19.41 (p. 681).

Tracheal obstruction

External compression by enlarged mediastinal lymph nodes containing metastatic deposits, usually from a bronchial carcinoma, is a more frequent cause of tracheal obstruction than the uncommon primary benign or malignant tumours. The trachea may also be compressed by a retrosternal goitre (see Fig. 19.10, p. 655). Rare causes include an aneurysm of the aortic arch and (in children) tuberculous mediastinal lymph nodes. Tracheal stenosis is an occasional complication of tracheostomy, prolonged intubation, Wegener's granulomatosis (p. 1113) or trauma.

Clinical features and management

Stridor can be detected in every patient with severe tracheal narrowing. Bronchoscopic examination of the trachea should be undertaken without delay to determine the site, degree and nature of the obstruction.

Localised tumours of the trachea can be resected, but reconstruction after resection may be technically difficult. Endobronchial laser therapy, bronchoscopically placed tracheal stents, chemotherapy and radiotherapy are alternatives to surgery. The choice of treatment depends upon the nature of the tumour and the general health of the patient. Benign tracheal strictures can sometimes be dilated but may require resection.

Tracheo-oesophageal fistula

This may be present in newborn infants as a congenital abnormality. In adults, it is usually due to malignant lesions in the mediastinum, such as carcinoma or lymphoma, eroding both the trachea and oesophagus to produce a communication between them. Swallowed liquids enter the trachea and bronchi through the fistula and provoke coughing.

Surgical closure of a congenital fistula, if undertaken promptly, is usually successful. There is usually no curative treatment for malignant fistulae, and death from overwhelming pulmonary infection rapidly supervenes.

DISEASES OF THE PLEURA, DIAPHRAGM AND CHEST WALL

Diseases of the pleura

Pleurisy

Pleurisy is not a diagnosis but a term used to describe pleuritic pain resulting from any one of a number of disease processes involving the pleura. Pleurisy is a common feature of pulmonary infection and infarction; it may also occur in malignancy.

Clinical features

Sharp pain that is aggravated by deep breathing or coughing is characteristic. On examination, rib movement is restricted and a pleural rub may be present. Sometimes this is only audible in deep inspiration or near the pericardium (pleuro-pericardial rub). The other clinical features depend on the cause. Loss of a pleural rub and diminution in the chest pain may indicate either recovery or the development of a pleural effusion.

Every patient should have a chest X-ray, but if normal, this does not exclude a pulmonary cause of pleurisy. A preceding history of cough, purulent sputum and pyrexia is presumptive evidence of a pulmonary infection which may not have been severe enough to produce a radiographic abnormality, or which may have resolved before the chest X-ray was taken.

Management

The primary cause of pleurisy must be treated. The symptomatic treatment of pleural pain is described on page 684.

Pleural effusion

See page 658.

Empyema

This is a collection of pus in the pleural space. The pus may be as thin as serous fluid or so thick that it is impossible to aspirate even through a wide-bore needle. Microscopically, neutrophil leucocytes are present in large numbers. The causative organism may or may not be isolated from the pus. An empyema may involve the whole pleural space or only part of it ('loculated' or 'encysted' empyema) and is usually unilateral.

Aetiology

Empyema is always secondary to infection in a neighbouring structure, usually the lung, most commonly due to the bacterial pneumonias and tuberculosis. Over 40% of patients with community-acquired pneumonia develop an associated pleural effusion ('parapneumonic' effusion) and about 15% of these become secondarily infected. Other causes are infection of a haemothorax following trauma or surgery, oesophageal rupture and rupture of a subphrenic abscess through the diaphragm. Despite the widespread availability of antibiotics effective against pneumonia, empyema remains a significant cause of morbidity and mortality even in developed countries. This reflects delays in the diagnosis or in the instigation of appropriate therapy.

Pathology

Both layers of pleura are covered with a thick, shaggy inflammatory exudate. The pus in the pleural space is often under considerable pressure, and if the condition is not adequately treated, pus may rupture into a bronchus causing a bronchopleural fistula and pyopneumothorax, or track through the chest wall with the formation of a subcutaneous abscess or sinus, so-called empyema necessitans.

An empyema will only heal if infection is eradicated and the empyema space is obliterated, allowing apposition of the visceral and parietal pleural layers. This can only occur if re-expansion of the compressed lung is secured at an early stage by removal of all the pus from the pleural space. Successful re-expansion and resolution will not occur if:

- the visceral pleura becomes grossly thickened and rigid due to delayed treatment or inadequate drainage of the infected pleural fluid
- the pleural layers are kept apart by air entering the pleura through a bronchopleural fistula

- there is underlying disease in the lung, such as bronchiectasis, bronchial carcinoma or pulmonary TB preventing re-expansion.

In these circumstances an empyema tends to become chronic, and healing will only occur with surgical intervention.

Clinical features

An empyema should be suspected in patients with pulmonary infection if there is persisting or recurrent pyrexia despite treatment with a suitable antibiotic. In other cases the illness associated with the primary infection may be so slight that it passes unrecognised and the first definite clinical features are due to the empyema itself. Once an empyema has developed, systemic features are prominent (Box 19.105).

19.105 Clinical features of empyema

Systemic features

- Pyrexia, usually high and remittent
- Rigors, sweating, malaise and weight loss
- Polymorphonuclear leucocytosis, high CRP

Local features

- Pleural pain; breathlessness; cough and sputum usually because of underlying lung disease; copious purulent sputum if empyema ruptures into a bronchus (bronchopleural fistula)
- Clinical signs of pleural effusion

Investigations

Radiological examination

The appearances may be indistinguishable from those of pleural effusion. When air is present in addition to pus (pyopneumothorax), a horizontal 'fluid level' marks the air/liquid interface. Ultrasound shows the position of the fluid, the extent of pleural thickening and whether fluid is in a single collection or multiloculated by fibrin and debris. Sometimes, pleural adhesions confine the empyema to form a 'D'-shaped shadow against the inside of the chest wall. CT gives information on the pleura, the underlying lung parenchyma and patency of the major bronchi.

Aspiration of fluid

Ultrasound or CT is used to identify the optimal site to undertake aspiration, which is best performed using a wide-bore needle. If the fluid is thick and turbid pus, empyema is confirmed. Other features suggesting empyema are a fluid glucose < 3.3 mmol/L (60 mg/dL), LDH > 1000 U/L or a fluid pH < 7.0 ($H^+ > 100$ nmol/L). However, pH measurement should be avoided if pus is thick, as it damages blood gas machines. The pus is frequently sterile on culture if antibiotics have already been given. The distinction between tuberculous and non-tuberculous disease can be difficult and often requires pleural biopsy, histology and culture.

Management

Treatment of non-tuberculous empyema

When the patient is acutely ill and the pus is sufficiently thin, a wide-bore intercostal tube should be inserted into the most dependent part of the empyema space (using

ultrasound or CT guidance in difficult cases) and connected to an underwater-seal drain system. If the initial aspirate reveals turbid fluid or frank pus, or if loculations are seen on ultrasound, the tube should be put on suction (-5 to -10 cm H_2O) and flushed regularly with 20 mL normal saline. Trials have failed to show any benefit from intrapleural fibrinolytic therapy in empyema. An antibiotic directed against the organism causing the empyema should be given for 2–4 weeks. Empirical antibiotic treatment (e.g. intravenous co-amoxiclav or cefuroxime with metronidazole) should be used if the organism is unknown.

An empyema can often be aborted if these measures are started early. If, however, the intercostal tube is not providing adequate drainage—e.g. when the pus is thick or loculated, surgical intervention is required. The empyema cavity is cleared of pus and adhesions, and a wide-bore tube inserted to allow optimal drainage. Surgical 'decortication' of the lung may also be required if gross thickening of the visceral pleura is preventing re-expansion of the lung.

Treatment of tuberculous empyema

Antituberculosis chemotherapy must be started immediately (p. 693) and the pus in the pleural space aspirated through a wide-bore needle until it ceases to reaccumulate. Intercostal tube drainage is often required. In many patients, no other treatment is necessary but surgery is occasionally required to ablate a residual empyema space. Fibrothorax, with restriction and encasement of the lung in thickened, often calcified pleura is a late complication.

Spontaneous pneumothorax

Pneumothorax is the presence of air in the pleural space, which can either occur spontaneously, or result from iatrogenic injury or trauma to the lung or chest wall (Box 19.106). Primary spontaneous pneumothorax occurs in patients with no history of lung disease in whom smoking, tall stature and the presence of apical subpleural blebs are additional risk factors. Secondary pneumothorax affects patients with pre-existing lung disease and is associated with higher mortality rates (Fig. 19.62).

Clinical features

The most common symptoms are sudden-onset unilateral pleuritic chest pain or breathlessness. In those with

19.106 Classification of pneumothorax

Spontaneous

Primary

- No evidence of overt lung disease. Air escapes from the lung into the pleural space through rupture of a small subpleural emphysematous bulla or pleural bleb, or the pulmonary end of a pleural adhesion

Secondary

- Underlying lung disease, most commonly COPD and TB; also seen in asthma, lung abscess, pulmonary infarcts, bronchogenic carcinoma, all forms of fibrotic and cystic lung disease

Traumatic

- Iatrogenic (e.g. following thoracic surgery or biopsy) or chest wall injury

Fig. 19.62 Bimodal age distribution for hospital admissions for pneumothorax in England. The incidence of primary spontaneous pneumothorax peaks in males aged 15–30. Secondary spontaneous pneumothorax occurs mainly in males > 55 years.

underlying chest disease, breathlessness can be severe and may not resolve spontaneously. In patients with a small pneumothorax, physical examination may be normal. A larger pneumothorax (> 15% of the hemithorax) results in decreased or absent breath sounds (p. 643). The combination of absent breath sounds and resonant percussion note is diagnostic of pneumothorax.

Occasionally, the communication between the airway and the pleural space acts as a one-way valve, allowing air to enter the pleural space during inspiration but not to escape on expiration. Large amounts of trapped air accumulate progressively in the pleural space and the intrapleural pressure rises to well above atmospheric levels. This is a tension pneumothorax. The pressure causes mediastinal displacement towards the opposite side, with compression of the opposite normal lung and impairment of systemic venous return, causing cardiovascular compromise (Fig. 19.63C). Clinically, the findings are rapidly progressive breathlessness associated with a marked tachycardia, hypotension, cyanosis and tracheal displacement away from the side of the silent hemithorax. Occasionally, tension pneumothorax may occur without mediastinal shift, if malignant disease or scarring has splinted the mediastinum.

Where the communication between the airway and the pleural space seals off as the lung deflates and does

not re-open, the pneumothorax is referred to as 'closed' (Fig. 19.63A). In such circumstances the mean pleural pressure remains negative, spontaneous reabsorption of air and re-expansion of the lung occur over a few days or weeks, and infection is uncommon. This contrasts with an 'open' pneumothorax, where the communication fails to seal and air continues to pass freely between the bronchial tree and pleural space (Fig. 19.63B). An example of the latter is a bronchopleural fistula, which, if large, can also facilitate the transmission of infection from the airways into the pleural space, leading to empyema. An open pneumothorax is commonly seen following rupture of an emphysematous bulla, tuberculous cavity or lung abscess into the pleural space.

Investigations

The chest X-ray shows the sharply defined edge of the deflated lung with complete translucency (no lung markings) between this and the chest wall (p. 643). Care must be taken to differentiate between a large pre-existing emphysematous bulla and a pneumothorax to avoid misdirected attempts at aspiration. Where doubt exists, CT is useful in distinguishing bullae from pleural air. X-rays also show the extent of any mediastinal displacement and reveal any pleural fluid or underlying pulmonary disease.

Management

Primary pneumothorax in which the lung edge is less than 2 cm from the chest wall and the patient is not breathless normally resolves without intervention. In young patients presenting with a moderate or large spontaneous primary pneumothorax, percutaneous needle aspiration of air is a simple and well-tolerated alternative to intercostal tube drainage, with a 60–80% chance of avoiding the need for a chest drain (Fig. 19.64). In patients with significant underlying chronic lung disease, however, secondary pneumothorax may cause respiratory distress. In these patients, the success rate of aspiration is much lower, and intercostal tube drainage and inpatient observation are usually required, particularly in those over 50 years old and those with respiratory compromise.

When needed, intercostal drains are inserted in the 4th, 5th or 6th intercostal space in the mid-axillary line, connected to an underwater seal or one-way Heimlich

Fig. 19.63 Types of spontaneous pneumothorax. **A** Closed type. **B** Open type. **C** Tension (valvular) type.

Fig. 19.64 Management of spontaneous pneumothorax.

(1) Immediate decompression is required prior to insertion of intercostal drain. (2) Aspirate in the 2nd intercostal space anteriorly in the mid-clavicular line using a 16 F cannula; discontinue if resistance is felt, the patient coughs excessively, or > 2.5 L of air are removed. (3) Beware: the post-aspiration chest X-ray is not a reliable indicator of whether a pleural leak remains, and all patients should be told to attend again immediately in the event of deterioration.

valve, and secured firmly to the chest wall. Clamping of an intercostal drain is potentially dangerous and rarely indicated. The drain should be removed 24 hours after the lung has fully reinflated and bubbling stopped. Continued bubbling after 5–7 days is an indication for surgery. If bubbling in the drainage bottle stops before full reinflation, the tube is either blocked, kinked or displaced. Supplemental oxygen may speed resolution as it accelerates the rate at which nitrogen is reabsorbed by the pleura.

Patients with a closed pneumothorax should be advised not to fly as the trapped gas expands at altitude. After complete resolution, there is no clear evidence to indicate how long patients should avoid flying, although guidelines suggest that a wait of 1–2 weeks, with confirmation of full inflation prior to flight, is prudent. Patients should also be advised to stop smoking and informed about the risks of a recurrent pneumothorax.

Recurrent spontaneous pneumothorax

After primary spontaneous pneumothorax, recurrence occurs within a year of either aspiration or tube

drainage in approximately 25% of patients, and should prompt definitive treatment. Surgical pleurodesis is recommended in all patients following a second pneumothorax and should be considered following the first episode of secondary pneumothorax if low respiratory reserve makes recurrence hazardous. Pleurodesis can be achieved by pleural abrasion or parietal pleurectomy at thoracotomy or thoracoscopy.

Asbestos-related pleural disease

Asbestos-related lung disease is described on page 712. In the pleura, the chronic tissue reaction may take a variety of clinical and radiological forms.

Benign pleural plaques

Pleural plaques are discrete raised areas situated on the pleura, chest wall, diaphragm, pericardium or mediastinum. They are strongly associated with asbestos exposure but do not usually cause any impairment of lung function and do not contribute to disability. Pleural plaques gradually calcify with time, making them more obvious on radiological imaging (Fig. 19.65).

Benign pleural effusion

Benign asbestos pleurisy occurs in around 20% of asbestos workers, usually within 10 years of exposure but sometimes much later. They present with features of pleurisy including pleural pain, fever and leucocytosis. The pleural liquid may be blood-stained, and differentiation of this benign condition from a malignant effusion caused by mesothelioma can be difficult. The disease is self-limiting but may cause diffuse pleural fibrosis.

Diffuse pleural fibrosis

This involves the visceral pleura, and if sufficiently extensive it may restrict chest expansion and cause breathlessness. Typical appearances on chest X-ray include thickening of the pleura along the chest wall and obliteration of the costophrenic angles (which is uncommon with pleural plaques). Early manifestations may be detected on CT, including the appearance of parenchymal bands. On occasion, shrinkage of the pleura

Fig. 19.65 Asbestos-related benign pleural plaques. Chest X-ray showing extensive calcified pleural plaques ('candle wax' appearance), particularly marked on the diaphragm and lateral pleural surfaces.

results in 'round atelectasis', which has the appearance of a mass adjacent to the pleura. This may cause confusion with a tumour.

Mesothelioma

Mesothelioma is a malignant tumour affecting the pleura (pleural mesothelioma) or, less commonly, the peritoneum (peritoneal mesothelioma). Although all fibre types are implicated, crocidolite (p. 712) appears to be the most potent cause. A time lag of 20 years or more between asbestos exposure and the development of mesothelioma is typical. In the UK, the incidence of mesothelioma has increased markedly over the past 20 years and is predicted to peak between 2011 and 2015.

The condition most frequently presents with chest pain or breathlessness from a pleural effusion. Histological diagnosis is difficult and generous (often surgical) pleural biopsies are needed, although tumour may invade along the surgical track following biopsy. The main differential diagnosis is adenocarcinoma and differentiation is aided by the characteristic immunohistochemistry profile. The prognosis is poor (usually in the order of 12–18 months), although small survival advantages have been reported following the use of chemotherapy. Radiotherapy may be helpful in preventing tumour growth through previous chest drain or biopsy sites. Highly selected patients may be considered for radical surgery; but in general, a palliative approach is all that is possible.

19.107 Pleural disease in old age

- **Spontaneous pneumothorax:** invariably associated with underlying lung disease in old age and has a significant mortality. Surgical or chemical pleurodesis is advised in all such patients.
- **Rib fracture:** common cause of pleural-type pain; may be spontaneous (due to coughing), traumatic or pathological. Underlying osteomalacia may contribute to poor healing, especially in the housebound with no exposure to sunlight.
- **Tuberculosis:** should always be considered and actively excluded in any elderly patient presenting with a unilateral pleural effusion.
- **Mesothelioma:** more common in older than younger people due to a long latency between asbestos exposure (often > 20 years) and the development of disease.
- **Analgesia:** frail older people are particularly sensitive to the respiratory depressant effects of opiate-based analgesia and careful monitoring is required when using these agents for pleural pain.

Diseases of the diaphragm

Congenital disorders

Diaphragmatic hernias

Congenital defects of the diaphragm can allow herniation of abdominal viscera. Posteriorly situated hernias through the foramen of Bochdalek are more common than anterior hernias through the foramen of Morgagni.

Eventration of the diaphragm

Abnormal elevation or bulging of one hemidiaphragm, more often the left, results from total or partial absence of muscular development of the septum transversum. Most eventrations are asymptomatic and are detected by chance on X-ray in adult life, but severe respiratory distress can be caused in infancy if the diaphragmatic muscular defect is extensive.

Acquired disorders

Diaphragmatic paralysis

Phrenic nerve damage leading to paralysis of a hemidiaphragm may be idiopathic but is most often due to bronchial carcinoma (Box 19.108). It may also be damaged by disease of cervical vertebrae, tumours of the cervical cord, shingles, trauma including road traffic and birth injuries, surgery, and stretching of the nerve by mediastinal masses and aortic aneurysms. Paralysis of one hemidiaphragm results in loss of approximately 20% of ventilatory capacity, but is not usually noticed by otherwise healthy individuals. The diagnosis is suggested by elevation of the hemidiaphragm on chest X-ray and is confirmed by using ultrasound screening to demonstrate paradoxical upward movement of the paralysed hemidiaphragm on sniffing.

Bilateral diaphragmatic weakness occurs in peripheral neuropathies of any type including Guillain-Barré syndrome (p. 1229), in disorders affecting the anterior horn cells, e.g. poliomyelitis (p. 1210), in muscular dystrophies and in connective tissue disorders such as SLE and polymyositis (pp. 1107 and 1111).

Other acquired diaphragmatic disorders

Hiatus hernia is common (p. 864). Diaphragmatic rupture is usually caused by a crush injury and may not be detected until years later. Respiratory disorders that cause pulmonary hyperinflation, e.g. emphysema, and those which result in small stiff lungs, e.g. diffuse pulmonary fibrosis, decrease diaphragmatic efficiency and predispose to fatigue. Severe skeletal deformity, such as kyphosis, causes gross distortion of diaphragmatic muscle configuration and mechanical disadvantage.

19.108 Causes of elevation of a hemidiaphragm

- Phrenic nerve paralysis
- Eventration of the diaphragm
- Decrease in volume of one lung (e.g. lobectomy, unilateral pulmonary fibrosis)
- Severe pleuritic pain
- Pulmonary infarction
- Subphrenic abscess
- Large volume of gas in the stomach or colon
- Large tumours or cysts of the liver

Deformities of the chest wall

Thoracic kyphoscoliosis

Abnormalities of alignment of the dorsal spine and their consequent effects on thoracic shape may be caused by:

- congenital abnormality
- vertebral disease, including tuberculosis, osteoporosis and ankylosing spondylitis
- trauma
- neuromuscular disease such as poliomyelitis.

Simple kyphosis (increased anteroposterior curvature) causes less pulmonary embarrassment than kyphoscoliosis (anteroposterior and lateral curvature). Kyphoscoliosis, if severe, restricts and distorts expansion of the chest wall, causing ventilation-perfusion mismatch in the lungs and impaired diaphragmatic function. Patients with severe deformity may develop type II respiratory failure (initially manifest during sleep), pulmonary hypertension and right ventricular failure. They can often be successfully treated with non-invasive ventilatory support (p. 194).

Pectus excavatum

Pectus excavatum (funnel chest) is an idiopathic condition in which the body of the sternum, usually only the lower end, is curved inwards. The heart is displaced to the left and may be compressed between the sternum and the vertebral column; however, only rarely is there associated disturbance of cardiac function. The deformity may restrict chest expansion and reduce vital capacity. Operative correction is rarely performed, and only for cosmetic reasons.

Pectus carinatum

Pectus carinatum (pigeon chest) is frequently caused by severe asthma during childhood. Very occasionally, this deformity can be produced by rickets or be idiopathic.

Diseases affecting multiple endocrine glands 793

Endocrine disease causes clinical syndromes with symptoms and signs involving many organ systems, reflecting the diverse effects

of hormone deficiency and excess. The emphasis of the clinical examination depends on the gland or hormone that is thought to be abnormal.

Diabetes mellitus (Ch. 21) and thyroid disease are the most common endocrine diseases.

6 Examination of the visual fields by confrontation

- Sit opposite patient
- You and patient cover opposite eyes
- Bring red pin (or wiggling finger) slowly into view from extreme of your vision, as shown
- Ask patient to say 'now' when it comes into view
- Continue to move pin into centre of vision and ask patient to tell you if it disappears
- Repeat in each of four quadrants
- Repeat in other eye

A bitemporal hemianopia is the classical finding in pituitary macroadenomas (p. 787)

6 Examination in Graves' ophthalmopathy

- **Inspect** from front and side
 - Periorbital oedema (Fig. 20.8)
 - Conjunctival inflammation (chemosis)
 - Corneal ulceration
 - Proptosis (exophthalmos)*
 - Lid retraction*

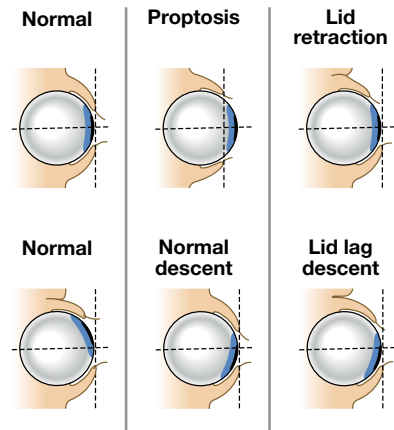

- **Range of eye movements**
 - Lid lag on descending gaze*
 - Diplopia on lateral gaze

- **Pupillary reflexes**
 - Afferent defect (pupils constrict further on swinging light to unaffected eye, Box 26.26)

- **Vision**
 - Visual acuity impaired
 - Loss of colour vision
 - Visual field defects

- **Ophthalmoscopy**
 - Optic disc pallor
 - Papilloedema

*Note position of eyelids relative to iris.

Right proptosis and afferent pupillary defect

7 Examination of the thyroid gland

- **Inspect** from front to side
- **Palpate** from behind
 - Thyroid moves on swallowing
 - Cervical lymph nodes
 - Tracheal deviation
- **Auscultate** for bruit
 - Ask patient to hold breath
 - If present, check for radiating murmur
- **Percuss** for retrosternal thyroid
- Consider systemic signs of thyroid dysfunction (Box 20.7)
 - incl. tremor, palmar erythema, warm peripheries, tachycardia, lid lag
- Consider signs of Graves' disease
 - incl. ophthalmopathy, pretibial myxoedema

Abnormal findings

- Diffuse soft goitre with bruit
 - Graves' disease (p. 745)
- Diffuse firm goitre
 - Hashimoto's thyroiditis (p. 748)
- Diffuse tender goitre
 - Subacute thyroiditis (p. 748)
- Multinodular goitre (p. 750)
 - ± Retrosternal extension, tracheal compression
- Solitary nodule (p. 744)
 - Adenoma, cyst or carcinoma
- Cervical lymphadenopathy
 - Suggests carcinoma

Endocrinology concerns the synthesis, secretion and action of hormones. These are chemical messengers released from endocrine glands that coordinate the activities of many different cells. Endocrine diseases can therefore affect multiple organs and systems. This chapter describes the principles of endocrinology before dealing with the function and diseases of each gland in turn.

Some endocrine diseases are common, particularly those of the thyroid gland, reproductive system and β cells of the pancreas (Ch. 21). For example, thyroid dysfunction occurs in more than 10% of the population in areas with iodine deficiency, such as the Himalayas, and 4% of women aged 20–50 years in the UK. Some endocrine diseases are becoming more common in association with emerging diseases; HIV infection is associated in particular with adrenal insufficiency. Less common endocrine syndromes are described later in the chapter.

Few endocrine therapies have been evaluated by randomised controlled trials, in part because hormone replacement therapy (for example, with thyroxine) has obvious clinical benefits and placebo-controlled trials would be unethical, and in part because many endocrine diseases are rare, making trials difficult to perform. Recommendations for 'evidence-based medicine' are, therefore, relatively scarce. They relate mainly to use of therapy that is 'optional' and/or recently available, such as oestrogen replacement in post-menopausal women and growth hormone replacement.

AN OVERVIEW OF ENDOCRINOLOGY

Functional anatomy and physiology

Some endocrine glands, such as the parathyroids and pancreas, respond directly to metabolic signals, but most are controlled by hormones released from the pituitary gland. Anterior pituitary hormone secretion is controlled in turn by substances produced in the hypothalamus and released into portal blood which drains directly down the pituitary stalk (Fig. 20.1). Posterior pituitary hormones are synthesised in the hypothalamus and transported down nerve axons to be released from the posterior pituitary. Hormone release in the hypothalamus and pituitary is regulated by numerous stimuli and through feedback control by hormones produced by the target glands (thyroid, adrenal cortex and gonads). These integrated endocrine systems are called 'axes', and are listed in Figure 20.2.

A wide variety of molecules act as hormones. Peptides (e.g. insulin), glycoproteins (e.g. thyroid-stimulating hormone, TSH) and amines (e.g. noradrenaline/nor-epinephrine) act on specific cell surface receptors which signal through G-proteins and/or enzymes on the cytosolic side of the plasma membrane. Other hormones (e.g. steroids, triiodothyronine and vitamin D) bind to specific intracellular receptors, which in turn bind to response elements on DNA to regulate gene transcription (p. 41).

The classical model of endocrine function involves hormones which are synthesised in endocrine glands, are released into the circulation, and act at sites distant from those of secretion (as in Fig. 20.1). However, additional levels of regulation are now recognised. Many other organs secrete hormones or contribute to the

Fig. 20.1 An archetypal endocrine axis. Regulation by negative feedback and direct control is shown along with the equilibrium between active circulating free hormone and bound or metabolised hormone.

peripheral metabolism and activation of prohormones. A notable example is the production of oestrogens from adrenal androgens in adipose tissue by the enzyme aromatase. Some hormones such as neurotransmitters act in a paracrine fashion to affect adjacent cells or act in an autocrine way to affect behaviour of the cell that produces the hormone.

Endocrine pathology

For each endocrine axis or major gland, diseases can be classified as shown in Box 20.1. Pathology arising within the gland is often called 'primary' disease (e.g. primary hypothyroidism in Hashimoto's thyroiditis), while abnormal stimulation of the gland is often called 'secondary' disease (for example, secondary hypothyroidism in patients with a pituitary tumour and TSH deficiency). Two types of endocrine disease affect multiple glands (p. 794): organ-specific autoimmune diseases (which are common) and multiple endocrine neoplasia (MEN) syndromes (which are rare).

Investigation of endocrine disease

Biochemical investigations play a central role in endocrinology. Most hormones can be measured in blood, but the circumstances in which the sample is taken are often crucial, especially for hormones with pulsatile secretion such as growth hormone; diurnal variation such as cortisol; or monthly variation such as oestrogen or progesterone. Other investigations such as imaging and biopsy are

Fig. 20.2 The principal endocrine 'axes' and glands. **A** Endocrine axes. Some major endocrine glands are not controlled by the pituitary. These include the parathyroid glands (regulated by calcium concentrations, p. 764), the adrenal zona glomerulosa (regulated by the renin–angiotensin system, p. 769) and the endocrine pancreas (Ch. 21). Italics show negative regulation. (ACTH = adrenocorticotrophic hormone; ADH = antidiuretic hormone, arginine vasopressin; CRH = corticotrophin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone-releasing hormone; GnRH = gonadotrophin-releasing hormone; IGF-1 = insulin-like growth factor-1; IGF-BP3 = IGF-binding protein-3; LH = luteinising hormone; T_3 = triiodothyronine; T_4 = thyroxine; TRH = thyrotrophin-releasing hormone; TSH = thyroid-stimulating hormone) **B** Endocrine glands.

20.1 Classification of endocrine disease

Hormone excess

- Primary gland over-production
- Secondary to excess trophic substance

Hormone deficiency

- Primary gland failure
- Secondary to deficient trophic hormone

Hormone hypersensitivity

- Failure of inactivation of hormone
- Target organ over-activity/hypersensitivity

Hormone resistance

- Failure of activation of hormone
- Target organ resistance

Non-functioning tumours

usually reserved for patients who present with a tumour. The principles of investigation are shown in Box 20.2. The choice of test is often pragmatic, taking local access to reliable sampling facilities and laboratory measurements into account.

Presenting problems in endocrine disease

Endocrine diseases present in many different ways and to clinicians in many different disciplines. Classical syndromes are described in relation to individual glands in the following sections. Often, however, the presentation is with non-specific symptoms (Box 20.3) or with asymptomatic biochemical abnormalities. In addition, endocrine

20.2 Principles of endocrine investigation

Timing of measurement

- Release of many hormones is rhythmical (pulsatile, circadian or monthly), so random measurement may be invalid and sequential or dynamic tests may be required

Choice of dynamic biochemical tests

- Abnormalities are often characterised by loss of normal regulation of hormone secretion
- If hormone deficiency is suspected, choose a stimulation test
- If hormone excess is suspected, choose a suppression test
- The more tests there are to choose from, the less likely it is that any single test is infallible, so avoid interpreting one result in isolation

Imaging

- Secretory cells also take up substrates, which can be labelled
- Most endocrine glands have a high prevalence of 'incidentalomas', so do not scan unless the biochemistry confirms endocrine dysfunction or the primary problem is a tumour

Biopsy

- Many endocrine tumours are difficult to classify histologically (e.g. adrenal carcinoma and adenoma)

diseases are encountered in the differential diagnosis of common complaints discussed in other chapters of this book, including electrolyte abnormalities (Ch. 16), hypertension (Ch. 18), obesity (Ch. 5) and osteoporosis (Ch. 25). Although diseases of the adrenal glands, hypothalamus and pituitary are relatively rare, their diagnosis often relies on astute clinical observation in a patient with non-specific complaints, so it is important that clinicians are familiar with their key features.

20.3 Examples of non-specific presentations of endocrine disease

Symptom	Most likely endocrine disorder(s)
Lethargy and depression	Hypothyroidism, diabetes mellitus, hyperparathyroidism, hypogonadism, adrenal insufficiency, Cushing's syndrome
Weight gain	Hypothyroidism, Cushing's syndrome
Weight loss	Thyrotoxicosis, adrenal insufficiency, diabetes mellitus
Polyuria and polydipsia	Diabetes mellitus, diabetes insipidus, hyperparathyroidism, hypokalaemia (Conn's syndrome)
Heat intolerance	Thyrotoxicosis, menopause
Palpitations	Thyrotoxicosis, pheochromocytoma
Headache	Acromegaly, pituitary tumour, pheochromocytoma
Muscle weakness (usually proximal)	Thyrotoxicosis, Cushing's syndrome, hypokalaemia (e.g. Conn's syndrome), hyperparathyroidism, hypogonadism
Coarsening of features	Acromegaly, hypothyroidism

THE THYROID GLAND

Diseases of the thyroid predominantly affect females and are common, occurring in about 5% of the population. The thyroid axis is involved in the regulation of cellular differentiation and metabolism in virtually all nucleated cells, so that disorders of thyroid function have diverse manifestations. Structural diseases of the thyroid gland, such as goitre, commonly occur in patients with normal thyroid function. Disease of the thyroid are summarised in Box 20.4.

20.4 Classification of thyroid disease

	Primary	Secondary
Hormone excess	Graves' disease Multinodular goitre Adenoma Subacute thyroiditis	Pituitary TSHoma
Hormone deficiency	Hashimoto's thyroiditis Atrophic hypothyroidism	Hypopituitarism
Hormone hypersensitivity	–	
Hormone resistance	Thyroid hormone resistance syndrome 5'-monodeiodinase deficiency	
Non-functioning tumours	Differentiated carcinoma Medullary carcinoma Lymphoma	

Functional anatomy, physiology and investigations

Thyroid physiology is illustrated in Figure 20.3. The parafollicular C cells secrete calcitonin, which is of no apparent physiological significance in humans. The follicular epithelial cells synthesise thyroid hormones by incorporating iodine into the amino acid tyrosine on the surface of thyroglobulin (Tg), a protein secreted into the colloid of the follicle. Iodide is a key substrate for thyroid hormone synthesis; a dietary intake in excess of 100 µg/day is required to maintain thyroid function in adults. The thyroid secretes predominantly thyroxine (T₄) and only a small amount of triiodothyronine (T₃); approximately 85% of T₃ in blood is produced from T₄ by a family of monodeiodinase enzymes which are active in many tissues including liver, muscle, heart and kidney. T₄ can be regarded as a pro-hormone, since it has a longer half-life in blood than T₃ (approximately 1 week compared with approximately 18 hours), and binds and activates thyroid hormone receptors less effectively than T₃. T₄ can also be converted to the inactive metabolite, reverse T₃.

T₃ and T₄ circulate in plasma almost entirely (> 99%) bound to transport proteins, mainly thyroxine-binding globulin (TBG). It is the unbound or free hormones which diffuse into tissues and exert diverse metabolic

Fig. 20.3 Structure and function of the thyroid gland. (1) Thyroglobulin (Tg) is synthesised and secreted into the colloid of the follicle. (2) Inorganic iodide (I⁻) is actively transported into the follicular cell ('trapping'). (3) Iodide is transported on to the colloidal surface by a transporter (pendrin, defective in Pendred's syndrome) and 'organified' by the thyroid peroxidase enzyme, which incorporates it into the amino acid tyrosine on the surface of Tg to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). (4) Iodinated tyrosines couple to form T₃ and T₄. (5) Tg is endocytosed. (6) Tg is cleaved by proteolysis to free the iodinated tyrosine and thyroid hormones. (7) Iodinated tyrosine is dehalogenated to recycle the iodide. (8) T₄ is converted to T₃ by 5'-monodeiodinase.

actions. Some laboratories use assays which measure total T₄ and T₃ in plasma but it is increasingly common to measure free T₄ and free T₃. The advantage of the free hormone measurements is that they are not influenced by changes in the concentration of binding proteins; in pregnancy, for example, TBG levels are increased and total T₃ and T₄ may be raised, but free thyroid hormone levels are normal.

Production of T₃ and T₄ in the thyroid is stimulated by thyrotrophin (thyroid-stimulating hormone, TSH), a glycoprotein released from the thyrotroph cells of the anterior pituitary in response to the hypothalamic tripeptide, thyrotrophin-releasing hormone (TRH). A circadian rhythm of TSH secretion can be demonstrated with a peak at 0100 hrs and trough at 1100 hrs, but the variation is small so that thyroid function can be assessed reliably from a single blood sample taken at any time of day and does not usually require any dynamic stimulation or suppression tests. There is a negative feedback of thyroid hormones on the hypothalamus and pituitary such that in thyrotoxicosis, when plasma concentrations of T₃ and T₄ are raised, TSH secretion is suppressed. Conversely, in hypothyroidism due to disease of the thyroid gland, low T₃ and T₄ are associated with high circulating TSH levels. The anterior pituitary is very sensitive to minor changes in thyroid hormone levels within the normal range. Although the reference range for free T₄ is 9–21

pmol/L (700–1632 pg/dL), a rise or fall of 5 pmol/L in an individual in whom the level is usually 15 pmol/L would be associated on the one hand with undetectable TSH, and on the other hand with a raised TSH. For this reason, TSH is usually regarded as the most useful investigation of thyroid function. However, interpretation of TSH values without considering thyroid hormone levels may be misleading in patients with pituitary disease (see Box 20.56, p. 784). Moreover, TSH may take several weeks to 'catch up' with T₄ and T₃ levels, for example, when prolonged suppression of TSH in thyrotoxicosis is relieved by antithyroid therapy. Common patterns of abnormal thyroid function test results and their interpretation are shown in Box 20.5.

Other modalities commonly employed in the investigation of thyroid disease include measurement of antibodies against the TSH receptor or other thyroid antigens (see Box 20.8, p. 740), radioisotope imaging, fine needle aspiration biopsy and ultrasound. Their use is described below.

Presenting problems in thyroid disease

The most common presentations are hyperthyroidism (thyrotoxicosis), hypothyroidism and enlargement of the thyroid (goitre). Widespread availability of thyroid

20.5 How to interpret thyroid function test results

TSH	T ₄	T ₃	Most likely interpretation(s)
U.D.	Raised	Raised	Primary thyrotoxicosis
U.D.	Normal ¹	Raised	Primary T₃-toxicosis
U.D.	Normal ¹	Normal ¹	Subclinical thyrotoxicosis
U.D.	Raised	Low, normal or raised ²	Sick euthyroidism/non-thyroidal illness
U.D.	Low	Low	Secondary hypothyroidism⁵ Transient thyroiditis in evolution
Normal	Low	Low ³	Secondary hypothyroidism⁵
Mildly elevated 5–20 mU/L	Low	Low ³	Primary hypothyroidism Secondary hypothyroidism⁵
Elevated > 20 mU/L	Low	Low ³	Primary hypothyroidism
Mildly elevated 5–20 mU/L	Normal ⁴	Normal ³	Subclinical hypothyroidism
Elevated 20–500 mU/L	Normal	Normal	Artefact Endogenous IgG antibodies which interfere with TSH assay
Elevated	Raised	Raised	Non-compliance with T₄ replacement—recent 'loading' dose Secondary thyrotoxicosis⁵ Thyroid hormone resistance

¹Usually upper part of reference range.
²Depending on the assay system.
³T₃ is not a sensitive indicator of hypothyroidism and should not be requested.
⁴Usually lower part of normal range.
⁵i.e. secondary to pituitary or hypothalamic disease. Note that TSH assays may report detectable TSH.
 (U.D. = undetectable)

function tests has led to the increasingly frequent identification of patients with abnormal results who are either asymptomatic or have non-specific complaints such as tiredness and weight gain.

Thyrotoxicosis

Thyrotoxicosis describes a constellation of clinical features arising from elevated circulating levels of thyroid hormone. The most common causes are Graves' disease, multinodular goitre and autonomously functioning thyroid nodules (toxic adenoma) (Box 20.6). Thyroiditis is more common in parts of the world where relevant viral infections occur, such as North America.

Clinical assessment

The clinical manifestations of thyrotoxicosis are shown in Box 20.7 and an approach to differential diagnosis is given in Figure 20.4. The most common symptoms are weight loss with a normal or increased appetite, heat intolerance, palpitations, tremor and irritability. Tachycardia, palmar erythema and lid lag are common signs. Not all patients have a palpable goitre, but experienced clinicians can discriminate the diffuse soft

20.6 Causes of thyrotoxicosis and their relative frequencies

Cause	Frequency ¹ (%)
Graves' disease	76

⁴Human chorionic gonadotrophin has thyroid-stimulating activity.

goitre of Graves' disease from the irregular enlargement of a multinodular goitre. All causes of thyrotoxicosis can cause lid retraction and lid lag, due to potentiation of sympathetic innervation of the levator palpebrae muscles, but only Graves' disease causes other features of ophthalmopathy, including periorbital oedema, conjunctival irritation, exophthalmos and diplopia. Pretibial myxoedema (p. 733) and the rare thyroid acropachy (a periosteal hypertrophy indistinguishable from finger clubbing) are also specific to Graves' disease.

Investigations

The first-line investigations are serum T₃, T₄ and TSH. If abnormal values are found, the tests should be repeated and the abnormality confirmed in view of the likely need for prolonged medical treatment or destructive therapy. In most patients serum T₃ and T₄ are both elevated but T₄ is in the upper part of the normal range and T₃ raised (T₃ toxicosis) in about 5%. Serum TSH is undetectable in primary thyrotoxicosis but values can be raised in the very rare syndrome of secondary thyrotoxicosis caused by a TSH-producing pituitary adenoma. When biochemical thyrotoxicosis has been confirmed, further investigations should be undertaken to determine the underlying cause, including measurement of TSH receptor antibodies (TRAb, elevated in Graves' disease, Box 20.8) and isotope scanning, as shown in Figure 20.4. Other non-specific abnormalities are common (Box 20.9). An ECG may demonstrate sinus tachycardia or atrial fibrillation.

Radio-iodine uptake tests measure the proportion of isotope which is trapped in the whole gland, but have been largely superseded by ^{99m}technetium scintigraphy scans which also indicate trapping, are quicker to

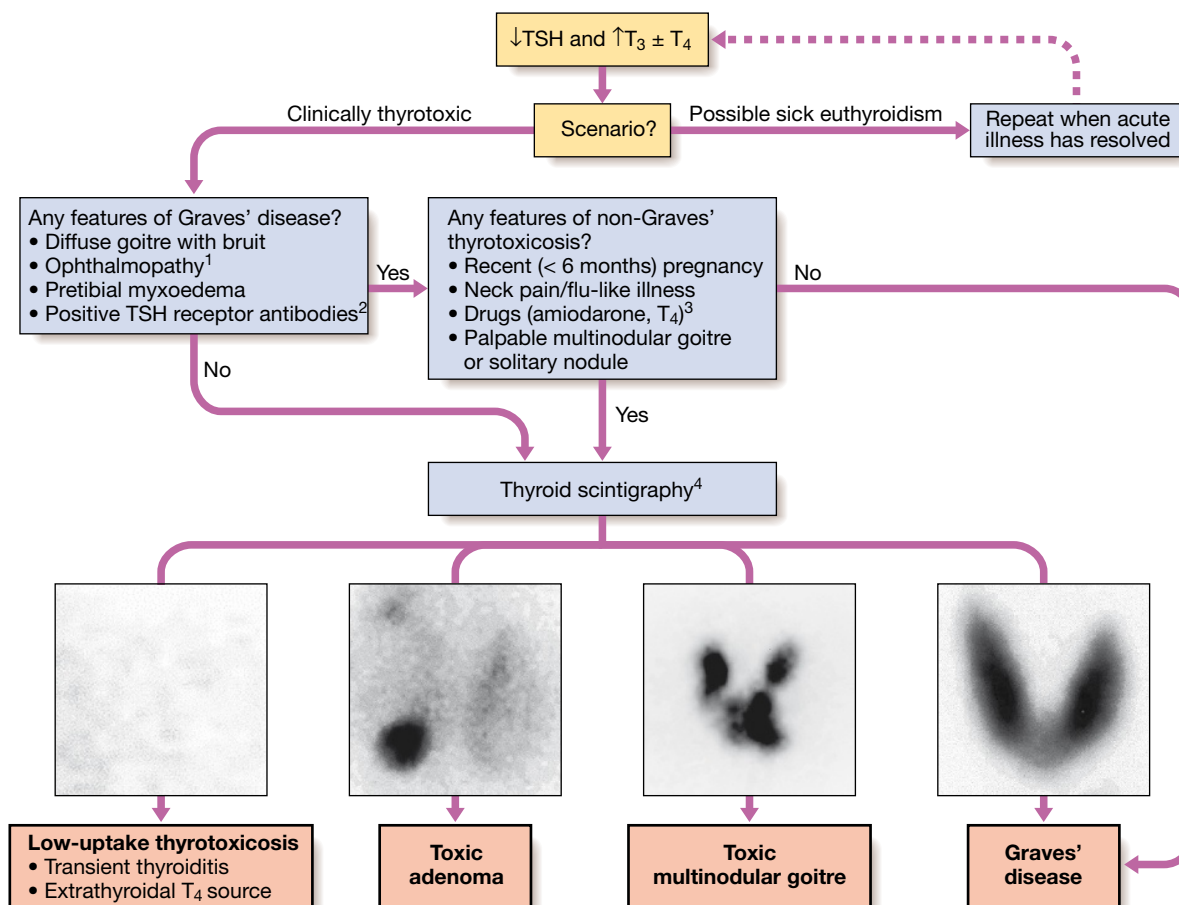

Fig. 20.4 Establishing the differential diagnosis in thyrotoxicosis. (1) Graves' ophthalmopathy refers to clinical features of exophthalmos and periorbital and conjunctival oedema, not simply the lid lag and lid retraction which can occur in all forms of thyrotoxicosis. (2) TSH receptor antibodies are very rare in patients without autoimmune thyroid disease, but only occur in 80–95% of patients with Graves' disease; a positive test is therefore confirmatory, but a negative test does not exclude Graves' disease. Other thyroid antibodies (e.g. anti-peroxidase and anti-thyroglobulin antibodies) are unhelpful in the differential diagnosis since they occur frequently in the population and are found with several of the disorders which cause thyrotoxicosis. (3) Scintigraphy is not necessary in most cases of drug-induced thyrotoxicosis. (4) ^{99m}TcTechnetium pertechnetate scans of patients with thyrotoxicosis. In low-uptake thyrotoxicosis, most commonly due to a viral, post-partum or iodine-induced thyroiditis, there is negligible isotope detected in the region of the thyroid, although uptake is apparent in nearby salivary glands (not shown here). In a toxic adenoma there is lack of uptake of isotope by the rest of the thyroid gland due to suppression of serum TSH. In multinodular goitre there is relatively low, patchy uptake within the nodules; such an appearance is not always associated with a palpable thyroid. In Graves' disease there is diffuse uptake of isotope.

perform with a lower dose of radioactivity, and provide a higher-resolution image. In low-uptake thyrotoxicosis, the cause is usually a transient thyroiditis (p. 748). Occasionally, patients induce 'factitious thyrotoxicosis' by consuming excessive amounts of a thyroid hormone preparation, most often levothyroxine. The exogenous thyroxine suppresses pituitary TSH secretion and hence iodine uptake, serum thyroglobulin and release of endogenous thyroid hormones. The $T_4:T_3$ ratio (typically 30:1 in conventional thyrotoxicosis) is increased to above 70:1 because circulating T_3 in factitious thyrotoxicosis is derived exclusively from the peripheral monodeiodination of T_4 and not from thyroid secretion. The combination of negligible iodine uptake, high $T_4:T_3$ ratio and a low or undetectable thyroglobulin is diagnostic.

Management

Definitive treatment of thyrotoxicosis depends on the underlying cause and may include antithyroid

drugs, radioactive iodine or surgery. A non-selective β -adrenoceptor antagonist (β -blocker), such as propranolol (160 mg daily) or nadolol (40–80 mg daily), will alleviate but not abolish symptoms in most patients within 24–48 hours. Beta-blockers should not be used for long-term treatment of thyrotoxicosis, but are extremely useful in the short term, whilst patients are awaiting hospital consultation or following ^{131}I therapy.

Atrial fibrillation in thyrotoxicosis

Atrial fibrillation occurs in about 10% of patients with thyrotoxicosis. The incidence increases with age so that almost half of all males with thyrotoxicosis over the age of 60 are affected (Fig. 20.5). Moreover, subclinical thyrotoxicosis (p. 744) is a risk factor for atrial fibrillation. Characteristically, the ventricular rate is little influenced by digoxin, but responds to the addition of a β -blocker. Thromboembolic vascular complications are particularly common in thyrotoxic atrial fibrillation so that anticoagulation with warfarin is required,

20.7 Clinical features of thyroid dysfunction

Thyrotoxicosis		Hypothyroidism	
Symptoms	Signs	Symptoms	Signs
Common			
Weight loss despite normal or increased appetite	Weight loss	Weight gain	Weight gain
Heat intolerance	Tremor	Cold intolerance	
Palpitations	Palmar erythema	Fatigue, somnolence	
Dyspnoea	Sinus tachycardia	Dry skin	
Irritability, emotional lability	Lid retraction, lid lag	Dry hair	
Fatigue		Menorrhagia	
Sweating			
Tremor			
Less common			
Osteoporosis (fracture, loss of height)	Goitre with bruit ¹	Constipation	Hoarse voice
Diarrhoea, steatorrhoea	Atrial fibrillation ²	Hoarseness	Facial features:
Angina	Systolic hypertension/ increased pulse pressure	Carpal tunnel syndrome	Purplish lips
Ankle swelling	Cardiac failure ²	Alopecia	Malar flush
Anxiety, psychosis	Hyper-reflexia	Aches and pains	Periorbital oedema/myxoedema
Muscle weakness	Ill-sustained clonus	Muscle stiffness	Loss of lateral eyebrows
Periodic paralysis (predominantly in Chinese)	Proximal myopathy	Deafness	Anaemia
Pruritus	Bulbar myopathy ²	Depression	Carotenaemia
Alopecia		Infertility	Erythema ab igne (Granny's tartan)
Amenorrhoea/oligomenorrhoea			Bradycardia
Infertility, spontaneous abortion			Hypertension
Loss of libido, impotence			Delayed relaxation of tendon reflexes
Excessive lacrimation			Dermal myxoedema
Rare			
Vomiting	Lymphadenopathy	Psychosis (myxoedema madness)	Ileus
Apathy	Spider naevi	Galactorrhoea	Ascites
Anorexia	Onycholysis	Impotence	Pericardial and pleural effusions
Exacerbation of asthma	Pigmentation		Cerebellar ataxia
	Gynaecomastia		Myotonia

¹In Graves' disease only.²Features found particularly in elderly patients.

20.8 Prevalence of thyroid autoantibodies (%)

	Antibodies to:		
	Thyroid peroxidase ¹	Thyroglobulin	TSH receptor ²
Normal population	8–27	5–20	0
Graves' disease	50–80	50–70	80–95
Autoimmune hypothyroidism	90–100	80–90	10–20
Multinodular goitre	~30–40	~30–40	0
Transient thyroiditis	~30–40	~30–40	0

¹Thyroid peroxidase (TPO) antibodies are the principal component of what was previously measured as thyroid 'microsomal' antibodies.²TSH receptor antibodies (TRAb) can be agonists (stimulatory, causing Graves' thyrotoxicosis) or antagonists ('blocking', causing hypothyroidism).

unless contraindicated. Once thyroid hormone and TSH concentrations have been returned to normal, atrial fibrillation will spontaneously revert to sinus rhythm in about 50% of patients, but cardioversion may be required in the remainder.

20.9 Non-specific laboratory abnormalities in thyroid dysfunction*

Thyrotoxicosis
<ul style="list-style-type: none"> Serum enzymes <ul style="list-style-type: none"> Raised alanine aminotransferase, γ-glutamyl transferase (GGT), and alkaline phosphatase from liver and bone Raised bilirubin Mild hypercalcaemia Glycosuria <ul style="list-style-type: none"> Associated diabetes mellitus 'Lag storage' glycosuria
Hypothyroidism
<ul style="list-style-type: none"> Serum enzymes <ul style="list-style-type: none"> Raised creatine kinase, aspartate aminotransferase, lactate dehydrogenase (LDH) Hypercholesterolaemia Anaemia <ul style="list-style-type: none"> Normochromic normocytic or macrocytic Hyponatraemia

*These abnormalities are not useful in differential diagnosis, so the tests should be avoided and any further investigation undertaken only if abnormalities persist when the patient is euthyroid.

Fig. 20.5 Age-related incidence of atrial fibrillation in patients with thyrotoxicosis.

Thyrotoxic crisis ('thyroid storm')

This is a rare but life-threatening complication of thyrotoxicosis. The most prominent signs are fever, agitation, confusion, tachycardia or atrial fibrillation and, in the older patient, cardiac failure. It is a medical emergency, which has a mortality of 10% despite early recognition and treatment. Thyrotoxic crisis is most commonly precipitated by infection in a patient with previously unrecognised or inadequately treated thyrotoxicosis. It may also develop shortly after subtotal thyroidectomy in an ill-prepared patient or within a few days of ^{131}I therapy when acute irradiation damage may lead to a transient rise in serum thyroid hormone levels.

Patients should be rehydrated and given a broad-spectrum antibiotic and propranolol, either orally (80 mg 6-hourly) or intravenously (1–5 mg 6-hourly). Sodium ipodate (500 mg per day orally) will restore serum T_3 levels to normal in 48–72 hours. This is a radiographic contrast medium which not only inhibits the release of thyroid hormones, but also reduces the conversion of T_4 to T_3 and is, therefore, more effective than potassium iodide or Lugol's solution. Dexamethasone (2 mg 6-hourly) and amiodarone have similar effects. Oral carbimazole 40–60 mg daily (p. 746) should be given to inhibit the synthesis of new thyroid hormone. If the patient is unconscious or uncooperative, carbimazole can be administered rectally with good effect, but no preparation is available for parenteral use. After 10–14 days the patient can usually be maintained on carbimazole alone.

Thyrotoxicosis and pregnancy

Thyrotoxicosis during pregnancy is usually due to Graves' disease and its treatment is described on pages 745–747. Thyrotoxicosis within the first 6 months after pregnancy may be due to post-partum thyroiditis, which is described on page 747. See also Box 20.19 (p. 753).

Hypothyroidism

Hypothyroidism is a common condition with various causes (Box 20.10), but autoimmune disease (Hashimoto's thyroiditis) and thyroid failure following ^{131}I or surgical

20.10 Causes of hypothyroidism

treatment of thyrotoxicosis account for over 90% of cases, except in areas where iodine deficiency is endemic. Women are affected approximately six times more frequently than men.

Clinical assessment

The clinical presentation depends on the duration and severity of the hypothyroidism. Those in whom complete thyroid failure has developed insidiously over months or years may present with many of the clinical features listed in Box 20.7. A consequence of prolonged hypothyroidism is the infiltration of many body tissues by the mucopolysaccharides, hyaluronic acid and chondroitin sulphate, resulting in a low-pitched voice, poor hearing, slurred speech due to a large tongue, and compression of the median nerve at the wrist (carpal tunnel syndrome). Infiltration of the dermis gives rise to non-pitting oedema (myxoedema) which is most marked in the skin of the hands, feet and eyelids. The resultant periorbital puffiness is often striking and, when combined with facial pallor due to vasoconstriction and anaemia, or a lemon-yellow tint to the skin due to carotenaemia, purplish lips and malar flush, the clinical diagnosis is simple. Most cases of hypothyroidism are not clinically obvious, however, and a high index of suspicion needs to be maintained so that the diagnosis is

not overlooked in the middle-aged woman complaining of non-specific symptoms such as tiredness, weight gain, depression or carpal tunnel syndrome.

The key discriminatory features in the history and examination are highlighted in Figure 20.6. Care must be taken to identify patients with transient hypothyroidism, in whom life-long thyroxine therapy is inappropriate. This is often observed during the first 6 months after subtotal thyroidectomy or ^{131}I treatment of Graves' disease, in the post-thyrotoxic phase of subacute thyroiditis and in post-partum thyroiditis. In these conditions thyroxine treatment is not always necessary as the patient may be asymptomatic during the short period of thyroid failure.

Investigations

In the vast majority of cases hypothyroidism results from an intrinsic disorder of the thyroid gland (primary hypothyroidism). In this situation serum T_4 is low and TSH is elevated, usually in excess of 20 mU/L. Measurements of serum T_3 are unhelpful since they do not discriminate reliably between euthyroidism and hypothyroidism. The rare condition of secondary hypothyroidism is caused by failure of TSH secretion in a patient with hypothalamic or anterior pituitary disease.

This is characterised by a low serum T_4 but TSH may be low, normal or even slightly elevated (pp. 784–785). Other non-specific abnormalities are shown in Box 20.9. In severe prolonged hypothyroidism, the electrocardiogram (ECG) classically demonstrates sinus bradycardia with low-voltage complexes and ST segment and T wave abnormalities. Measurement of thyroid peroxidase antibodies is helpful, but further investigations are rarely required (see Fig. 20.6).

Management

Treatment is with thyroxine replacement. It is customary to start with a low dose of 50 μg per day for 3 weeks, increasing thereafter to 100 μg per day for a further 3 weeks and finally to a maintenance dose of 100–150 μg per day. Thyroxine has a half-life of 7 days so it should always be taken as a single daily dose and at least 6 weeks should pass before repeating thyroid function tests and adjusting the dose, usually in increments of 25 μg per day. Patients feel better within 2–3 weeks. Reduction in weight and periorbital puffiness occurs quickly, but the restoration of skin and hair texture and resolution of any effusions may take 3–6 months. As illustrated in Figure 20.6, most patients do not require specialist review but will require life-long thyroxine therapy.

Fig. 20.6 An approach to adults with suspected primary hypothyroidism. This scheme ignores congenital causes of hypothyroidism (see Box 20.10) such as thyroid aplasia and dysmorphogenesis (associated with nerve deafness in Pendred's syndrome), which are usually diagnosed in childhood. (1) Immunoreactive TSH may be detected at normal or even modestly elevated levels in patients with pituitary failure; unless T_4 is only marginally low then TSH should be > 20 mU/L to confirm the diagnosis of primary hypothyroidism. (2) The usual abnormality in sick euthyroidism is a low TSH, but any pattern can occur. (3) Thyroid peroxidase antibodies are highly sensitive, but not very specific for autoimmune thyroid disease (see Boxes 20.8 and 20.10). (4) Specialist advice is most appropriate where indicated. Secondary hypothyroidism is rare, but is suggested by deficiency of pituitary hormones or by clinical features of pituitary tumour such as headache or visual field defect (p. 787). Rare causes of hypothyroidism with goitre include dysmorphogenesis and infiltration of the thyroid (see Box 20.10).

The dose of thyroxine should be adjusted to maintain serum TSH within the reference range. To achieve this, serum T_4 often needs to be in the upper part of the normal range or even slightly raised, because the T_3 required for receptor activation is derived exclusively from conversion of T_4 within the target tissues, without the usual contribution from thyroid secretion. Some physicians advocate combined replacement with T_4 and T_3 but this approach remains controversial and no ideal preparation exists (Box 20.11). Some patients remain symptomatic despite normalisation of TSH and may wish to take extra thyroxine which suppresses TSH values. However, there is evidence that suppressed TSH is a risk factor for osteoporosis and atrial fibrillation (p. 744; subclinical thyrotoxicosis), so this approach cannot be recommended.

It is important to measure thyroid function every 1–2 years once the dose of thyroxine is stabilised. This encourages patient compliance with therapy and allows adjustment for variable underlying thyroid activity and other changes in thyroxine requirements (Box 20.12).

EBM 20.11 Therapy with T_3 in addition to T_4 in hypothyroidism

'One RCT showed that combined $T_3 + T_4$ has beneficial effects on neuropsychological tests compared with T_4 alone. However, these findings were not replicated in more recent RCTs, no satisfactory combined synthetic preparation is available and the potency of animal thyroid extract is too variable.'

Box 20.12 Situations in which an adjustment of the dose of levothyroxine may be necessary

Increased dose required

Use of other medication

- Increase T_4 clearance
 - Phenobarbital
 - Phenytoin
 - Carbamazepine
 - Rifampicin
 - Sertraline*
 - Chloroquine*
- Interfere with intestinal T_4 absorption
 - Colestyramine
 - Sucralfate
 - Aluminium hydroxide
 - Ferrous sulphate
 - Dietary fibre supplements
 - Calcium carbonate

Pregnancy or oestrogen therapy

- Increases concentration of serum thyroxine-binding globulin

After surgical or ^{131}I ablation of Graves' disease

- Reduces thyroidal secretion with time

Malabsorption, e.g. coeliac disease

Decreased dose required

Ageing

- Decreases T_4 clearance

Graves' disease developing in patient with long-standing primary hypothyroidism

- Switch from production of blocking to stimulating TSH receptor antibodies

*Mechanism not fully established.

In some poorly compliant patients, thyroxine is taken diligently or even in excess for a few days prior to a clinic visit, resulting in the seemingly anomalous combination of a high serum T_4 and high TSH (see Box 20.5, p. 738).

Thyroxine replacement in ischaemic heart disease

Hypothyroidism and ischaemic heart disease are common conditions which often occur together. Although angina may remain unchanged in severity or paradoxically disappear with restoration of metabolic rate, exacerbation of myocardial ischaemia, infarction and sudden death are recognised complications of thyroxine replacement, even using doses as low as 25 µg per day. In patients with known ischaemic heart disease, thyroid hormone replacement should be introduced at low dose and increased very slowly under specialist supervision. It has been suggested that T_3 has an advantage over T_4 , since T_3 has a shorter half-life and any adverse effect will reverse more quickly, but the more distinct peak in hormone levels after each dose of T_3 is a disadvantage. Coronary artery surgery or angioplasty is required in the minority of patients with angina who cannot tolerate full thyroxine replacement therapy despite maximal anti-anginal therapy.

Hypothyroidism in pregnancy

Most pregnant women with primary hypothyroidism require an increase in the dose of thyroxine of approximately 50 µg daily to maintain normal TSH levels. This may reflect increased metabolism of thyroxine by the placenta and increased serum thyroxine-binding globulin during pregnancy, resulting in an increase in the total thyroid hormone pool to maintain the same free T_4 and T_3 concentrations. Recent research suggests that inadequate maternal T_4 therapy is associated with impaired cognitive development in their offspring. Serum TSH and free T_4 should be measured during each trimester and the dose of thyroxine adjusted to maintain a normal TSH. See also Box 20.19 (p. 753).

Myxoedema coma

This is a rare presentation of hypothyroidism in which there is a depressed level of consciousness, usually in an elderly patient who appears myxoedematous. Body temperature may be as low as 25°C, convulsions are not uncommon and cerebrospinal fluid (CSF) pressure and protein content are raised. The mortality rate is 50% and survival depends upon early recognition and treatment of hypothyroidism and other factors contributing to the altered consciousness level, such as phenothiazines, cardiac failure, pneumonia, dilutional hyponatraemia and respiratory failure.

Myxoedema coma is a medical emergency and treatment must begin before biochemical confirmation of the diagnosis. Suspected cases should be treated with an intravenous injection of 20 µg triiodothyronine followed by further injections of 20 µg 8-hourly until there is sustained clinical improvement. In survivors there is a rise in body temperature within 24 hours and, after 48–72 hours, it is usually possible to switch patients on to oral thyroxine in a dose of 50 µg daily. Unless it is apparent that the patient has primary hypothyroidism, the thyroid failure should also be assumed to be secondary to hypothalamic or pituitary disease and treatment given with hydrocortisone 100 mg i.m. 8-hourly, pending the results of T_4 , TSH and cortisol measurement (p. 784).

Other measures include slow rewarming (p. 102), cautious use of intravenous fluids, broad-spectrum antibiotics and high-flow oxygen. Occasionally, assisted ventilation may be necessary.

Asymptomatic abnormal thyroid function tests

One of the most common problems in medical practice is how to manage patients with abnormal thyroid function tests who have no obvious signs or symptoms of thyroid disease. These can be divided into three categories.

Subclinical thyrotoxicosis

Serum TSH is undetectable, and serum T_3 and T_4 are at the upper end of the reference range. This combination is most often found in older patients with multinodular goitre. These patients are at increased risk of atrial fibrillation and osteoporosis, and hence the consensus view is that they have mild thyrotoxicosis and require therapy, usually with ^{131}I . Otherwise, annual review is essential as the conversion rate to overt thyrotoxicosis with elevated T_4 and/or T_3 concentrations is 5% each year.

Subclinical hypothyroidism

Serum TSH is raised, and serum T_3 and T_4 concentrations are at the lower end of the reference range. This may persist for many years, although there is a risk of progression to overt thyroid failure, particularly if antibodies to thyroid peroxidase are present or if the TSH rises above 10 mU/L. In patients with non-specific symptoms, a trial of thyroxine therapy may be appropriate. In those with positive autoantibodies or TSH > 10 mU/L it is better to treat the thyroid failure early rather than risk loss to follow-up and subsequent presentation with profound hypothyroidism. Thyroxine should be given in a dose sufficient to restore the serum TSH concentration to normal.

Non-thyroidal illness ('sick euthyroidism')

This typically presents with a low serum TSH, raised T_4 and normal or low T_3 , in a patient with systemic illness who does not have clinical evidence of thyroid disease. These abnormalities are caused by decreased peripheral conversion of T_4 to T_3 , altered levels of binding proteins and their affinity for thyroid hormones, and often reduced secretion of TSH. During convalescence, serum TSH concentrations may increase to levels found in primary hypothyroidism. Because thyroid function tests are difficult to interpret in patients with non-thyroidal illness it is wise to avoid performing thyroid function tests unless there is clinical evidence of concomitant thyroid disease. If an abnormal result is found, treatment should only be given with specialist advice and the diagnosis should be re-evaluated after recovery.

Thyroid enlargement

Palpable thyroid enlargement is common, affecting about 5% of the population, but only a minority seek medical attention, often because a friend or relative has noticed a lump in the neck. Multinodular goitres and solitary nodules sometimes present with acute painful enlargement due to haemorrhage into a nodule. There are numerous causes of thyroid enlargement (Box 20.13), ranging from the soft diffuse goitre of puberty and youth, to the multinodular goitre of middle age and beyond, and the

20.13 Causes of thyroid enlargement

Diffuse goitre

- Simple goitre¹ (p. 750)
- Hashimoto's thyroiditis¹ (p. 748)
- Graves' disease (p. 745)
- Drugs
 - iodine, amiodarone (p. 749), lithium
- Iodine deficiency (endemic goitre)¹ (p. 749)
- Suppurative thyroiditis²
- Transient thyroiditis² (p. 748)
- Dyshormonogenesis¹ (p. 752)
- Infiltrative
 - Amyloidosis, sarcoidosis etc
- Riedel's thyroiditis² (p. 752)

Multinodular goitre (p. 750)

Solitary nodule

- Simple cyst
- Colloid nodule
- Follicular adenoma (p. 751)
- Papillary carcinoma (p. 751)
- Follicular carcinoma (p. 751)
- Medullary cell carcinoma (p. 752)
- Anaplastic carcinoma
- Lymphoma
- Metastasis

¹Goitre likely to shrink with thyroxine therapy.

²Usually tender.

solitary nodule which can present at any age. Whereas diffuse and multinodular goitre are almost invariably benign, there is a 1:20 chance of malignancy in the truly solitary lesion.

Palpation of the neck (including the thyroid gland and any lymph nodes, p. 732) will allow discrimination of the following distinct groups of patients. Thyroid function tests should always be performed.

Diffuse goitre

In the absence of thyrotoxicosis or hypothyroidism a diffuse goitre rarely needs further investigation or treatment unless it is very large and causing cosmetic symptoms or compression of other local structures (resulting in stridor or dysphagia). The presence of autoantibodies may support the diagnosis of Graves' disease or Hashimoto's thyroiditis, while their absence in a younger patient suggests a simple goitre. Thyroxine therapy is sometimes justified in an attempt to shrink the goitre.

Multinodular goitre

This condition is described on page 750. It is usually necessary to confirm the clinical diagnosis using ^{99m}Tc scintigraphy (see Fig. 20.4, p. 739) or ultrasonography. Sometimes one of the nodules is much larger than any other (a 'dominant' nodule); if such a nodule is 'cold' on isotope scanning, it may be investigated in the same way as a truly solitary nodule since the risk of malignancy is not negligible in such lesions.

Solitary thyroid nodule

It is important to determine whether the nodule is benign or malignant. It is rarely possible to make this distinction on clinical grounds alone, although the presence of cervical lymphadenopathy increases the likelihood of malignancy. However, a solitary nodule presenting in childhood or adolescence, particularly if there is a past history of head and neck irradiation, or one presenting in the elderly should heighten suspicion of a primary thyroid

malignancy (pp. 751–752). Very occasionally, a secondary deposit from a renal, breast or lung carcinoma presents as a painful, rapidly growing solitary thyroid nodule.

Investigations

Serum T_3 , T_4 and TSH should be measured in all patients with a solitary thyroid nodule. The finding of undetectable TSH is very suggestive of a benign autonomously functioning thyroid follicular adenoma, but this diagnosis can only be confirmed by thyroid isotope scanning (see Fig. 20.4, p. 739).

For euthyroid patients, the most useful investigation is fine needle aspiration of the nodule. This can be performed in the outpatient clinic using a standard 21-gauge needle and a 20 mL syringe, usually making several passes through different parts of the lesion. Aspiration may be therapeutic in the small proportion of patients in whom the swelling is a cyst, although recurrence on more than one occasion is an indication for surgery. Cytological examination can differentiate benign (80%) from definitely malignant or indeterminate nodules (20%), of which 25–50% are confirmed as cancer at surgery. The advantage of fine needle aspiration over isotope scanning is that a much higher proportion of patients avoid surgery; isotope scanning identifies suspicious 'cold nodules', but most of these are benign. The limitations of fine needle aspiration are that it cannot differentiate between follicular adenoma and carcinoma and that in 10–20% of cases an inadequate specimen is obtained. Ultrasound-guided needle aspiration can be helpful in increasing the quality of specimens.

Management

Solitary nodules with a solid component in which cytology either is inconclusive or shows malignant cells are treated by surgical excision. Those in which malignancy is confirmed by formal histology are then treated as described on page 751. Benign lesions are sometimes excised, if they are growing, but the majority of patients can be reassured.

Autoimmune thyroid disease

Thyroid diseases are amongst the most prevalent antibody-mediated autoimmune diseases and are associated with other organ-specific autoimmunity (Ch. 4 and p. 794). Autoantibodies may produce inflammation and destruction of thyroid tissue resulting in hypothyroidism, goitre (in Hashimoto's thyroiditis) or sometimes even transient thyrotoxicosis ('Hashitoxicosis'), or they may stimulate the TSH receptor to cause thyrotoxicosis (in Graves' disease). There is overlap between these conditions, since some patients have multiple autoantibodies.

Graves' disease

Graves' disease can occur at any age but is unusual before puberty and most commonly affects women aged 30–50 years. The most common manifestation is thyrotoxicosis with or without a diffuse goitre. The clinical features and differential diagnosis are described on pages 738–740. Graves' disease also causes ophthalmopathy and rarely pretibial myxoedema (p. 732). These extra-thyroidal features usually occur in thyrotoxic patients, but can occur in the absence of thyroid dysfunction.

Graves' thyrotoxicosis

Pathophysiology

The thyrotoxicosis results from the production of IgG antibodies directed against the TSH receptor on the thyroid follicular cell, which stimulate thyroid hormone production and proliferation of follicular cells, leading to goitre in the majority of patients. These antibodies are termed thyroid-stimulating immunoglobulins or TSH receptor antibodies (TRAb) and can be detected in the serum of 80–95% of patients with Graves' disease. The concentration of TRAb in the serum is presumed to fluctuate to account for the natural history of Graves' thyrotoxicosis (Fig. 20.7). The thyroid failure seen in some patients may result from the presence of blocking antibodies against the TSH receptor, and from tissue destruction by cytotoxic antibodies and cell-mediated immunity.

There is an association of Graves' disease with HLA-B8, DR3 and DR2 and with inability to secrete the water-soluble glycoprotein form of the ABO blood group antigens. There is 50% concordance for thyrotoxicosis between monozygotic twins, but only 5% concordance between dizygotic twins.

A suggested trigger for the development of thyrotoxicosis in genetically susceptible individuals may be infection with viruses or bacteria. Certain strains of the gut organisms *Escherichia coli* and *Yersinia enterocolitica* possess cell membrane TSH receptors; antibodies to these microbial antigens may cross-react with the TSH receptors on the host thyroid follicular cell. In regions of iodine deficiency (p. 749), iodine supplementation can precipitate thyrotoxicosis, but only in those with pre-existing subclinical Graves' disease. Smoking is weakly associated with Graves' thyrotoxicosis, but strongly linked with the development of ophthalmopathy.

Management

Symptoms of thyrotoxicosis respond to β -blockade (p. 739), but definitive treatment requires control of thyroid hormone secretion. The different options are compared in Box 20.14. For patients under 40 years of age most clinicians adopt the empirical approach of prescribing a course of carbimazole and recommending surgery if relapse occurs, while ^{131}I is employed as first- or second-line treatment in those aged over 40. A number of observational studies have linked therapeutic ^{131}I with increased incidence of some malignancies, particularly of the thyroid and gastrointestinal tract, but the results have been inconsistent; the association may be with Graves' disease rather than its therapy, and the magnitude of the effect, if any, is small. Experience from the Chernobyl disaster suggests that younger people are more sensitive to radiation-induced thyroid cancer. In many centres, however, ^{131}I is used more extensively, even in young patients.

Antithyroid drugs. The most commonly used are carbimazole and its active metabolite, methimazole (not available in the UK). Propylthiouracil is equally effective. These drugs reduce the synthesis of new thyroid hormones by inhibiting the iodination of tyrosine (see Fig. 20.3, p. 737). Carbimazole also has an immunosuppressive action, leading to a reduction in serum TRAb concentrations, but this is not enough to influence the natural history of the thyrotoxicosis significantly.

Fig. 20.7 Natural history of the thyrotoxicosis of Graves' disease.

A and **B** The majority (60%) of patients have either prolonged periods of thyrotoxicosis of fluctuating severity, or periods of alternating relapse and remission. **C** It is the minority who experience a single short-lived episode followed by prolonged remission and, in some cases, by the eventual onset of hypothyroidism.

Antithyroid drugs should be introduced at high doses (carbimazole 40–60 mg daily or propylthiouracil 400–600 mg daily). Usually this results in subjective improvement within 10–14 days and renders the patient clinically and biochemically euthyroid at 3–4 weeks. At this point the dose can be reduced and titrated to maintain T_4 and TSH within their reference range. In most patients carbimazole is continued at 5–20 mg/day for 12–18 months in the hope that remission will occur. Thyrotoxicosis relapses in at least 50% of cases, usually within 2 years of stopping treatment. Rarely, T_4 and TSH levels fluctuate between those of thyrotoxicosis and hypothyroid-

ism at successive review appointments, despite good drug compliance, presumably due to rapidly changing concentrations of TRAb. In these patients satisfactory control can be achieved by blocking thyroid hormone synthesis with carbimazole 30–40 mg daily and adding thyroxine 100–150 µg daily as replacement therapy.

Antithyroid drugs can have adverse effects. The most common is a rash. Agranulocytosis is a rare but potentially serious complication which cannot be predicted by routine measurement of white blood cell count but which is reversible on stopping treatment. Patients should be warned to stop the drug and seek medical advice immediately should a severe sore throat or fever develop whilst on treatment. If side-effects do develop, another member of the group can be substituted as cross-sensitivity between the antithyroid drugs is unusual.

Subtotal thyroidectomy. Patients should be rendered euthyroid with antithyroid drugs before operation. Potassium iodide, 60 mg 8-hourly orally, is often added for 2 weeks before surgery to inhibit thyroid hormone release and reduce the size and vascularity of the gland, making surgery technically easier. Complications of surgery are rare. One year after surgery, 80% of patients are euthyroid, 15% are permanently hypothyroid and 5% remain thyrotoxic. Thyroid failure within 6 months of operation may be temporary. Long-term follow-up of patients treated surgically is necessary, as the late development of hypothyroidism and recurrence of thyrotoxicosis are well recognised.

Radioactive iodine. ^{131}I is administered orally as a single dose, and is trapped and organified in the thyroid (see Fig. 20.3, p. 737). Although ^{131}I decays within a few weeks, it has long-lasting inhibitory effects on survival and replication of follicular cells. The variable radio-iodine uptake and radiosensitivity of the gland means that the choice of dose is empirical; in most centres approximately 400 MBq (10 mCi) is given orally. This regimen is effective in 75% of patients within

20.14 Comparison of treatments for the thyrotoxicosis of Graves' disease

Management	Common indications	Contraindications	Disadvantages/complications
Antithyroid drugs (carbimazole, propylthiouracil)	First episode in patients < 40 yrs	Breastfeeding (propylthiouracil suitable)	Hypersensitivity rash 2% Agranulocytosis 0.2% > 50% relapse rate usually within 2 years of stopping drug
Subtotal thyroidectomy	Large goitre Poor drug compliance, especially in young patients Recurrent thyrotoxicosis after course of antithyroid drugs in young patients	Previous thyroid surgery Dependence upon voice, e.g. opera singer, lecturer ¹	Hypothyroidism (~25%) Transient hypocalcaemia (10%) Permanent hypoparathyroidism (1%) Recurrent laryngeal nerve palsy ¹ (1%)
Radio-iodine	Patients > 40 yrs ² Recurrence following surgery irrespective of age Other serious comorbidity	Pregnancy or planned pregnancy within 6 months of treatment Active Graves' ophthalmopathy ³	Hypothyroidism, ~40% in first year, 80% after 15 years Most likely treatment to result in exacerbation of ophthalmopathy ³

¹It is not only vocal cord palsy due to recurrent laryngeal nerve damage which alters the voice following thyroid surgery; the superior laryngeal nerves are frequently transected and result in minor changes in voice quality.

²In many institutions, ^{131}I is used more liberally and prescribed for much younger patients.

³The extent to which radio-iodine exacerbates ophthalmopathy is controversial and practice varies; some use prednisolone for 4 months to reduce this risk (see Box 20.15).

EBM 20.15 Effects of ^{131}I and prednisolone in Graves' ophthalmopathy

'The deterioration of ophthalmopathy, which occurs in some patients following ^{131}I therapy, can be prevented by a 3-month course of oral prednisolone.'

• Bartalena L, et al. *N Engl J Med* 1989; 321:1349–1352.

For further information:  www.rcplondon.ac.uk

4–12 weeks. During the lag period, symptoms can be controlled by a β -blocker or, in more severe cases, by carbimazole. However, carbimazole reduces the efficacy of ^{131}I therapy because it prevents organification of ^{131}I in the gland, and so should be avoided until 48 hours after radio-iodine administration. If thyrotoxicosis persists after 6 months, a further dose of ^{131}I can be given. The disadvantage of ^{131}I treatment is that the majority of patients eventually develop hypothyroidism. ^{131}I is usually avoided in patients with Graves' ophthalmopathy and evidence of active orbital inflammation, and used only with caution in those with 'burnt out' eye disease (Box 20.15). In women of reproductive age, pregnancy must be excluded before administration of ^{131}I and avoided for 6 months thereafter; men are also advised against fathering children for 6 months.

Thyrotoxicosis in pregnancy

The coexistence of pregnancy and thyrotoxicosis is unusual, as anovulatory cycles are common in thyrotoxic patients and autoimmune disease tends to remit during pregnancy, when the maternal immune response is suppressed. Thyroid function tests must be interpreted in the knowledge that thyroid-binding globulin, and hence total T_4 and T_3 levels, are increased in pregnancy and that TSH normal ranges may be lower (see Box 20.19, p. 753); a fully suppressed TSH with elevated free thyroid hormone levels indicates thyrotoxicosis. The thyrotoxicosis is almost always caused by Graves' disease. Both mother and fetus must be considered, since maternal thyroid hormones, TRAb and antithyroid drugs can all cross the placenta to some degree, exposing the fetus to the risks of thyrotoxicosis, iatrogenic hypothyroidism and goitre.

Thyrotoxicosis should be treated with antithyroid drugs which cross the placenta and also treat the fetus, whose thyroid gland is exposed to the action of maternal TRAb. Propylthiouracil may be preferable to carbimazole since the latter might be associated with a skin defect in the child, known as aplasia cutis. In order to avoid fetal hypothyroidism and goitre, it is important to use the smallest dose of antithyroid drug (optimally less than 150 mg propylthiouracil per day) that will maintain maternal (and presumably fetal) free T_4 , T_3 and TSH within their respective normal ranges. Frequent review of mother and fetus (using ultrasonography and heart rate monitoring) is important. TRAb levels can be measured in the third trimester to predict the likelihood of neonatal thyrotoxicosis. When TRAb levels are not elevated, the antithyroid drug can be discontinued 4 weeks before the expected date of delivery to minimise the risk of fetal hypothyroidism at the time of maximum brain development. After delivery, if antithyroid drug is required and the patient wishes to breastfeed, then

propylthiouracil is the drug of choice, as it is excreted in the milk to a much lesser extent than carbimazole.

If subtotal thyroidectomy is necessary because of poor drug compliance or drug hypersensitivity, it is most safely performed in the second trimester. Radioactive iodine is absolutely contraindicated, as it invariably induces fetal hypothyroidism.

Graves' ophthalmopathy

This condition is immunologically mediated, but the autoantigen has not been identified. Within the orbit (and the dermis) there is cytokine-mediated proliferation of fibroblasts which secrete hydrophilic glycosaminoglycans. The resulting increase in interstitial fluid content, combined with a chronic inflammatory cell infiltrate, causes marked swelling and ultimately fibrosis of the extraocular muscles (Fig. 20.8) and a rise in retrobulbar pressure. The eye is displaced forwards (proptosis, exophthalmos; see p. 733) and in severe cases there is optic nerve compression.

Ophthalmopathy, like thyrotoxicosis (see Fig. 20.7), typically follows an episodic course and it is helpful to distinguish patients with active inflammation (peri-orbital oedema and conjunctival inflammation with changing orbital signs) from those in whom the inflammation has 'burnt out'. Eye disease is detectable in up to 50% of thyrotoxic patients at presentation, but active ocular inflammation may occur before or after thyrotoxic episodes (exophthalmic Graves' disease). It is more common in cigarette smokers and is exacerbated by poor control of thyroid function, especially hypothyroidism.

Fig. 20.8 Graves' disease. **A** Bilateral ophthalmopathy in a 42-year-old man. The main symptoms were diplopia in all directions of gaze and reduced visual acuity in the left eye. The periorbital swelling is due to retrobulbar fat prolapsing into the eyelids, and increased interstitial fluid as a result of raised intraorbital pressure. **B** Transverse CT of the orbits, showing the enlarged extraocular muscles. This is most obvious at the apex of the left orbit (arrow), where compression of the optic nerve caused reduced visual acuity.

The most frequent presenting symptoms are related to increased exposure of the cornea, resulting from proptosis and lid retraction. There may be excessive lacrimation made worse by wind and bright light, a 'gritty' sensation in the eye, and pain due to conjunctivitis or corneal ulceration. In addition, there may be reduction of visual acuity and/or visual fields as a consequence of corneal oedema or optic nerve compression. Other signs of optic nerve compression include reduced colour vision and a relative afferent pupillary defect (pp. 733 and 1163). If the extraocular muscles are involved and do not act in concert, diplopia results.

The majority of patients require no treatment other than reassurance. Methylcellulose eye drops and gel counter the gritty discomfort of dry eyes, and tinted glasses or side shields attached to spectacle frames reduce the excessive lacrimation triggered by sun or wind. Severe inflammatory episodes are treated with glucocorticoids (e.g. daily oral prednisolone or pulsed i.v. methylprednisolone) and sometimes orbital irradiation. Loss of visual acuity is an indication for urgent surgical decompression of the orbit. In 'burnt out' disease, surgery to the eyelids and/or ocular muscles may improve conjunctival exposure, cosmetic appearance and diplopia.

Pretibial myxoedema

This infiltrative dermopathy occurs in fewer than 10% of patients with Graves' disease and has similar pathological features as occur in the orbit. It takes the form of raised pink-coloured or purplish plaques on the anterior aspect of the leg, extending on to the dorsum of the foot (p. 732). The lesions may be itchy and the skin may have a 'peau d'orange' appearance with growth of coarse hair; less commonly, the face and arms are affected. Treatment is rarely required, but in severe cases topical glucocorticoids may be helpful.

Hashimoto's thyroiditis

Hashimoto's thyroiditis is characterised by destructive lymphoid infiltration of the thyroid, ultimately leading to a varying degree of fibrosis and thyroid enlargement. There is an increased risk of thyroid lymphoma (p. 752), although this is exceedingly rare. The nomenclature of autoimmune hypothyroidism is confusing. Some authorities reserve the term 'Hashimoto's thyroiditis' for patients with positive anti-thyroid peroxidase autoantibodies and a firm goitre who may or may not be hypothyroid, and use the term 'spontaneous atrophic hypothyroidism' for hypothyroid patients without a goitre in whom TSH receptor-blocking antibodies may be more important than anti-peroxidase antibodies. However, these syndromes can both be considered as variants of the same underlying disease process.

Hashimoto's thyroiditis increases in incidence with age and affects approximately 3.5 per 1000 women and 0.8 per 1000 men each year. Many present with a small or moderately sized diffuse goitre, which is characteristically firm or rubbery in consistency. The goitre may be soft, however, and impossible to differentiate from simple goitre (p. 750) by palpation alone. Around 25% of patients are hypothyroid at presentation. In the remainder, serum T_4 is normal and TSH normal or raised, but these patients are at risk of developing overt hypothyroidism in future years. Anti-thyroid peroxidase

antibodies are present in the serum in more than 90% of patients with Hashimoto's thyroiditis. In those under the age of 20 years, antinuclear factor (ANF) may also be positive.

Thyroxine therapy is indicated as treatment for hypothyroidism (p. 742), and also to shrink an associated goitre. In this context, the dose of thyroxine should be sufficient to suppress serum TSH to low but detectable levels.

Transient thyroiditis

Subacute (de Quervain's) thyroiditis

In its classical painful form, subacute thyroiditis is a transient inflammation of the thyroid gland occurring after infection with Coxsackie, mumps or adenoviruses. There is pain in the region of the thyroid that may radiate to the angle of the jaw and the ears, and is made worse by swallowing, coughing and movement of the neck. The thyroid is usually palpably enlarged and tender. Systemic upset is common. Affected patients are usually females aged 20–40 years. Painless transient thyroiditis can also occur after viral infection and in patients with underlying autoimmune disease. The condition can also be precipitated by drugs, including interferon- α and lithium.

Irrespective of the clinical presentation, inflammation in the thyroid gland occurs and is associated with release of colloid and stored thyroid hormones, but also with damage to follicular cells and impaired synthesis of new thyroid hormones. As a result, T_4 and T_3 levels are raised for 4–6 weeks until the preformed colloid is depleted. Thereafter, there is usually a period of hypothyroidism of variable severity before the follicular cells recover and normal thyroid function is restored within 4–6 months (Fig. 20.9). In the thyrotoxic phase, the iodine uptake is low, because the damaged follicular cells are unable to trap iodine and because TSH secretion is suppressed. Low-titre thyroid autoantibodies appear transiently in the serum, and the erythrocyte sedimentation rate (ESR) is usually raised. High-titre autoantibodies suggest an underlying autoimmune pathology and greater risk of recurrence and ultimate progression to hypothyroidism.

Fig. 20.9 Thyroid function tests in an episode of transient thyroiditis. This pattern might be observed in classical subacute (de Quervain's) thyroiditis, painless thyroiditis or post-partum thyroiditis. The duration of each phase varies between patients. Note that the lower limit of detection of TSH is close to the lower limit of the normal range.

The pain and systemic upset usually respond to simple measures such as non-steroidal anti-inflammatory drugs (NSAIDs). Occasionally, however, it may be necessary to prescribe prednisolone 40 mg daily for 3–4 weeks. The thyrotoxicosis is mild and treatment with a β -blocker is usually adequate. Antithyroid drugs are of no benefit because thyroid hormone synthesis is impaired rather than enhanced. Careful monitoring of thyroid function and symptoms is required so that thyroxine can be prescribed temporarily in the hypothyroid phase. Care must be taken to identify patients presenting with hypothyroidism who are in the later stages of a transient thyroiditis, since they are unlikely to require life-long thyroxine therapy (see Fig. 20.6, p. 742).

Post-partum thyroiditis

The maternal immune response, which is modified during pregnancy to allow survival of the fetus, is enhanced after delivery and may unmask previously unrecognised subclinical autoimmune thyroid disease. Surveys have shown that transient biochemical disturbances of thyroid function occur in 5–10% of women within 6 months of delivery (see Box 20.19, p. 753). Those affected are likely to have anti-thyroid peroxidase antibodies in the serum in early pregnancy. Symptoms of thyroid dysfunction are rare and there is no association between postnatal depression and abnormal thyroid function tests. However, symptomatic thyrotoxicosis presenting for the first time within 12 months of childbirth is likely to be due to post-partum thyroiditis and the diagnosis is confirmed by a negligible radioisotope uptake. The clinical course and treatment are similar to painless subacute thyroiditis (see above). Post-partum thyroiditis tends to recur after subsequent pregnancies and eventually patients progress over a period of years to permanent hypothyroidism.

Iodine-associated thyroid disease

Iodine deficiency

Thyroid enlargement is extremely common in certain mountainous parts of the world, such as the Andes, the Himalayas and central Africa, where there is dietary iodine deficiency (endemic goitre). Most patients are euthyroid with normal or raised TSH levels, although hypothyroidism can occur with severe iodine deficiency. Iodine supplementation programmes have abolished this condition in most developed countries.

Iodine-induced thyroid dysfunction

Iodine has complex effects on thyroid function. Very high concentrations of iodine inhibit thyroid hormone release and this forms the rationale for iodine treatment of thyroid storm (p. 741) and prior to subtotal thyroidectomy (p. 746). Iodine administration initially enhances, but then inhibits, iodination of tyrosine and thyroid hormone synthesis (see Fig. 20.3, p. 737). The resulting effect of iodine on thyroid function varies according to whether the patient has an iodine-deficient diet or underlying thyroid disease. In iodine-deficient parts of the world, transient thyrotoxicosis may be precipitated by prophylactic iodination programmes. In iodine-sufficient areas, thyrotoxicosis can be precipitated by radiographic contrast medium or expectorants in

individuals who have underlying thyroid disease predisposing to thyrotoxicosis, such as multinodular goitre or Graves' disease in remission. Induction of thyrotoxicosis by iodine is called the Jod-Basedow effect. Chronic excess iodine administration can, however, result in hypothyroidism. Increased iodine within the thyroid gland down-regulates iodine trapping, so that uptake is low in all circumstances.

Amiodarone

The anti-arrhythmic agent amiodarone has a structure that is analogous to T_4 (Fig. 20.10) and contains huge amounts of iodine; a 200 mg dose contains 75 mg iodine, compared with a daily dietary requirement of just 125 μ g. Amiodarone also has a cytotoxic effect on thyroid follicular cells and inhibits conversion of T_4 to T_3 . Most patients receiving amiodarone have normal thyroid function, but up to 20% develop hypothyroidism or thyrotoxicosis and so thyroid function should be monitored regularly. The ratio of T_4 : T_3 is elevated and TSH provides the best indicator of thyroid function.

The thyrotoxicosis can be classified as either:

- type I: a Jod-Basedow effect in patients with underlying thyroid disease, *or*
- type II: thyroiditis due to cytotoxicity, resulting in a transient thyrotoxicosis.

These patterns can overlap and can be difficult to distinguish clinically, as iodine uptake is low in both. There is no widely accepted management algorithm, although the iodine excess renders the gland completely resistant to radioiodine. Antithyroid drugs may be effective in patients with the type I form, but are ineffective in type II thyrotoxicosis. Prednisolone is beneficial in the type II form. A pragmatic approach is to commence combination therapy with an antithyroid drug and glucocorticoid in patients with significant thyrotoxicosis. A rapid response (within 1–2 weeks) usually indicates a type II picture and permits withdrawal of the antithyroid therapy; a slower response suggests a type I picture, when antithyroid drugs may be continued and prednisolone withdrawn. Potassium perchlorate can also be used to inhibit iodine trapping in the thyroid. If the cardiac state allows, amiodarone should be discontinued, but it has a long half-life (50–60 days) so its effects are long-lasting. To minimise the risk of type I thyrotoxicosis, thyroid function should be measured in all patients prior to

Fig. 20.10 The structure of amiodarone and T_4 . Note the similarities.

commencement of amiodarone therapy, and amiodarone avoided if TSH is suppressed.

Hypothyroidism should be treated with thyroxine, which can be given while amiodarone is continued.

Simple and multinodular goitre

These terms describe diffuse or multinodular enlargement of the thyroid, which occurs sporadically and is of unknown aetiology.

Simple diffuse goitre

This form of goitre usually presents between the ages of 15 and 25 years, often during pregnancy, and tends to be noticed, not by the patient, but by friends and relatives. Occasionally, there is a tight sensation in the neck, particularly when swallowing. The goitre is soft and symmetrical and the thyroid is enlarged to two or three times its normal size. There is no tenderness, lymphadenopathy or overlying bruit. Concentrations of T_3 , T_4 and TSH are normal and no thyroid autoantibodies are detected in the serum. No treatment is necessary and in most cases the goitre regresses. In some, however, the unknown stimulus to thyroid enlargement persists and, as a result of recurrent episodes of hyperplasia and involution during the following 10–20 years, the gland becomes multinodular with areas of autonomous function.

Multinodular goitre

The natural history is shown in Figure 20.11. Patients with thyroid enlargement in the absence of thyroid dysfunction or positive autoantibodies (i.e. with ‘simple goitre’, see above) as young adults may progress to develop nodules. These nodules grow at varying rates and secrete thyroid hormone ‘autonomously’, thereby suppressing TSH-dependent growth and function in the rest of the gland. Ultimately, complete suppression of TSH occurs in about 25% of cases, with T_4 and T_3 levels often within the normal range (subclinical thyrotoxicosis, p. 744) but sometimes elevated (toxic multinodular goitre, Fig. 20.4, p. 739). Opinions differ as to whether

Fig. 20.11 Natural history of simple goitre.

the nodules represent multiple adenomas or focal hyperplasia. There are reports that the prevalence of foci of thyroid cancer is increased in multinodular goitres, but for practical purposes patients can be reassured that it is a benign condition and malignancy need only be considered in patients with a large ‘dominant’ nodule that is ‘cold’ (i.e. does not take up radioisotope, p. 744).

Clinical features and investigations

Multinodular goitre is usually diagnosed in patients presenting with thyrotoxicosis, a large goitre with or without tracheal compression, or sudden painful swelling caused by haemorrhage into a nodule or cyst. The goitre is nodular or lobulated on palpation and may extend retrosternally; however, not all multinodular goitres causing thyrotoxicosis are easily palpable. Very large goitres may cause mediastinal compression with stridor (Fig. 20.12), dysphagia and obstruction of the superior vena cava. Hoarseness due to recurrent laryngeal nerve palsy can occur, but is far more suggestive of thyroid carcinoma.

Fig. 20.12 Multinodular goitre with retrosternal extension and tracheal compression. [A] A flow-volume loop (p. 650) showing a square-shaped inspiratory curve indicating extrathoracic airflow obstruction. [B] A CT scan of the upper mediastinum showing a large retrosternal goitre (black arrows) with marked deviation and compression of the trachea (white arrow).

The diagnosis can be confirmed by a radioisotope thyroid scan (see Fig. 20.4, p. 739) and/or ultrasonography. In patients with large goitres a flow-volume loop is a good screening test for significant tracheal compression (see Fig. 20.12). If intervention is contemplated, a CT or MRI of the thoracic inlet should be performed to quantify the degree of tracheal displacement or compression and the extent of retrosternal extension. In those with a 'dominant', 'cold' nodule, fine needle aspiration is indicated to exclude thyroid cancer.

Management

If the goitre is small, no treatment is necessary but annual thyroid function testing should be arranged, as the natural history is progression to a toxic multinodular goitre. Partial thyroidectomy is indicated for large goitres which cause mediastinal compression or which are cosmetically unattractive. ^{131}I can result in a significant reduction in thyroid size and may be of value in elderly patients (Box 20.16). Unfortunately, recurrence 10–20 years later is not uncommon. Thyroxine therapy is of no benefit in shrinking multinodular goitres and may simply aggravate any associated thyrotoxicosis.

In toxic multinodular goitre treatment is usually with ^{131}I . The iodine uptake is lower than in Graves' disease so a higher dose may be administered (up to 800 MBq (approximately 20 mCi)) and hypothyroidism is less common. In thyrotoxic patients with a large goitre, partial thyroidectomy may be indicated. Long-term treatment with antithyroid drugs is not usually employed, as relapse is invariable after drug withdrawal.

Asymptomatic patients with subclinical thyrotoxicosis (p. 744) are increasingly being treated with ^{131}I on the grounds that a suppressed TSH is a risk factor for atrial fibrillation and, particularly in post-menopausal women, osteoporosis.

EBM 20.16 Medical therapy to shrink non-toxic multinodular goitre

' ^{131}I , but not thyroxine therapy, reduces thyroid volume in patients with large multinodular goitres and normal thyroid function.'

• Wesche MFT, et al. J Clin Endocrinol Metab 2001; 86:998–1005.

Thyroid neoplasia

Patients with thyroid tumours usually present with a solitary nodule (p. 744). Most are benign and a few of these, called 'toxic adenomas', secrete excess thyroid hormones. Primary thyroid malignancy is rare, accounting for less than 1% of all carcinomas, and has an incidence of 25 per million per annum. As shown in Box 20.17, it can be classified according to the cell type of origin. With the exception of medullary carcinoma, thyroid cancer is more common in females.

Toxic adenoma

The presence of a toxic solitary nodule is the cause of less than 5% of all cases of thyrotoxicosis. The nodule is a follicular adenoma, which autonomously secretes excess

20.17 Malignant thyroid tumours

Type of tumour	Frequency (%)	Age at presentation (years)	20-year survival (%)
Follicular cells			
Differentiated carcinoma			
Papillary	70	20–40	95
Follicular	10	40–60	60
Undifferentiated carcinoma			
Anaplastic	5	> 60	< 1
Parafollicular C cells			
Medullary carcinoma	5–10	> 40*	50
Lymphocytes			
Lymphoma	5–10	> 60	10

*Patients with medullary carcinoma as part of MEN type 2 (p. 793) may present in childhood.

thyroid hormones and inhibits endogenous TSH secretion with subsequent atrophy of the rest of the thyroid gland. The adenoma is usually greater than 3 cm in diameter.

Most patients are female and over 40 years of age. Although many nodules are palpable, the diagnosis can be made with certainty only by isotope scanning (see Fig. 20.4, p. 739). The thyrotoxicosis is usually mild and in almost 50% of patients the plasma T_3 alone is elevated (T_3 thyrotoxicosis). ^{131}I (400–800 MBq (10–20 mCi)) is highly effective and is an ideal treatment since the atrophic cells surrounding the nodule do not take up iodine and so receive little or no radiation. For this reason, permanent hypothyroidism is unusual. A surgical hemithyroidectomy is an alternative.

Differentiated carcinoma

Papillary carcinoma

This is the most common of the malignant thyroid tumours and accounts for 90% of irradiation-induced thyroid cancer. It may be multifocal and spread is to regional lymph nodes. Some patients present with cervical lymphadenopathy and no apparent thyroid enlargement; in such instances, the primary lesion may be less than 10 mm in diameter.

Follicular carcinoma

This is always a single encapsulated lesion. Spread to cervical lymph nodes is rare. Metastases are blood-borne and are most often found in bone, lungs and brain.

Management

This is usually by total thyroidectomy followed by a large dose of ^{131}I (3700 MBq (approximately 100 mCi)) in order to ablate any remaining thyroid tissue, normal or malignant. Thereafter, long-term treatment with thyroxine in a dose sufficient to suppress TSH (usually 150–200 µg daily) is important, as there is evidence that growth of differentiated thyroid carcinomas is TSH-dependent. Follow-up is by measurement of serum thyroglobulin, which should be undetectable in patients whose normal thyroid has been ablated and who are taking a suppressive dose of thyroxine. Detectable thyroglobulin is suggestive of tumour recurrence or metastases, which may be localised

by whole-body scanning with ^{131}I and may respond to further radio-iodine therapy. For meaningful results, isotope scanning requires serum TSH concentrations to be elevated ($> 20 \text{ mU/L}$). In the past this was achieved by stopping thyroxine for 4–6 weeks, inducing symptomatic hypothyroidism. The availability of recombinant human TSH now allows measurement of stimulated thyroglobulin and radio-iodine uptake without the need to stop thyroxine therapy.

Prognosis

Most patients have an excellent prognosis when treated appropriately. Those under 50 years of age with papillary carcinoma have a near-normal life expectancy if the tumour is less than 2 cm in diameter, confined to the thyroid and cervical nodes, and of low-grade malignancy histologically. Even for patients with distant metastases at presentation, the 10-year survival is approximately 40%.

Anaplastic carcinoma and lymphoma

These two conditions are difficult to distinguish clinically but are distinct cytologically and histologically. Patients are usually elderly women in whom there is rapid thyroid enlargement over 2–3 months. The goitre is hard and symmetrical. There is usually stridor due to tracheal compression and hoarseness due to recurrent laryngeal nerve palsy. There is no effective treatment of anaplastic carcinoma, although radiotherapy may afford temporary relief of mediastinal compression. The prognosis for lymphoma, which may arise from pre-existing Hashimoto's thyroiditis, is better (p. 1037). External irradiation often produces dramatic goitre shrinkage and, when combined with chemotherapy, may result in survival for 5 years or more.

Medullary carcinoma

This tumour arises from the parafollicular C cells of the thyroid. In addition to calcitonin, the tumour may secrete 5-hydroxytryptamine (5-HT, serotonin), various peptides of the tachykinin family, ACTH and prostaglandins. As a consequence, carcinoid syndrome (p. 782) and Cushing's syndrome (p. 770) may occur.

Patients usually present in middle age with a firm thyroid mass. Cervical lymphadenopathy is common, but distant metastases are rare initially. Serum calcitonin levels are raised and are useful in monitoring response to treatment. Despite the very high levels of calcitonin found in some patients, hypocalcaemia is extremely rare.

Treatment is by total thyroidectomy with removal of affected cervical nodes. Since the C cells do not concentrate iodine, there is no role for ^{131}I therapy. Prognosis is very variable, some patients surviving 20 years or more and others less than 1 year.

Medullary carcinoma of the thyroid may occur sporadically, or in families as part of the MEN type 2 syndrome (p. 793).

Riedel's thyroiditis

This is not a form of thyroid cancer, but the presentation is similar and the differentiation can usually only be made by thyroid biopsy. It is an exceptionally rare condition of unknown aetiology in which there is extensive infiltration of the thyroid and surrounding structures with fibrous tissue. There may be associated

20.18 The thyroid gland in old age

Thyrotoxicosis

- **Causes:** commonly due to multinodular goitre.
- **Clinical features:** apathy, anorexia, proximal myopathy, atrial fibrillation and cardiac failure predominate.
- **Non-thyroidal illness:** thyroid function tests are performed more frequently in the elderly, but interpretation may be altered by intercurrent illness.

Hypothyroidism

- **Clinical features:** non-specific features such as physical and mental slowing are often attributed to increasing age and the diagnosis is delayed.
- **Myxoedema coma** (p. 743): more likely in the elderly.
- **Thyroxine dose:** to avoid exacerbating latent or established heart disease, the starting dose should be $25 \mu\text{g}$ daily. Thyroxine requirements fall with increasing age and few patients need $> 100 \mu\text{g}$ daily.
- **Other medication** (see Box 20.12, p. 743): may interfere with absorption or metabolism of thyroxine, necessitating an increase in dose.

mediastinal and retroperitoneal fibrosis. Presentation is with a slow-growing goitre which is irregular and stony-hard. There is usually tracheal and oesophageal compression necessitating partial thyroidectomy. Other recognised complications include recurrent laryngeal nerve palsy, hypoparathyroidism and eventually hypothyroidism.

Congenital thyroid disease

Early treatment with thyroxine is essential to prevent irreversible brain damage in children with congenital hypothyroidism. Routine screening of TSH levels in blood spot samples obtained 5–7 days after birth (as part of the Guthrie test) has revealed an incidence of approximately 1 in 3000, resulting from thyroid agenesis, ectopic or hypoplastic glands, or dyshormonogenesis. Congenital hypothyroidism is thus six times more common than phenylketonuria. It is now possible to start thyroid replacement therapy within 2 weeks of birth. Developmental assessment of infants treated at this early stage has revealed no differences between cases and controls in most children.

Dyshormonogenesis

Several autosomal recessive defects in thyroid hormone synthesis have been described; the most common results from deficiency of the intrathyroidal peroxidase enzyme. Homozygous individuals present with congenital hypothyroidism; heterozygotes present in the first two decades of life with goitre, normal thyroid hormone levels and a raised TSH. The combination of dyshormonogenetic goitre and nerve deafness is known as Pendred's syndrome and is due to mutations in pendrin, the protein which transports iodide to the luminal surface of the follicular cell (see Fig. 20.3, p. 737).

Thyroid hormone resistance

This is a rare disorder in which the pituitary and hypothalamus are resistant to feedback suppression of TSH by T_3 , sometimes due to mutations in the

20.19 Thyroid disease in pregnancy

Normal pregnancy

- **Trimester-specific normal ranges:** should be used to interpret thyroid function test results in pregnancy. In the first trimester, TSH is lower and free T_4 and T_3 higher, in part due to thyroid stimulation by human chorionic gonadotrophin (hCG). In later pregnancy, free T_4 and T_3 are lower. Binding globulin levels are induced by oestrogen, so total T_4 and T_3 levels are invariably high.
- **Iodine requirements:** increased in pregnancy. The World Health Organization (WHO) recommends minimum intake of 200 $\mu\text{g/day}$.
- **Screening of thyroid function and autoantibodies:** not recommended for every woman, but should be performed in first trimester in those with a personal or family history of thyroid disease, goitre, other autoimmune disease including type 1 diabetes, or when there is clinical suspicion of thyroid dysfunction.

Thyrotoxicosis

- **Hyperemesis gravidarum:** associated with thyrotoxic biochemistry, sometimes requiring antithyroid drugs.
- **Subclinical thyrotoxicosis:** not usually treated, to avoid fetal hypothyroidism.
- **Anti-thyroid drugs:** propylthiouracil is first choice.

Hypothyroidism

- **Preterm labour and impaired cognitive development in the offspring:** may be associated with even subclinical hypothyroidism.
- **Thyroxine replacement therapy dose requirements:** increase by 30–50% from early in pregnancy. Monitoring to maintain TSH results within the trimester-specific reference range is recommended in early pregnancy and at least once in each trimester.

Post-partum thyroiditis

- **Screening:** not recommended for every woman, but thyroid function should be tested 4–6 weeks post-partum in those with a personal history of thyroid disease, goitre or other autoimmune disease including type 1 diabetes, those known to have positive anti-thyroid peroxidase antibodies, or when there is clinical suspicion of thyroid dysfunction.

thyroid hormone receptor β or due to defects in monoiodinase activity. The result is high levels of TSH, T_4 and T_3 , often with a moderate goitre which may not be noted until adulthood. Thyroid hormone signalling is highly complex and involves different isozymes of both monoiodinases and thyroid hormone receptors in different tissues. For that reason, other tissues may or may not share the resistance to thyroid hormone and there may be features of thyrotoxicosis (e.g. tachycardia). This condition can be difficult to distinguish from an equally rare TSH-producing pituitary tumour (see Box 20.5, p. 738); administration of TRH results in elevation of TSH in thyroid hormone resistance and not in TSHoma, but an MRI scan of the pituitary may be necessary to exclude a macroadenoma.

THE REPRODUCTIVE SYSTEM

Clinical practice in reproductive medicine is shared between several specialties, including gynaecology,

urology, paediatrics, psychiatry and endocrinology. The following section is focused on disorders managed by endocrinologists.

Functional anatomy, physiology and investigations

The physiology of male and female reproductive function is illustrated in Figures 20.13 and 20.14 respectively. Pathways for synthesis of sex steroids are shown in Figure 20.20 (p. 770).

The male

In the male, the testis subserves two principal functions: synthesis of testosterone by the interstitial Leydig cells under the control of luteinising hormone (LH), and spermatogenesis by Sertoli cells under the control of follicle-stimulating hormone (FSH) (but also requiring adequate testosterone). Negative feedback suppression of LH is mediated principally by testosterone, while secretion of another hormone by the testis, inhibin, suppresses FSH. The axis can be assessed easily by a random blood sample for testosterone, LH and FSH. If testosterone is marginally low, it may be worth repeating sampling in the morning, when values are somewhat higher. Testosterone is largely

Fig. 20.13 Male reproductive physiology.

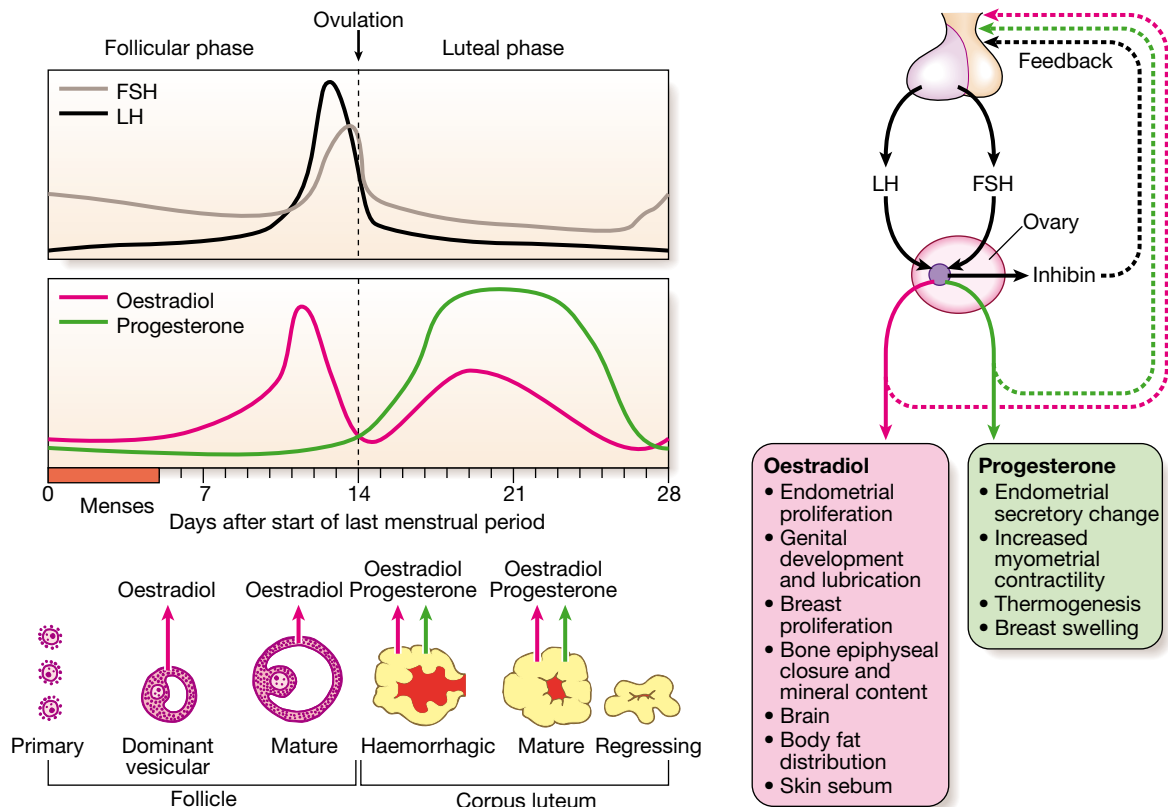

Fig. 20.14 Female reproductive physiology and the normal menstrual cycle.

bound in plasma to sex hormone-binding globulin, and this can also be measured to calculate the 'free androgen index' or the 'bioavailable' testosterone. Testicular function can also be tested by semen analysis.

There is no equivalent of the menopause in men, although testosterone concentrations decline slowly from the fourth decade onwards.

The female

In the female, physiology is complicated by variations in function during the normal menstrual cycle. FSH stimulates growth and development of ovarian follicles during the first 14 days after the menses. This leads to a gradual increase in oestradiol production from granulosa cells, which initially suppresses FSH secretion (negative feedback) but then, above a certain level, stimulates an increase in both the frequency and amplitude of gonadotrophin-releasing hormone (GnRH) pulses, resulting in a marked increase in LH secretion (positive feedback). The mid-cycle 'surge' of LH induces ovulation. After release of the ovum the follicle differentiates into a corpus luteum which secretes progesterone. Withdrawal of progesterone results in menstrual bleeding. Circulating levels of oestrogen and progesterone in pre-menopausal women are, therefore, critically dependent on the time of the cycle. The most useful 'test' of ovarian function is a careful menstrual history. In addition, ovulation can be confirmed by measuring plasma progesterone levels during the luteal phase ('day 21 progesterone') or by tracking changes in oestrogen and progesterone metabolites in urine specimens collected at weekly intervals.

Cessation of menstruation (the menopause) occurs at an average age of approximately 50 years in developed countries. In the 5 years before, there is a gradual increase in the number of anovulatory cycles and this is referred to as the climacteric. Oestrogen and inhibin secretion falls and negative feedback results in increased pituitary secretion of LH and FSH (typically to levels > 30 U/L ($3.3 \mu\text{g/L}$)).

The pathophysiology of male and female reproductive dysfunction is summarised in Box 20.20.

Presenting problems in reproductive disease

Delayed puberty

Puberty is considered to be delayed if the onset of the physical features of sexual maturation has not occurred by a chronological age that is 2.5 standard deviations above the national average. In the UK this is by the age of 14 in boys and 13 in girls. Genetic factors have a major influence in determining the timing of the onset of puberty, such that the age of menarche (the onset of menstruation) is often comparable within sibling and mother-daughter pairs and within ethnic groups. However, because there is also a threshold for body weight that acts as a trigger for normal puberty, the onset of puberty can be influenced by other factors including nutritional status and chronic illness (p. 107).

20.20 Classification of diseases of the reproductive system

	Primary	Secondary
Hormone excess	Polycystic ovarian syndrome Granulosa cell tumour Leydig cell tumour Teratoma	Pituitary gonadotrophinoma
Hormone deficiency	Menopause Hypogonadism (see Box 20.21) Turner's syndrome Klinefelter's syndrome	Hypopituitarism Kallmann's syndrome (isolated GnRH deficiency) Severe systemic illness, including anorexia nervosa
Hormone hypersensitivity	Idiopathic hirsutism	
Hormone resistance	Androgen resistance syndromes Complete ('testicular feminisation') Partial (Reifenstein's syndrome) 5 α -reductase type 2 deficiency	
Non-functioning tumours	Ovarian cysts Carcinoma Teratoma Seminoma	

Clinical assessment

The differential diagnosis is shown in Box 20.21. The key issue is to determine whether the delay in puberty is simply because the 'clock is running slow' (constitutional delay of puberty) or because there is pathology in the hypothalamus/pituitary (hypogonadotrophic hypogonadism) or the gonads (hypergonadotrophic hypogonadism). A general history and physical examination should be performed with particular reference to previous or current medical disorders, social circumstances and family history. Body proportions, sense of smell and pubertal stage should be carefully documented and, in boys, the presence or absence of testes in the scrotum noted. Current weight and height may be plotted on centile charts along with parental heights. Previous growth measurements in childhood, which can usually be obtained from health records, are extremely useful. Children with constitutional delay have usually always been small, but have maintained a normal growth velocity that is appropriate for bone age. Poor linear growth, with 'crossing of the centiles', is more likely to be associated with acquired disease.

Constitutional delay of puberty

This is the most common cause of delayed puberty. Affected children are healthy and have usually been more than 2 standard deviations below the mean height for their age throughout childhood. There is often a history of delayed puberty in siblings or parents. 'Bone age' can be estimated by X-rays of epiphyses, usually in the wrist and hand; in constitutional delay, bone age is lower than chronological age. Constitutional delay of puberty should be considered as a normal variant as puberty will commence

20.21 Causes of delayed puberty and hypogonadism

Constitutional delay

Hypogonadotrophic hypogonadism

- Structural hypothalamic/pituitary disease (see Box 20.57)
- Functional gonadotrophin deficiency
 - Chronic systemic illness (e.g. asthma, malabsorption, coeliac disease, cystic fibrosis, renal failure)
 - Psychological stress
 - Anorexia nervosa
 - Excessive physical exercise
 - Hyperprolactinaemia
 - Other endocrine disease (e.g. Cushing's syndrome, primary hypothyroidism)
- Isolated gonadotrophin deficiency (Kallmann's syndrome)

Hypergonadotrophic hypogonadism

- Acquired gonadal damage
 - Chemotherapy/radiotherapy to gonads
 - Trauma/surgery to gonads
 - Autoimmune gonadal failure
 - Mumps orchitis
 - Tuberculosis
 - Haemochromatosis
- Developmental/congenital gonadal disorders
 - Steroid biosynthetic defects
 - Anorchidism/cryptorchidism in males
 - Klinefelter's syndrome (47XXY, male phenotype)
 - Turner's syndrome (45XO, female phenotype)

spontaneously. However, affected children can experience significant psychological distress because of their lack of physical development, particularly when compared with their peers.

Hypogonadotrophic hypogonadism

This may be due to structural, inflammatory or infiltrative disorders of the pituitary and/or hypothalamus (see Box 20.57, p. 786). In such circumstances, other pituitary hormones, such as growth hormone, are also likely to be deficient.

'Functional' gonadotrophin deficiency is caused by a variety of factors, including low body weight, chronic systemic illness (as a consequence of the disease itself or secondary malnutrition), endocrine disorders and profound psychosocial stress.

Isolated gonadotrophin deficiency is usually due to a genetic abnormality that affects the synthesis of either GnRH or gonadotrophins. The most common form is Kallmann's syndrome, in which there is primary GnRH deficiency and, in most affected individuals, agenesis or hypoplasia of the olfactory bulbs resulting in anosmia or hyposmia. If isolated gonadotrophin deficiency is left untreated, the epiphyses fail to fuse, resulting in tall stature with disproportionately long arms and legs relative to trunk height (eunuchoid habitus).

Cryptorchidism (undescended testes) and gynaecomastia are commonly observed in all forms of hypogonadotrophic hypogonadism.

Hypergonadotrophic hypogonadism

Hypergonadotrophic hypogonadism associated with delayed puberty is usually due to Klinefelter's syndrome

in boys and Turner's syndrome in girls (p. 761). Other causes of primary gonadal failure are shown in Box 20.21.

Investigations

Key measurements are LH and FSH, testosterone (in boys) and oestradiol (in girls). Chromosome analysis is performed if gonadotrophin concentrations are elevated. If gonadotrophin concentrations are low, then the differential diagnosis lies between constitutional delay and hypogonadotrophic hypogonadism. A plain X-ray of the wrist and hand may be compared with a set of standard films to obtain a bone age. Full blood count, renal function, liver function, thyroid function and coeliac disease autoantibodies (p. 879) should be measured, but further tests may be unnecessary if the blood tests are normal and the child has all the clinical features of constitutional delay. If hypogonadotrophic hypogonadism is suspected, neuroimaging and further investigations will be required (p. 784).

Management

Puberty can be induced using low doses of oral oestrogen in girls (e.g. ethinylestradiol 2 µg daily) or testosterone in boys (e.g. depot testosterone ester injections 50 mg i.m. each month). Higher doses carry a risk of early fusion of epiphyses. This therapy should be given in a specialist clinic where the progress of puberty and growth can be carefully monitored. In children with constitutional delay, this 'priming' therapy can be discontinued when endogenous puberty is established, usually in less than a year. In children with hypogonadism, the underlying cause should be treated and reversed if possible. If hypogonadism is permanent, then sex hormone doses are gradually increased during puberty and full adult replacement doses given when development is complete.

Amenorrhoea

Primary amenorrhoea describes the condition of a female patient who has never menstruated; this usually occurs as a manifestation of delayed puberty, but may also be a consequence of anatomical defects of the female reproductive system, such as endometrial hypoplasia or vaginal agenesis. Secondary amenorrhoea describes the cessation of menstruation. The causes of this common presentation are shown in Box 20.22. In non-pregnant women, secondary amenorrhoea is almost invariably a

consequence of either ovarian or hypothalamic/pituitary dysfunction. Premature ovarian failure (premature menopause) is defined, arbitrarily, as occurring before 40 years of age. Rarely, endometrial adhesions (Asherman's syndrome) can form after uterine curettage, surgery or infection, e.g. with tuberculosis or schistosomiasis, preventing endometrial proliferation and shedding.

Clinical assessment

The underlying cause can often be suspected from associated clinical features and the patient's age. Hypothalamic/pituitary disease and premature ovarian failure result in oestrogen deficiency, which causes a variety of symptoms usually associated with the menopause (Box 20.23). If there is weight loss, then this may be primary, as in anorexia nervosa (p. 249), or secondary to underlying disease such as tuberculosis or malabsorption. Weight gain may suggest hypothyroidism, Cushing's syndrome or, very rarely, a hypothalamic lesion. Hirsutism, obesity and long-standing irregular periods suggest the polycystic ovarian syndrome (PCOS, p. 760). The presence of other autoimmune disease raises the possibility of autoimmune premature ovarian failure. The breasts should be examined for galactorrhoea and a vaginal examination should be performed, particularly if disease of the uterus is suspected.

Investigations

Pregnancy should be excluded in women of reproductive age by measuring human chorionic gonadotrophin (hCG) in a sample of urine. Serum LH, FSH, oestradiol, prolactin, testosterone, T₄ and TSH should be measured, and in the absence of a menstrual cycle, can be taken at any time. Investigation of hyperprolactinaemia is described on page 789. High concentrations of LH and FSH with low or low normal oestradiol suggest primary ovarian failure. Ovarian autoantibodies may be positive when there is an underlying autoimmune aetiology, and a karyotype should be performed in younger women to exclude mosaic Turner's syndrome. Elevated LH, prolactin and testosterone levels with normal oestradiol are common in PCOS. Low levels of LH, FSH and oestradiol suggest hypothalamic or pituitary disease.

There is some overlap in gonadotrophin and oestrogen concentrations between women with hypogonadotrophic hypogonadism and PCOS. If there is doubt as to the underlying cause of secondary amenorrhoea, then the response to 5 days of treatment with an oral progestogen (e.g. medroxyprogesterone acetate 10 mg 12-hourly) can be assessed. In women with PCOS, the progestogen will cause maturation of the endometrium and menstruation

20.22 Causes of secondary amenorrhoea

Physiological

- Pregnancy
- Menopause

Hypogonadotrophic hypogonadism (see Box 20.21)

Ovarian dysfunction

- Hypergonadotrophic hypogonadism (see Box 20.21)
- Polycystic ovarian syndrome
- Androgen-secreting tumours

Uterine dysfunction

- Asherman's syndrome

20.23 Symptoms of oestrogen deficiency

Vasomotor effects

- Hot flushes
- Sweating

Psychological

- Anxiety
- Irritability
- Emotional lability

Genitourinary

- Dyspareunia
- Urgency of micturition
- Vaginal infections

will occur a few days after the progestogen is stopped. In women with hypogonadotrophic hypogonadism, menstruation does not occur following progestogen withdrawal because the endometrium is atrophic as a result of oestrogen deficiency. If doubt persists in distinguishing oestrogen deficiency from a uterine abnormality, the capacity for menstruation can be tested with 1 month of treatment with cyclical oestrogen and progestogen (usually administered as a combined oral contraceptive pill).

Assessment of bone mineral density by dual energy X-ray absorptiometry (DEXA, p. 1118) may be appropriate in patients with low androgen and oestrogen levels.

Management

Where possible, the underlying cause should be treated. For example, women with functional amenorrhoea due to excessive exercise and low weight should be encouraged to reduce their exercise and regain some weight. The management of structural pituitary and hypothalamic disease is described on page 788 and PCOS on page 761.

In oestrogen-deficient women, replacement therapy may be necessary to treat symptoms and/or to prevent osteoporosis. Women who have had a hysterectomy can be treated with oestrogen alone, but those with a uterus should be treated with combined oestrogen/progestogen therapy, since unopposed oestrogen increases the risk of endometrial cancer. Cyclical hormone replacement therapy (HRT) regimens typically involve giving oestrogen on days 1–21 and progestogen on days 14–21 of the cycle and this can be conveniently administered as the oral contraceptive pill. If oestrogenic side-effects (fluid retention, weight gain, hypertension and thrombosis) are a concern, then lower-dose oral or transdermal HRT may be more appropriate.

The timing of the discontinuation of oestrogen replacement therapy is still a matter of debate. In post-menopausal women HRT has been shown to relieve menopausal symptoms and to prevent osteoporotic fractures, but is associated with adverse effects, which are related to the duration of therapy and to the patient's age (Box 20.24). In patients with premature menopause HRT should be continued up to the age of 50 years but

EBM 20.24 Hormone replacement therapy (HRT) in post-menopausal women

'Administering HRT for 5 years to 10 000 women aged 50–79 years prevents 5 hip fractures and 6 cases of colorectal cancer, while inducing 8 extra cases of breast cancer, 8 of pulmonary embolism, 7 of coronary heart disease and 8 of stroke. The risks increase with age.'

• Writing Group for the Women's Health Initiative Investigators. JAMA 2002; 288:321–333.

only continued beyond this age if there are continued symptoms of oestrogen deficiency on discontinuation.

Management of infertility in oestrogen-deficient women is described on page 758.

Male hypogonadism

The clinical features of both hypo- and hypergonadotrophic hypogonadism include loss of libido, lethargy with muscle weakness, and decreased frequency of shaving. Patients may also present with gynaecomastia, infertility, delayed puberty and/or anaemia of chronic disease. The causes of hypogonadism are listed in Box 20.21.

Investigations

Male hypogonadism is confirmed by demonstrating a low serum testosterone level. The distinction between hypo- and hypergonadotrophic hypogonadism is by measurement of random LH and FSH. Patients with hypogonadotrophic hypogonadism should be investigated as described for pituitary disease on pages 784–785. Patients with hypergonadotrophic hypogonadism should have the testes examined for cryptorchidism or atrophy and a karyotype performed (to identify Klinefelter's syndrome).

Management

Testosterone replacement is indicated in hypogonadal men to prevent osteoporosis and to restore muscle power and libido. Routes of testosterone administration are shown in Box 20.25. First-pass hepatic metabolism of testosterone is highly efficient so bioavailability of ingested preparations is poor. Doses of systemic

20

20.25 Options for androgen replacement therapy

Route of administration	Preparation	Dose	Frequency	Comments
Intramuscular	Testosterone enantate	50–250 mg	Every 3–4 wks	Produces peaks and troughs of testosterone levels which are outside the physiological range and may be symptomatic
Intramuscular	Testosterone undecanoate	1000 mg	Every 3 mths	Smoother profile than testosterone enantate, less frequent injections
Subcutaneous	Testosterone pellets	600–800 mg	Every 4–6 mths	Smoother profile than testosterone enantate, but implantation causes scarring and infection
Transdermal	Testosterone patch	5–10 mg	Daily	Stable testosterone levels, but high incidence of skin hypersensitivity
Transdermal	Testosterone gel	50–100 mg	Daily	Stable testosterone levels; transfer of gel can occur following skin-to-skin contact with another person
Oral	Testosterone undecanoate	40–120 mg	12-hourly	Very variable testosterone levels; risk of hepatotoxicity

testosterone can be titrated against symptoms; circulating testosterone levels may provide only a rough guide to dosage because they may be highly variable (see Box 20.25). Testosterone therapy can aggravate prostatic carcinoma; prostate-specific antigen (PSA) should be measured before commencing testosterone therapy in men older than 50 years and monitored annually thereafter. Haemoglobin concentration should also be monitored in older men as androgen replacement can cause polycythaemia. Testosterone replacement inhibits spermatogenesis; treatment for fertility is described below.

Infertility

Infertility affects around 1 in 7 couples of reproductive age, often causing substantial psychological distress. The main causes are listed in Box 20.26. In women, infertility may result from anovulation or from abnormalities of the reproductive tract that prevent fertilisation or embryonic implantation, most commonly damaged fallopian tubes from previous infection. In men, infertility may result from impaired sperm quality (e.g. reduced motility) or number. Azoospermia or oligospermia is usually idiopathic, but may be a consequence of hypogonadism (see Box 20.21). Microdeletions of the Y chromosome are increasingly recognised as a cause of severely abnormal spermatogenesis. In many couples, more than one factor causing subfertility is present, and in a substantial proportion no cause can be identified.

20.26 Causes of infertility

Female factor (35–40%)

Ovulatory dysfunction

- Polycystic ovarian syndrome
- Hypogonadotrophic hypogonadism (see Box 20.21)
- Hypergonadotrophic hypogonadism (see Box 20.21)

Tubular dysfunction

- Pelvic inflammatory disease (chlamydia, gonorrhoea)
- Endometriosis
- Previous sterilisation
- Previous pelvic or abdominal surgery

Cervical and/or uterine dysfunction

- Congenital abnormalities
- Fibroids
- Asherman's syndrome
- Treatment for cervical carcinoma

Male factor (35–40%)

Reduced sperm quality or production

- Y chromosome microdeletions
- Varicocele
- Hypogonadotrophic hypogonadism (see Box 20.21)
- Hypergonadotrophic hypogonadism (see Box 20.21)

Tubular dysfunction

- Varicocele
- Congenital abnormality of vas deferens/epididymis
- Previous vasectomy
- Previous sexually transmitted infection (chlamydia, gonorrhoea)

Unexplained or mixed factor (20–35%)

Clinical assessment

A history of previous pregnancies, relevant infections and surgery is important in both men and women. A sexual history must be explored sensitively as some couples have intercourse infrequently or only when they consider the woman to be ovulating, and psychosexual difficulties are common. Irregular and/or infrequent menstrual periods are an indicator of anovulatory cycles in the woman, in which case causes such as PCOS should be considered. In men, the testes should be examined to confirm that both are in the scrotum and to identify any structural abnormality, such as small size, absent vas deferens or the presence of a varicocele.

Investigations

Investigations are generally performed after a couple has failed to conceive despite unprotected intercourse for 12 months, unless there is an obvious abnormality (e.g. amenorrhoea). Investigations are guided by the history and examination; for example, if the male partner already has a child then the focus may, at least initially, be on the woman, but otherwise both partners need to be investigated. The male partner should provide at least two fresh semen samples, over an interval of several weeks, for analysis of sperm count and quality. Home testing for ovulation (either by commercial urine dipstick kits, temperature measurement, or assessment of cervical mucus) is not recommended as the information provided is often counterbalanced by increased anxiety if interpretation is inconclusive. In women with regular periods, ovulation can be confirmed by an elevated serum progesterone concentration on day 21 of the menstrual cycle. In women with irregular periods, such as in PCOS, weekly urine samples can be collected over several months to detect any peaks in progesterone metabolites which indicate ovulation. Transvaginal ultrasound can be used to assess uterine and ovarian anatomy. Tubal patency may be examined at laparoscopy or by hysterosalpingography (HSG; a radio-opaque medium is injected into the uterus and should normally outline the fallopian tubes). In vitro assessments of sperm survival in cervical mucus may be ascertained in cases of unexplained infertility but are rarely helpful.

Management

Couples should be advised to have regular sexual intercourse, ideally every 2–3 days throughout the menstrual cycle. It is not uncommon for 'spontaneous' pregnancies to occur in couples undergoing investigations for infertility or with identified causes of male or female subfertility.

In women with anovulatory cycles secondary to PCOS (p. 760), anti-oestrogen therapy with clomifene or tamoxifen blocks negative feedback of oestrogen on the hypothalamus/pituitary and encourages gonadotrophin secretion and thus ovulation. In women with gonadotrophin deficiency or in whom anti-oestrogen therapy is unsuccessful, ovulation may be induced by direct stimulation of the ovary by daily injection of FSH and an injection of hCG to induce follicular rupture at the appropriate time. In hypothalamic disease, pulsatile GnRH therapy with a portable infusion pump can be used to stimulate pituitary gonadotrophin secretion (note that non-pulsatile administration of GnRH or its analogues paradoxically suppresses LH and FSH secretion). Whatever method of ovulation induction is employed, monitoring of response

is essential to avoid multiple ovulation. For clomifene, ultrasound monitoring is recommended for at least the first cycle. During gonadotrophin therapy, closer monitoring of follicular growth by transvaginal ultrasonography and blood oestradiol levels is mandatory. 'Ovarian hyperstimulation syndrome' is characterised by grossly enlarged ovaries and capillary leak with circulatory shock, pleural effusions and ascites. Anovulatory women who fail to respond to ovulation induction or who have primary ovarian failure may wish to consider using donated eggs or embryos, surrogacy and adoption.

Surgery to restore fallopian tube patency can be effective, but in vitro fertilisation (IVF) is normally recommended. IVF is widely used for many causes of infertility and in unexplained cases of prolonged (> 3 years) infertility. The success of IVF depends on age, with low success rates in women over 40 years.

Men with hypogonadotrophic hypogonadism who wish fertility are usually given injections of hCG several times a week (recombinant FSH may also be required in men with hypogonadism of pre-pubertal origin); it may take up to 2 years to achieve satisfactory sperm counts. Surgery is rarely an option in primary testicular disease, but removal of a varicocele can improve semen quality. Extraction of sperm from the epididymis for IVF, and intracytoplasmic sperm injection (ICSI, when single spermatozoa are injected into each oocyte), are being used increasingly in men with oligospermia or poor sperm quality who have primary testicular disease. Azoospermic men may opt to use donated sperm, but this is now in short supply.

Gynaecomastia

Gynaecomastia is the presence of glandular breast tissue in males. Normal breast development in women is oestrogen-dependent, while androgens oppose this effect. Gynaecomastia results from an imbalance between androgen and oestrogen activity, which may reflect androgen deficiency or oestrogen excess. Causes are listed in Box 20.27. The most common are physiological: for example, in the newborn baby (due to maternal and placental oestrogens), in pubertal boys (in whom oestradiol concentrations reach adult levels before testosterone) and in elderly men (due to decreasing testosterone concentrations). Prolactin excess alone does not cause gynaecomastia (p. 789).

20.27 Causes of gynaecomastia

Idiopathic

Physiological

Drug-induced

- Cimetidine
- Digoxin
- Anti-androgens (cyproterone acetate, spironolactone)
- Some exogenous anabolic steroids (diethylstilbestrol)

Hypogonadism (see Box 20.21)

Androgen resistance syndromes

Oestrogen excess

- Liver failure (impaired steroid metabolism)
- Oestrogen-secreting tumour (for example, of testis)
- hCG-secreting tumour (for example, of testis or lung)

Clinical assessment

A drug history is important. Gynaecomastia is often asymmetrical and palpation may allow breast tissue to be distinguished from the prominent adipose tissue around the nipple that is often observed in obesity. Features of hypogonadism should be sought (see above) and the testes examined for evidence of cryptorchidism, atrophy or a tumour.

Investigations

If a clinical distinction between gynaecomastia and adipose tissue cannot be made, then ultrasonography or mammography is required. A random blood sample should be taken for testosterone, LH, FSH, oestradiol, prolactin and hCG. Elevated oestrogen concentrations are found in testicular tumours and hCG-producing neoplasms.

Management

An adolescent with gynaecomastia who is progressing normally through puberty may be reassured that the gynaecomastia will usually resolve once development is complete. If puberty does not proceed in a harmonious manner, then there may be an underlying abnormality that requires investigation (p. 754). Gynaecomastia may cause significant psychological distress, especially in adolescent boys, and surgical excision may be justified for cosmetic reasons. Androgen replacement will usually improve gynaecomastia in hypogonadal males and any other identifiable underlying cause should be addressed if possible. The anti-oestrogen tamoxifen may also be effective in reducing the size of the breast tissue.

Hirsutism

Hirsutism refers to the excessive growth of thick terminal hair in an androgen-dependent distribution in women (upper lip, chin, chest, back, lower abdomen, thigh, forearm) and is one of the most common presentations of endocrine disease. It should be distinguished from hypertrichosis, which is generalised excessive growth of vellus hair. The aetiology of androgen excess is shown in Box 20.28.

Clinical assessment

The severity of hirsutism is subjective. Some women suffer profound embarrassment from a degree of hair growth which others would not consider remarkable. Important observations are a drug and menstrual history, calculation of body mass index, measurement of blood pressure, examination for virilisation (clitoromegaly, deep voice, male-pattern balding, breast atrophy), and associated features including acne vulgaris or Cushing's syndrome (p. 770). Hirsutism of recent onset associated with virilisation is suggestive of an androgen-secreting tumour, but this is rare.

Investigations

A random blood sample should be taken for testosterone, prolactin, LH and FSH. If there are clinical features of Cushing's syndrome, an overnight 1 mg dexamethasone suppression test should be performed (p. 772).

If testosterone levels are elevated above twice the upper limit of the normal female range, especially if this is associated with low LH and FSH, then causes other than idiopathic hirsutism and PCOS are more

20.28 Causes of hirsutism

Cause	Clinical features	Investigation findings	Treatment
Idiopathic	Often familial Mediterranean or Asian background	Normal	Cosmetic measures Anti-androgens
Polycystic ovarian syndrome (see Box 20.29)	Obesity Oligomenorrhoea or secondary amenorrhoea Infertility	LH:FSH ratio > 2.5:1 Minor elevation of androgens* Mild hyperprolactinaemia	Weight loss Cosmetic measures Anti-androgens (Metformin, glitazones may be useful)
Congenital adrenal hyperplasia (95% 21-hydroxylase deficiency)	Pigmentation History of salt-wasting in childhood, ambiguous genitalia, or adrenal crisis when stressed Jewish background	Elevated androgens* which suppress with dexamethasone Abnormal rise in 17OH-progesterone with ACTH	Glucocorticoid replacement administered in reverse rhythm to suppress early morning ACTH
Exogenous androgen administration	Athletes Virilisation	Low LH and FSH Analysis of urinary androgens may detect drug of misuse	Stop steroid misuse
Androgen-secreting tumour of ovary or adrenal cortex	Rapid onset Virilisation: clitoromegaly, deep voice, balding, breast atrophy	High androgens* which do not suppress with dexamethasone or oestrogen Low LH and FSH CT or MRI usually demonstrates a tumour	Surgical excision
Cushing's syndrome	Clinical features of Cushing's syndrome (p. 771)	Normal or mild elevation of adrenal androgens* See investigations (p. 772)	Treat the cause (p. 773)

*e.g. Serum testosterone levels in women: < 2 nmol/L (< 58 ng/dL) is normal; 2–5 nmol/L (58–144 ng/dL) is minor elevation; > 5 nmol/L (> 144 ng/dL) is high and requires further investigation.

likely, and the source of the androgen excess should be established. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency is diagnosed by a short ACTH stimulation test with measurement of 17OH-progesterone (p. 780). In patients with androgen-secreting tumours, serum testosterone does not suppress following dexamethasone (either as an overnight or a 48-hour low-dose suppression test) or oestrogen (30 µg daily for 7 days). The tumour should then be sought by CT or MRI of the adrenals and ovaries.

Management

This depends on the cause (see Box 20.28). Options for the treatment of PCOS and idiopathic hirsutism are similar and are described below.

Polycystic ovarian syndrome (PCOS)

PCOS describes a constellation of clinical and biochemical features (Box 20.29) for which the primary cause remains uncertain. PCOS often affects several family members and is aggravated by obesity. Women with PCOS vary in the severity and combination of features that they manifest; the diagnosis is usually made during investigation of patients presenting with hirsutism (p. 759) or amenorrhoea/oligomenorrhoea (p. 756) with or without infertility (p. 758). There is no universally accepted definition, but it has been recommended that PCOS requires the presence of two of the following three features:

- menstrual irregularity
- clinical or biochemical androgen excess
- multiple cysts in the ovaries (most readily detected by transvaginal ultrasound; Fig. 20.15).

Women with PCOS are at increased risk of glucose intolerance and some authorities recommend screening for type 2 diabetes and other cardiovascular risk factors associated with the metabolic syndrome (p. 802).

20.29 Features of polycystic ovarian syndrome

Mechanisms*	Manifestations
Pituitary dysfunction	High serum LH High serum prolactin
Anovulatory menstrual cycles	Oligomenorrhoea Secondary amenorrhoea Cystic ovaries Infertility
Androgen excess	Hirsutism Acne
Obesity	Hyperglycaemia Elevated oestrogens
Insulin resistance	Dyslipidaemia Hypertension

* These mechanisms are interrelated; it is not known which, if any, is primary. PCOS probably represents the common endpoint of several different pathologies.

Fig. 20.15 Polycystic ovary. A transvaginal ultrasound scan showing multiple cysts (some indicated by black arrows) in the ovary (highlighted by white arrows) of a woman with PCOS.

Management

This depends on the clinical problem, but all overweight women with PCOS should be encouraged to lose weight as this may improve the clinical manifestations (especially menstrual irregularity) and reduce the risk of type 2 diabetes.

Menstrual irregularity and infertility

Most women with PCOS have oligomenorrhoea, with irregular, heavy menstrual periods. This may not require treatment unless fertility is desired. Metformin (p. 820), by reducing insulin resistance, may restore regular ovulatory cycles in overweight women, although it is less effective than clomifene (p. 758) at restoring fertility as measured by successful pregnancy (Box 20.30). Thiazolidinediones (p. 821) also enhance insulin sensitivity and restore menstrual regularity in PCOS, but are contraindicated in women planning pregnancy.

In women who have very few periods each year or are amenorrhoeic, the high oestrogen concentrations associated with PCOS can cause endometrial hyperplasia. Progestogens can be administered on a cyclical basis to induce regular shedding of the endometrium and a withdrawal bleed, or a progestogen-impregnated intrauterine coil can be fitted.

Hirsutism

For hirsutism, most patients will have used cosmetic measures such as shaving, bleaching and waxing before

consulting a doctor. Electrolysis and laser treatment are effective for small areas, e.g. upper lip and chest hair, but are expensive. Eflornithine cream inhibits ornithine decarboxylase in hair follicles and may reduce hair growth when applied daily to affected areas of the face.

If these conservative measures are unsuccessful, then anti-androgen therapy may be employed (Box 20.31). The life cycle of each hair follicle is at least 3 months and so no improvement is likely before this time, when previous follicles have all shed their hair and replacement hair growth has been suppressed. Metformin and thiazolidinediones are less effective at treating hirsutism than at restoring menstrual regularity. Unless the patient has lost weight, the hirsutism will return if therapy is discontinued. The patient should be aware that prolonged exposure to some of these agents may not be desirable and that they should be discontinued in advance of pregnancy.

Turner's syndrome

Turner's syndrome affects approximately 1 in 2500 females. The syndrome is classically associated with a 45XO karyotype, but other cytogenetic abnormalities may be responsible, including mosaic forms (e.g. 45XO/46XX or 45XO/46XY) and partial deletions of an X chromosome.

Clinical features

These are shown in Figure 20.16.

Individuals with Turner's syndrome invariably have short stature from an early age and this is often the initial presenting symptom. It is probably due to haploinsufficiency of the *SHOX* gene, one copy of which is found on both the X and Y chromosomes, which encodes a protein that is predominantly found in bone fibroblasts.

The genital tract and external genitalia in Turner's syndrome are female in character, since this is the default developmental outcome in the absence of testes. Ovarian tissue develops normally until the third month of gestation, but thereafter there is gonadal dysgenesis with accelerated degeneration of oocytes and increased ovarian stromal fibrosis, resulting in 'streak ovaries'. The inability of the ovarian tissue to produce oestrogen results in loss of negative feedback and elevation of FSH and LH concentrations.

There is a wide variation in the spectrum of associated somatic abnormalities. The severity of the phenotype is, in part, related to the underlying cytogenetic abnormality. Mosaic individuals may have only mild short stature and may enter puberty spontaneously before developing gonadal failure.

Diagnosis and management

The diagnosis of Turner's syndrome can be confirmed by karyotype analysis. Short stature, although not directly due to growth hormone deficiency, responds to high doses of growth hormone. Prophylactic gonadectomy is recommended for individuals with 45XO/46XY mosaicism because there is an increased risk of gonadoblastoma. Pubertal development is induced with oestrogen therapy, but will result in

EBM 20.30 Treatment of infertility in women with PCOS

'In one RCT, 626 infertile women with PCOS were randomised to receive clomifene, metformin or combination therapy. After 6 months, the live birth rates were 22.5%, 7.2% and 26.8% respectively. Multiple births occurred in 6% of women receiving clomifene and none receiving metformin.'

• RS Legro, et al. *New Engl J Med* 2008; 356:551–566.

20.31 Anti-androgen therapy

Mechanism of action	Drug	Dose	Hazards
Androgen receptor antagonists	Cyproterone acetate	2, 50 or 100 mg on days 1–11 of 28-day cycle with ethinylestradiol 30 µg on days 1–21	Hepatic dysfunction Feminisation of male fetus Progesterone receptor agonist Dysfunctional uterine bleeding
	Spironolactone	100–200 mg daily	Electrolyte disturbance
	Flutamide	Not recommended	Hepatic dysfunction
5α-reductase inhibitors (prevent conversion of testosterone to active dihydrotestosterone)	Finasteride	5 mg daily	Limited clinical experience; possibly less efficacious than other treatments
Suppress ovarian steroid production and elevate sex hormone-binding globulin	Oestrogen	See combination with cyproterone acetate above or Conventional oestrogen-containing contraceptive	Venous thromboembolism Hypertension Weight gain Dyslipidaemia Increased breast and endometrial carcinoma
Suppress adrenal androgen production	Exogenous glucocorticoid to suppress ACTH	e.g. Hydrocortisone 5 mg on waking and dexamethasone 0.5 mg at bedtime	Cushing's syndrome

Fig. 20.16 Clinical features of Turner's syndrome (45X0). (IGT = impaired glucose tolerance)

fusion of the epiphyses and cessation of growth. Therefore, the timing of pubertal induction needs to be carefully planned. Adults with Turner's syndrome require long-term oestrogen replacement therapy and should be monitored periodically for the development of aortic root dilatation, hearing loss and other somatic complications.

Klinefelter's syndrome

Klinefelter's syndrome affects approximately 1 in 1000 males and is usually associated with a 47XXY karyotype. However, other cytogenetic variants may be responsible, especially 46XY/47XXY mosaicism. The principal pathological abnormality is dysgenesis of the seminiferous tubules. This is evident from infancy (and possibly even in utero) and progresses with age. By adolescence, hyalinisation and fibrosis are present within the seminiferous tubules and Leydig cell function is impaired, resulting in hypogonadism.

Clinical features

The diagnosis is typically made in adolescents who have presented with gynaecomastia and failure to progress normally through puberty. Affected individuals usually have small, firm testes. Tall stature is apparent from early childhood, reflecting characteristically long leg length associated with 47XXY, and may be exacerbated by androgen deficiency with lack of epiphyseal closure in puberty. Other clinical features may include learning difficulties and behavioural disorders, as well as an increased risk of breast cancer and type 2 diabetes in later life. The spectrum of clinical features is wide and some individuals, especially those with 46XY/47XXY mosaicism, may pass through puberty normally and be identified only when undergoing investigation for infertility.

Diagnosis and management

Klinefelter's syndrome is suggested by the typical phenotype in a patient with hypergonadotrophic hypogonadism and can be confirmed by karyotype analysis. Individuals with clinical and biochemical evidence of androgen deficiency require androgen replacement (see Box 20.25, p. 757).

Testicular tumours

Testicular tumours are uncommon, with a prevalence of 5 cases per 100 000 population. They occur mainly in young men between the age of 20 and 40 years. They often secrete α -fetoprotein (AFP) and β -human chorionic gonadotrophin (β -hCG), which are useful biochemical markers for both diagnosis and prognosis. Seminoma and teratoma account for 85% of all tumours of the testis. Leydig cell tumours are less common.

Seminomas arise from seminiferous tubules and represent a relatively low-grade malignancy. Metastases occur mainly via the lymphatics and may involve the lungs.

Teratomas arise from primitive germinal cells and tend to occur at a younger age than seminomas. They may contain cartilage, bone, muscle, fat and a variety of

20.32 Gonadal function in old age

- **Post-menopausal osteoporosis:** a major public health issue due to the high incidence of associated fragility fractures, especially of hip.
- **Hormone replacement therapy:** should only be prescribed above the age of 50 for the short-term relief of symptoms of oestrogen deficiency.
- **Sexual activity:** many older people remain sexually active.
- **'Male menopause':** does not occur, although testosterone concentrations do fall with age. Testosterone therapy in mildly hypogonadal men may be of benefit for body composition, muscle and bone. Large randomised trials are required to determine whether benefits outweigh potentially harmful effects on the prostate and the cardiovascular system.
- **Androgens in older women:** hirsutism and balding occur. In the rare patients in whom androgen levels are elevated this may be pathological, e.g. from an ovarian tumour.

other tissues, and are classified according to the degree of differentiation. Well-differentiated tumours are the least aggressive; at the other extreme, trophoblastic teratoma is highly malignant. Occasionally, teratoma and seminoma occur together.

Leydig cell tumours are usually small and benign, but secrete oestrogens leading to presentation with gynaecomastia (p. 759).

Clinical features and investigations

The common presentation is incidental discovery of a painless testicular lump, although some patients complain of a testicular ache.

All suspicious scrotal lumps should be imaged by ultrasound. Serum levels of AFP and β -hCG are elevated in extensive disease. Oestradiol may be elevated, suppressing LH, FSH and testosterone. Accurate staging is based on CT of the lungs, liver and retroperitoneal area.

Management and prognosis

The primary treatment is surgical orchidectomy. Subsequent treatment depends on the histological type and stage. Radiotherapy is the treatment of choice for early-stage seminoma. Teratoma confined to the testes may be managed conservatively, but more advanced cancers are treated with chemotherapy, usually the combination of bleomycin, etoposide and cisplatin. Follow-up is by CT and assessment of AFP and β -hCG. Retroperitoneal lymph node dissection is now only performed for residual or recurrent nodal masses.

The 5-year survival rate for patients with seminoma is 90–95%. For teratomas the 5-year survival varies between 60% and 95%, depending on tumour type, stage and volume.

THE PARATHYROID GLANDS

Parathyroid hormone (PTH) plays a key role in the regulation of calcium and phosphate homeostasis and vitamin D metabolism, as shown in Figure 20.17. The consequences of altered function of this axis in gut and

Fig. 20.17 Outline of calcium homeostasis showing interactions between parathyroid hormone (PTH), vitamin D and calcium. *Calcium in serum exists as 50% ionised (Ca^{2+}), 10% non-ionised or complexed with organic ions such as citrate and phosphate, and 40% protein-bound, mainly to albumin. It is the ionised calcium concentration which regulates PTH production.

renal disease are covered in Chapters 22 and 17, respectively. Other metabolic bone diseases are explored in Chapter 25. Here, the investigation of hypercalcaemia and hypocalcaemia and disorders of the parathyroid glands are discussed.

Functional anatomy, physiology and investigations

The four parathyroid glands lie behind the lobes of the thyroid. The parathyroid chief cells respond directly to changes in calcium concentrations via a G-protein-coupled cell surface receptor (the calcium-sensing receptor) located on the cell surface (see Fig. 20.17). When serum ionised calcium levels fall, PTH secretion rises. PTH is a single-chain polypeptide of 84 amino acids. It acts on the renal tubules to promote reabsorption of calcium and reduce reabsorption of phosphate, and on the skeleton to increase osteoclastic bone resorption and bone formation. PTH also promotes conversion of 25-hydroxycholecalciferol to the active metabolite 1,25-dihydroxycholecalciferol; the 1,25-dihydroxycholecalciferol, in turn, enhances calcium absorption from the gut.

More than 99% of total body calcium is in bone. Prolonged exposure of bone to high levels of PTH is associated increased osteoclastic activity and new bone formation, but the net effect is to cause bone loss with mobilisation of calcium into the extracellular fluid. In contrast, pulsatile release of PTH causes net bone gain, an effect that is exploited therapeutically in the treatment of osteoporosis (p. 1116).

The differential diagnosis of disorders of calcium metabolism usually requires measurement of calcium phosphate, alkaline phosphatase, renal function and sometimes 25(OH)D and PTH. Although the parathyroid glands detect and respond to ionised calcium levels, most clinical laboratories only measure total serum calcium levels and about 50% of total calcium is bound to organic ions, such as citrate or phosphate, and to proteins, especially albumin. Accordingly, if the serum albumin level is reduced, total calcium concentrations should be 'corrected' by adjusting the value for calcium upwards by 0.1 mmol/L (0.4 mg/dL) for each 5 g/L reduction in albumin below 40 g/L.

Calcitonin is secreted from the parafollicular C cells of the thyroid gland. Although calcitonin is a useful tumour marker in medullary carcinoma of thyroid (p. 752) and can be administered therapeutically in Paget's disease of bone (p. 1124), its release from the thyroid is of no clinical relevance to calcium homeostasis in humans.

Disorders of the parathyroid glands are summarised in Box 20.33.

Presenting problems in parathyroid disease

Hypercalcaemia

Hypercalcaemia is one of the most common biochemical abnormalities and is often detected during routine biochemical analysis in asymptomatic patients. However, it can present with chronic symptoms as described below, and occasionally as an acute emergency with severe hypercalcaemia and dehydration.

Box 20.33 Classification of diseases of the parathyroid glands

	Primary	Secondary
Hormone excess	Primary hyperparathyroidism Parathyroid adenoma Parathyroid carcinoma ¹ Parathyroid hyperplasia ² Tertiary hyperparathyroidism Following prolonged secondary hyperparathyroidism	Secondary hyperparathyroidism Chronic kidney disease Malabsorption Vitamin D deficiency
Hormone deficiency	Hypoparathyroidism Post-surgical Autoimmune Inherited	
Hormone hypersensitivity	Autosomal dominant hypercalciuric hypocalcaemia (activating mutation in CASR)	
Hormone resistance	Pseudohypoparathyroidism Familial hypocalciuric hypercalcaemia (inactivating mutation in CASR)	
Non-functioning tumours	Parathyroid carcinoma ¹	

¹Parathyroid carcinomas may or may not produce PTH.

²In multiple endocrine neoplasia (MEN) syndromes (p. 793).
(CASR = calcium-sensing receptor)

Causes of hypercalcaemia are listed in Box 20.34. Of these, primary hyperparathyroidism and malignant hypercalcaemia are by far the most common. Familial hypocalciuric hypercalcaemia (FHH) is a rare but important cause. Lithium may cause hyperparathyroidism by reducing the sensitivity of the calcium-sensing receptor.

Clinical assessment

Symptoms and signs of hypercalcaemia include polyuria and polydipsia, renal colic, lethargy, anorexia, nausea, dyspepsia and peptic ulceration, constipation, depression, drowsiness and impaired cognition. Patients with

malignant hypercalcaemia can have a rapid onset of symptoms and may have clinical features that help to localise the tumour.

The classic symptoms are described by the adage 'bones, stones and abdominal groans'. However, about 50% of patients with primary hyperparathyroidism are asymptomatic and many have non-specific symptoms. In others, symptoms may go unrecognised until patients present with renal calculi (5% of first stone formers and 15% of recurrent stone formers have primary hyperparathyroidism; p. 766). Hypertension is common in hyperparathyroidism. Parathyroid tumours are almost never palpable.

A family history of hypercalcaemia raises the possibility of FHH or MEN (p. 793).

Investigations

The most discriminant investigation is measurement of PTH. If PTH levels are detectable or elevated in the presence of hypercalcaemia then primary hyperparathyroidism is the most likely diagnosis. High plasma phosphate and alkaline phosphatase accompanied by renal impairment suggest tertiary hyperparathyroidism. Hypercalcaemia may cause nephrocalcinosis and renal tubular impairment, resulting in hyperuricaemia and hyperchloraemia.

Patients with FHH can present with a similar biochemical picture to primary hyperparathyroidism but typically have low urinary calcium excretion (a ratio of urinary calcium clearance to creatinine clearance of < 0.01). The diagnosis of FHH can be confirmed by screening family members for hypercalcaemia and/or a mutation in the gene encoding the calcium-sensing receptor.

If PTH is low and no other cause is apparent, then malignancy with or without bony metastases is likely. PTH-related peptide, which is often responsible for the hypercalcaemia associated with malignancy, is not detected by PTH assays, but can be measured by a specific assay (although this is not usually necessary). Unless the source is obvious, the patient should be screened for malignancy with a chest X-ray, myeloma screen (p. 1041) and CT as appropriate.

Management

Treatment of severe hypercalcaemia and primary hyperparathyroidism is described on pages 269 and 767, respectively. FHH does not require any specific intervention.

Hypocalcaemia

Aetiology

Hypocalcaemia is much less common than hypercalcaemia. The differential diagnosis is shown in Box 20.35. The most common cause of hypocalcaemia is a low serum albumin with normal ionised calcium concentration. Conversely, ionised calcium may be low in the face of normal total serum calcium in patients with alkalosis: for example, as a result of hyperventilation.

Hypocalcaemia may also develop as a result of magnesium depletion and should be considered in patients with malabsorption, on diuretic therapy or with a history of alcohol excess. Magnesium deficiency causes hypocalcaemia by impairing the ability of the parathyroid glands to secrete PTH (resulting in PTH concentrations that are low or inappropriately in

20.34 Causes of hypercalcaemia

With normal or elevated (i.e. inappropriate) PTH levels

- Primary or tertiary hyperparathyroidism
- Lithium-induced hyperparathyroidism
- Familial hypocalciuric hypercalcaemia

With low (i.e. suppressed) PTH levels

- Malignancy (e.g. lung, breast, renal, ovarian, colonic and thyroid carcinoma, lymphoma, multiple myeloma)
- Elevated 1,25(OH)₂ vitamin D (vitamin D intoxication, sarcoidosis, HIV, other granulomatous disease)
- Thyrotoxicosis
- Paget's disease with immobilisation
- Milk-alkali syndrome
- Thiazide diuretics
- Glucocorticoid deficiency

20.35 Differential diagnosis of hypocalcaemia

	Total serum calcium	Ionised serum calcium	Serum phosphate	Serum PTH	Comments
Hypoalbuminaemia	↓	↔	↔	↔	Adjust calcium upwards by 0.1 mmol/L (0.4 mg/dL) for every 5 g/L reduction in albumin below 40 g/L
Alkalosis Respiratory, e.g. hyperventilation Metabolic, e.g. Conn's syndrome	↔	↓	↔	↔ or ↑	Chapter 16
Vitamin D deficiency	↓	↓	↓	↑	Chapter 25
Chronic renal failure	↓	↓	↑	↑	Due to impaired vitamin D hydroxylation Serum creatinine ↑
Hypoparathyroidism	↓	↓	↑	↓	See text
Pseudohypoparathyroidism	↓	↓	↑	↑	Characteristic phenotype (see text)
Acute pancreatitis	↓	↓	↔ or ↓	↑	Usually clinically obvious Serum amylase ↑
Hypomagnesaemia	↓	↓	Variable	↓ or ↔	Treatment of hypomagnesaemia may correct hypocalcaemia

(↑ = levels increased; ↓ = levels reduced; ↔ = levels normal)

the normal range) and may also impair the actions of PTH on bone and kidney.

Clinical assessment

Mild hypocalcaemia is often asymptomatic but, with more profound reductions in serum calcium, tetany can occur. This is characterised by muscle spasms due to increased excitability of peripheral nerves.

Children are more liable to develop tetany than adults and present with a characteristic triad of carpopedal spasm, stridor and convulsions, although one or more of these may be found independently of the others. In carpopedal spasm, the hands adopt a characteristic position with flexion of the metacarpophalangeal joints of the fingers and adduction of the thumb ('main d'accoucheur'). Pedal spasm can also occur but is less frequent. Stridor is caused by spasm of the glottis. Adults can also develop carpopedal spasm in association with tingling of the hands and feet and around the mouth, but stridor and fits are rare.

Latent tetany may be detected by eliciting Trousseau's sign; inflation of a sphygmomanometer cuff on the upper arm to more than the systolic blood pressure is followed by carpal spasm within 3 minutes. Less specific is Chvostek's sign, in which tapping over the branches of the facial nerve as they emerge from the parotid gland produces twitching of the facial muscles.

Hypocalcaemia can cause papilloedema and prolongation of the ECG QT interval, which may predispose to ventricular arrhythmias. Prolonged hypocalcaemia and hyperphosphataemia (as in hypoparathyroidism) may cause calcification of the basal ganglia, grand mal epilepsy, psychosis and cataracts. Hypocalcaemia associated with hypophosphataemia, as in vitamin D deficiency, causes rickets in children and osteomalacia in adults (p. 1121).

20.36 Management of severe hypocalcaemia

Immediate management

- 10–20 mL 10% calcium gluconate i.v. over 10–20 minutes
- Continuous i.v. infusion may be required for several hours (equivalent of 10 mL 10% calcium gluconate/hr)
- Cardiac monitoring is recommended

If associated hypomagnesaemia

- 50 mmol magnesium chloride i.v. over 24 hours
- Most parenteral magnesium will be excreted in the urine, so further doses may be required to replenish body stores

Management

Emergency management of hypocalcaemia associated with tetany is described in Box 20.36. Treatment of chronic hypocalcaemia is described on page 768.

Primary hyperparathyroidism

Primary hyperparathyroidism is caused by autonomous secretion of PTH, usually by a single parathyroid adenoma which can vary in diameter from a few millimetres to several centimetres. It should be distinguished from secondary hyperparathyroidism, in which there is a physiological increase in PTH secretion to compensate for prolonged hypocalcaemia (such as in vitamin D deficiency, p. 1121), and tertiary hyperparathyroidism, in which continuous stimulation of the parathyroids over a prolonged period of time results in adenoma formation and autonomous PTH secretion (Box 20.37). This is most commonly seen in individuals with advanced chronic kidney disease (p. 487).

20.37 Hyperparathyroidism		
Type	Serum calcium	PTH
Primary	Raised	Not suppressed
Single adenoma (90%)		
Multiple adenomas (4%)		
Nodular hyperplasia (5%)		
Carcinoma (1%)		
Secondary	Low	Raised
Chronic renal failure		
Malabsorption		
Osteomalacia and rickets		
Tertiary	Raised	Not suppressed

The prevalence of primary hyperparathyroidism is about 1 in 800 and it is 2–3 times more common in women than men; 90% of patients are over 50 years of age. It also occurs in the familial MEN syndromes (p. 793), when hyperplasia or multiple adenomas of all four parathyroid glands rather than a solitary adenoma are more likely.

Clinical and radiological features

The clinical presentation of primary hyperparathyroidism is described on page 765. Parathyroid bone disease is now rare due to earlier diagnosis and treatment. Osteitis fibrosa results from increased bone resorption by osteoclasts with fibrous replacement in the lacunae. This may present as bone pain and tenderness, fracture and deformity. Chondrocalcinosis can occur due to deposition of calcium pyrophosphate crystals within articular cartilage. It typically affects the menisci at the knees and can result in secondary degenerative arthritis or predispose to attacks of acute pseudogout (p. 1101). Skeletal X-rays are usually normal in mild primary hyperparathyroidism, but in patients with advanced disease characteristic changes are observed. In the early stages there is demineralisation, with subperiosteal erosions and terminal resorption in the phalanges. A 'pepper-pot' appearance may be seen on lateral X-rays of the skull. Reduced bone mineral density, resulting in either osteopenia or osteoporosis, is now the most common skeletal manifestation of hyperparathyroidism. This is usually not evident radiographically and requires assessment by DEXA (p. 1118).

In nephrocalcinosis, scattered opacities may be visible within the renal outline. There may be soft tissue calcification in arterial walls, soft tissues of the hands and the cornea.

Investigations

The diagnosis can be confirmed by finding a raised PTH level in the presence of hypercalcaemia, provided that FHH is excluded (p. 768). Parathyroid scanning by ^{99m}Tc -sestamibi scintigraphy (Fig. 20.18) or ultrasound examination can be performed prior to surgery, in an attempt to localise an adenoma and allow a targeted resection. However, negative imaging does not exclude the diagnosis.

Management

The treatment of choice for primary hyperparathyroidism is surgery, with excision of a solitary parathyroid adenoma or hyperplastic glands. Experienced surgeons will identify solitary tumours in more than 90% of cases. Patients with parathyroid bone disease run a significant risk of developing hypocalcaemia post-operatively and in such patients treatment with active vitamin D metabolites and calcium supplements should be commenced in the immediate post-operative period. Often therapy can be gradually withdrawn after 2–3 weeks as the bone remineralises and the residual parathyroid tissue recovers.

Surgery is usually indicated for individuals aged less than 50 years, and in those with significant hypercalcaemia (corrected serum calcium $> 2.85 \text{ mmol/L}$ ($> 11.4 \text{ mg/dL}$)), clear-cut symptoms or documented complications (such as peptic ulceration, renal stones, renal impairment or osteoporosis). However, a large number of patients have only vague symptoms or are asymptomatic and for these individuals surgery has no clear advantage over conservative treatment. They should be reviewed every 6–12 months to assess symptoms, serum calcium levels and renal function, and undergo DEXA scans periodically. They should be encouraged to maintain a high oral fluid intake to avoid renal stones.

Occasionally, primary hyperparathyroidism presents with severe life-threatening hypercalcaemia. This is often due to dehydration and should be managed medically with intravenous fluids and bisphosphonates, as described on page 269. If this is not effective, then urgent parathyroidectomy should be considered.

Fig. 20.18 ^{99m}Tc -sestamibi scan of a patient with primary hyperparathyroidism secondary to a parathyroid adenoma. **A** After 1 hour, there is uptake in the thyroid gland (thick arrow) and the enlarged left inferior parathyroid gland (thin arrow). **B** After 3 hours, uptake is evident only in the parathyroid.

Cinacalcet is a calcimimetic which enhances the sensitivity of the calcium-sensing receptor and is licensed for tertiary hyperparathyroidism and as a treatment for patients with primary hyperparathyroidism who are unwilling to have surgery or are medically unfit.

Familial hypocalciuric hypercalcaemia

This autosomal dominant disorder is caused by an inactivating mutation in one of the alleles of the calcium-sensing receptor gene, which reduces the ability of the parathyroid gland to 'sense' ionised calcium concentrations. As a result, higher than normal calcium levels are required to suppress PTH secretion. The typical presentation is with mild hypercalcaemia with PTH concentrations that are 'inappropriately' at the upper end of the normal range or are slightly elevated. Calcium-sensing receptors in the renal tubules are also affected and this leads to increased renal tubular reabsorption of calcium and hypocalciuria. The hypercalcaemia of FHH is always asymptomatic and complications do not occur. The main risk of FHH is being subjected to an unnecessary (and ineffective) parathyroidectomy if misdiagnosed as having primary hyperparathyroidism. Testing of family members for hypercalcaemia is helpful in confirming the diagnosis and it is also possible to perform genetic testing. No treatment is necessary.

Hypoparathyroidism

The most common cause of hypoparathyroidism is damage to the parathyroid glands (or their blood supply) during thyroid surgery, although this complication is only permanent in 1% of thyroidectomies. Transient hypocalcaemia develops in 10% of patients 12–36 hours following subtotal thyroidectomy for Graves' disease. Rarely, hypoparathyroidism can occur as a result of infiltration of the glands, e.g. in haemochromatosis (p. 959) and Wilson's disease (p. 960).

There are a number of rare congenital or inherited forms of hypoparathyroidism. One form is associated with autoimmune polyendocrine syndrome type 1 (p. 794) and another with DiGeorge syndrome (p. 53). Autosomal dominant hypoparathyroidism (ADH) is the mirror image of familial hypocalciuric hypercalcaemia (see above) in that an activating mutation in the calcium-sensing receptor results in hypocalcaemia, hypercalciuria and PTH concentrations that are 'inappropriately' low.

Pseudohypoparathyroidism

In this disorder, the individual is functionally hypoparathyroid, but instead of PTH deficiency there is tissue resistance to the effects of PTH, such that PTH concentrations are markedly elevated. The PTH receptor itself is normal, but there are defective post-receptor mechanisms due to mutations at the *GNAS1* locus. There are several subtypes, but in the most common form (type 1a) features include short stature, short 4th metacarpals and metatarsals, rounded face, obesity and subcutaneous calcification (Albright's hereditary osteodystrophy, AHO).

The term 'pseudo-pseudohypoparathyroidism' is used to describe patients with AHO in whom serum calcium and PTH concentrations are normal. The inheritance

20.38 The parathyroid glands in old age

- **Osteoporosis:** always exclude osteomalacia and hyperparathyroidism by checking vitamin D and calcium concentrations.
- **Primary hyperparathyroidism:** more common with ageing. Older people can often be observed without surgical intervention.
- **Hypercalcaemia:** may cause confusion.
- **Vitamin D deficiency:** common because of poor diet and limited exposure to the sun.

of these disorders is an example of genetic imprinting (p. 49); inheritance of the defective allele from a mother with pseudohypoparathyroidism results in pseudohypoparathyroidism in the offspring, but inheritance from the father results in pseudo-pseudohypoparathyroidism.

Management of hypoparathyroidism

Persistent hypoparathyroidism and pseudohypoparathyroidism are treated with oral calcium salts and vitamin D analogues, either 1 α -hydroxycholecalciferol (alfacalcidol) or 1,25-dihydroxycholecalciferol (calcitriol). This therapy needs careful monitoring because of the risks of iatrogenic hypercalcaemia, hypercalciuria and nephrocalcinosis. Recombinant PTH is available as subcutaneous injection therapy for osteoporosis (p. 1116) and, although not currently licensed, has been used in hypoparathyroidism (but not in pseudohypoparathyroidism). It is much more expensive than calcium and vitamin D analogue therapy, but has the advantage that it is less likely to cause hypercalciuria. ADH usually does not require therapy.

THE ADRENAL GLANDS

The adrenals comprise several separate endocrine glands within a single anatomical structure. The adrenal medulla is an extension of the sympathetic nervous system which secretes catecholamines into capillaries rather than synapses. Most of the adrenal cortex is made up of cells which secrete cortisol and adrenal androgens, and form part of the hypothalamic-pituitary-adrenal (HPA) axis. The small outer glomerulosa of the cortex secretes aldosterone under the control of the renin-angiotensin system. These functions are important in the integrated control of cardiovascular, metabolic and immune responses to stress.

There is increasing evidence that subtle alterations in adrenal function contribute to the pathogenesis of common diseases such as hypertension, obesity and type 2 diabetes mellitus. However, classical syndromes of adrenal hormone deficiency and excess are relatively rare.

Functional anatomy and physiology

Adrenal anatomy and function are shown in Figure 20.19. Histologically, the cortex is divided into three zones, but these function as two units (zona glomerulosa and zonae fasciculata/reticularis) which produce corticosteroids in response to humoral stimuli. Pathways for the biosynthesis of corticosteroids are shown in Figure 20.20.

20

Fig. 20.19 Structure and function of the adrenal glands. (ACE = angiotensin-converting enzyme; JGA = juxtaglomerular apparatus; MR = mineralocorticoid receptor; β -LPH = β -lipotropic hormone, a fragment of the ACTH precursor peptide pro-opiomelanocortin which contains melanocyte-stimulating hormone activity)

Investigation of adrenal function is described under specific diseases below. The different types of adrenal disease are shown in Box 20.39.

Glucocorticoids

Cortisol is the major glucocorticoid in humans. Levels are highest in the morning on waking and lowest in the middle of the night. Cortisol rises dramatically during stress, including any illness. This elevation protects key metabolic functions (such as the maintenance of cerebral glucose supply during starvation) and inhibits poten-

tially damaging inflammatory responses to infection and injury. The clinical importance of cortisol deficiency is, therefore, most obvious at times of stress.

More than 95% of circulating cortisol is bound to protein, principally cortisol-binding globulin. It is the free fraction which is biologically active. Cortisol regulates cell function by binding to glucocorticoid receptors which regulate the transcription of many genes. It can also activate mineralocorticoid receptors, but it does not normally do so because most cells containing mineralocorticoid receptors also express an enzyme,

20.39 Classification of diseases of the adrenal glands		
	Primary	Secondary
Hormone excess	Non-ACTH-dependent Cushing's syndrome (see Box 20.40) Primary hyperaldosteronism (see Box 20.49, p. 777) Pheochromocytoma	ACTH-dependent Cushing's syndrome Secondary hyperaldosteronism
Hormone deficiency	Addison's disease (see Box 20.44, p. 775) Congenital adrenal hyperplasia	Hypopituitarism
Hormone hypersensitivity	11β-hydroxysteroid dehydrogenase type 2 deficiency Liddle's syndrome	
Hormone resistance	Pseudohypoaldosteronism Glucocorticoid resistance syndrome	
Non-functioning tumours	Adenoma Carcinoma (usually functioning) Metastatic tumours	

11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which converts cortisol to its inactive metabolite, cortisone. Loss of the protection of mineralocorticoid receptors by inhibition of 11β-HSD2 (e.g. by liquorice or as a result of an inherited enzyme defect) results in cortisol acting like aldosterone as a potent sodium-retaining steroid (see Box 20.49, p. 777).

Mineralocorticoids

Aldosterone is the most important mineralocorticoid. It binds to mineralocorticoid receptors in the kidney and causes sodium retention and increased excretion of potas-

sium and protons (Ch. 16). The principal stimulus to aldosterone secretion is angiotensin II, a peptide produced by activation of the renin-angiotensin system (see Fig. 20.19). Renin activity in the juxtaglomerular apparatus of the kidney is stimulated by low perfusion pressure in the afferent arteriole, low sodium filtration leading to low sodium concentrations at the macula densa, or increased sympathetic nerve activity. As a result, renin activity is increased in hypovolaemia and renal artery stenosis, and is approximately doubled when standing up from a recumbent position.

Catecholamines

In humans, only a small proportion of circulating noradrenaline (norepinephrine) is derived from the adrenal medulla; much more is released from sympathetic nerve endings. Conversion of noradrenaline to adrenaline (epinephrine) is catalysed by catechol-o-methyltransferase (COMT), which is induced by glucocorticoids. Blood flow in the adrenal is centripetal so that the medulla is bathed in high concentrations of cortisol and is the major source of circulating adrenaline. However, after surgical removal of the adrenal medullae, there appear to be no clinical consequences attributable to deficiency of circulating catecholamines.

Adrenal androgens

Adrenal androgens are secreted in response to ACTH and are the most abundant steroids in the blood stream. They are probably important in the initiation of puberty (the adrenarche). The adrenals are also the major source of androgens in adult females and may be important in female libido.

Presenting problems in adrenal disease

Cushing's syndrome

Cushing's syndrome is caused by excessive activation of glucocorticoid receptors. By far the most common cause is iatrogenic, due to prolonged administration of synthetic glucocorticoids such as prednisolone. Non-iatrogenic Cushing's syndrome is rare and is often a 'spot diagnosis' made by an astute clinician.

Aetiology

The causes are shown in Box 20.40. Amongst endogenous causes, pituitary-dependent cortisol excess (by convention, called Cushing's disease) accounts for approximately 80% of cases. Both Cushing's disease and

cortisol-secreting adrenal tumours are four times more common in women than men. In contrast, ectopic ACTH syndrome (often due to a small-cell carcinoma of the bronchus) is more common in men.

Clinical assessment

The diverse manifestations of glucocorticoid excess are shown in Figure 20.21. Many of these are not specific to Cushing's syndrome and, because spontaneous Cushing's syndrome is rare, the positive predictive value of any one feature alone is low. Moreover, some common disorders can be confused with Cushing's syndrome because they are associated with alterations in cortisol secretion: for example, obesity and depression (see Box 20.40). Features which favour Cushing's syndrome in an obese patient are bruising, myopathy and hypertension. Any clinical suspicion of cortisol excess is best resolved by further investigation.

It is vital to exclude iatrogenic causes in all patients with Cushing's syndrome since even inhaled or topical glucocorticoids can induce the syndrome in susceptible individuals. A careful drug history must therefore be taken before embarking on complex investigations.

Some clinical features are more common in ectopic ACTH syndrome. Unlike pituitary tumours secreting ACTH, ectopic tumours have no residual negative feedback sensitivity to cortisol, and both ACTH and cortisol levels are usually higher than with other causes. Very

Fig. 20.21 Cushing's syndrome. [A] Clinical features common to all causes. [B] A patient with Cushing's disease before treatment. [C] The same patient 1 year after the successful removal of an ACTH-secreting pituitary microadenoma by trans-sphenoidal surgery.

high ACTH levels are associated with marked pigmentation. Very high cortisol levels overcome the barrier of 11β -HSD2 in the kidney (p. 770) and cause hypokalaemic alkalosis. Hypokalaemia aggravates both myopathy and hyperglycaemia (by inhibiting insulin secretion). When the tumour secreting ACTH is malignant, then the onset is usually rapid and may be associated with cachexia. For these reasons, the classical features of Cushing's syndrome are less common in ectopic ACTH syndrome, and if present suggest that a less aggressive tumour (e.g. bronchial carcinoid) is responsible.

In Cushing's disease, the pituitary tumour is usually a microadenoma (< 10 mm in diameter); hence other features of a pituitary macroadenoma (hypopituitarism, visual failure or disconnection hyperprolactinaemia, p. 784) are rare.

Investigations

The large number of tests available for Cushing's syndrome reflects the limited specificity and sensitivity of

each test in isolation. Several tests are usually combined to establish the diagnosis. It is useful to divide investigations into those which establish whether the patient has Cushing's syndrome, and those which are used subsequently to define the cause.

A recommended sequence of investigations is shown in Figure 20.22 and the interpretation of these tests is shown in Box 20.41. Some additional tests are useful in all cases of Cushing's syndrome, including plasma electrolytes, glucose, glycosylated haemoglobin and bone mineral density measurement.

In iatrogenic Cushing's syndrome, cortisol levels are low unless the patient is taking a corticosteroid (such as prednisolone) which cross-reacts in immunoassays with cortisol.

Establishing the presence of Cushing's syndrome

Cushing's syndrome is confirmed by the demonstration of increased secretion of cortisol (measured in plasma

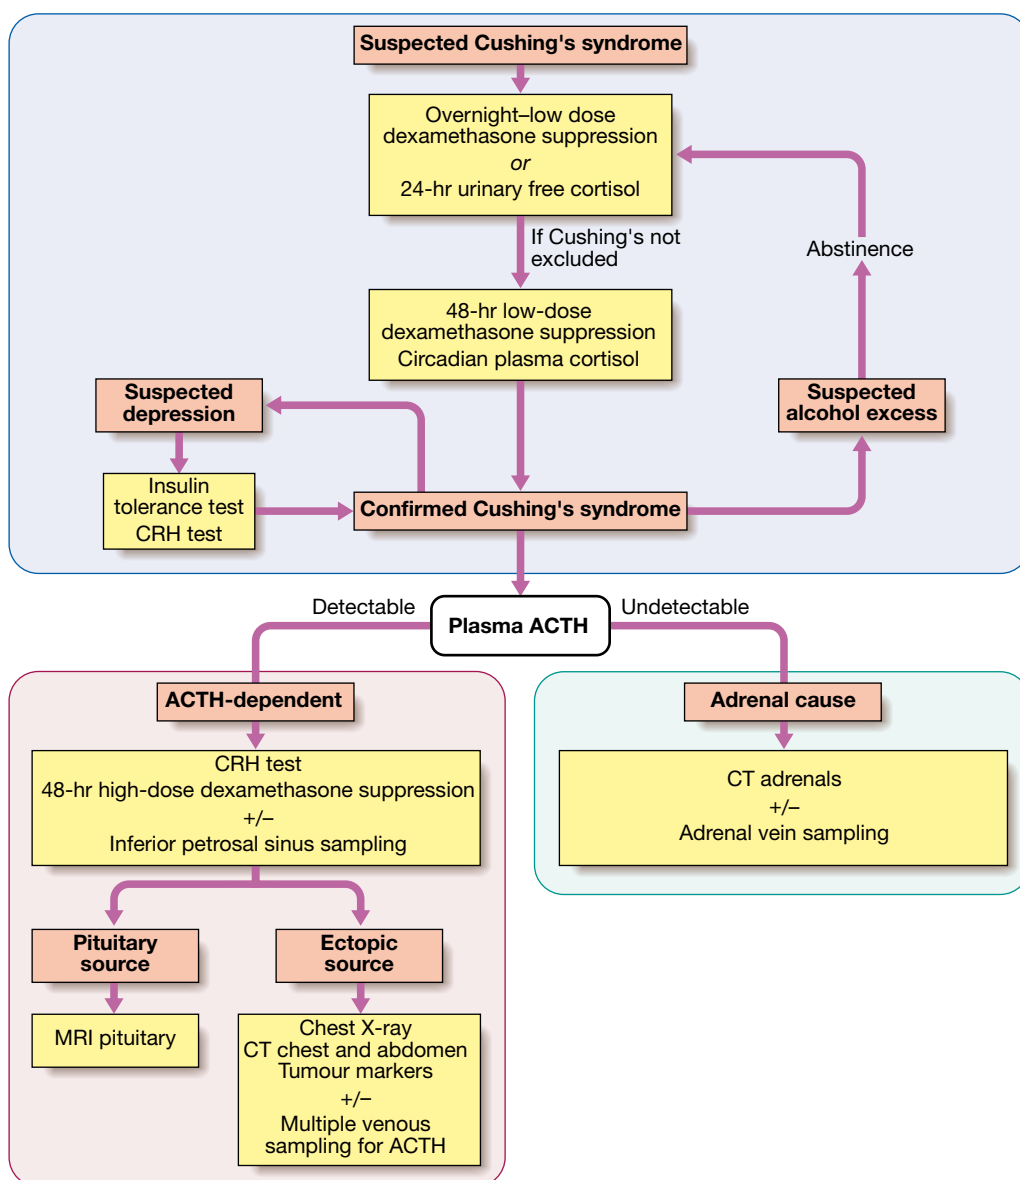

Fig. 20.22 Sequence of investigations in suspected spontaneous Cushing's syndrome. (CRH = corticotrophin-releasing hormone)

20.41 Tests for Cushing's syndrome

Test	Protocol	Interpretation
Urine free cortisol	24-hr timed collection (some centres use overnight collections corrected for creatinine)	Normal range depends on assay
Overnight dexamethasone suppression test	1 mg orally at midnight; measure plasma cortisol at 0800–0900 hrs	Plasma cortisol < 60 nmol/L (< 2.2 µg/dL) excludes Cushing's
Diurnal rhythm of plasma cortisol	Sample for cortisol at 0900 hrs and at 2300 hrs (requires acclimatisation to ward for at least 48 hrs)	Evening level > 75% of morning level in Cushing's
Low-dose dexamethasone suppression test	0.5 mg 6-hourly for 48 hrs; sample 24-hr urine cortisol during second day and 0900-hr plasma cortisol after 48 hrs	Urine cortisol < 100 nmol/day (36 µg/day) or plasma cortisol < 60 nmol/L (< 2.2 µg/dL) excludes Cushing's
Insulin tolerance test	Box 20.59, page 786	Peak plasma cortisol > 120% of baseline excludes Cushing's
High-dose dexamethasone suppression test	2 mg 6-hourly for 48 hrs; sample 24-hr urine cortisol at baseline and during second day	Urine cortisol < 50% of basal suggests pituitary-dependent disease; > 50% of basal suggests ectopic ACTH syndrome
Corticotrophin-releasing hormone test	100 µg ovine CRH i.v. and monitor plasma ACTH and cortisol for 2 hrs	Peak plasma cortisol > 120% and/or ACTH > 150% of basal values suggests pituitary-dependent disease; lesser responses suggest ectopic ACTH syndrome
Inferior petrosal sinus sampling	Catheters placed in both inferior petrosal sinuses and simultaneous sampling from these and peripheral blood for ACTH; may be repeated 10 minutes after peripheral CRH injection	ACTH concentration in either petrosal sinus > 200% peripheral ACTH suggests pituitary-dependent disease; < 150% suggests ectopic ACTH syndrome

20

or urine) that fails to suppress with relatively low doses of oral dexamethasone (see Box 20.41). Loss of diurnal variation, with elevated evening plasma cortisol, is also characteristic of Cushing's syndrome, but samples are awkward to obtain. Plasma cortisol levels are highly variable in healthy subjects and random measurement of daytime plasma cortisol is of no value in supporting or refuting the diagnosis.

Dexamethasone is used for suppression testing because, unlike prednisolone, it does not cross-react in radioimmunoassays for cortisol. The hypothalamic-pituitary-adrenal axis may 'escape' from suppression by dexamethasone if a more potent influence, such as psychological stress, supervenes.

In the rare cyclical Cushing's syndrome there is episodic excessive secretion of cortisol. If there is a strong clinical suspicion of Cushing's syndrome but initial screening tests are normal, then weekly 24-hour urine cortisol measurements for up to 3 months are sometimes justified.

Determining the underlying cause

Once the presence of Cushing's syndrome is confirmed, measurement of plasma ACTH is the key to establishing the differential diagnosis. In the presence of excess cortisol secretion, an undetectable ACTH indicates an adrenal tumour, while any detectable ACTH suggest a pituitary cause or ectopic ACTH. Tests to discriminate pituitary from ectopic sources of ACTH rely on the fact that pituitary tumours, but not ectopic tumours, retain some features of normal regulation of ACTH secretion. Thus, in pituitary-dependent Cushing's disease, ACTH secretion is suppressed by high-dose dexamethasone and ACTH is stimulated by corticotrophin-releasing hormone (CRH).

Techniques for localisation of tumours secreting ACTH or cortisol are listed in Figure 20.22. MRI detects around 70% of pituitary microadenomas secreting ACTH. Inferior petrosal sinus sampling with measurement of ACTH may be helpful in confirming Cushing's disease if the MRI does not show a microadenoma. CT or MRI detects most adrenal tumours; adrenal carcinomas are usually large (> 5 cm) and have other features of malignancy (p. 777).

Management

Untreated Cushing's syndrome has a 50% 5-year mortality. Most patients are treated surgically with medical therapy given for a few weeks prior to operation. A number of drugs are used to inhibit corticosteroid biosynthesis, including metyrapone and ketoconazole. The dose of these agents is best titrated against 24-hour urine free cortisol.

Cushing's disease

Trans-sphenoidal surgery with selective removal of the adenoma is the treatment of choice. Experienced surgeons can identify microadenomas which were not detected by MRI and cure about 80% of patients. If the operation is unsuccessful, then bilateral adrenalectomy is an alternative.

If bilateral adrenalectomy is used in patients with pituitary-dependent Cushing's syndrome, then there is a risk that the pituitary tumour will grow in the absence of the negative feedback suppression previously provided by elevated cortisol levels. This can result in Nelson's syndrome, with an aggressive pituitary macroadenoma and very high ACTH levels causing pigmentation. Nelson's syndrome can be prevented by pituitary irradiation.

Adrenal tumours

Adrenal adenomas are removed by laparoscopy or a loin incision. Surgery offers the only prospect of cure for adrenocortical carcinomas, but in general prognosis is poor with high rates of recurrence even in patients with localised disease at presentation. Although often used, there is little evidence that radiotherapy, chemotherapy or the adrenolytic drug mitotane improves recurrence rates or survival.

Ectopic ACTH syndrome

Localised tumours such as bronchial carcinoid should be removed surgically. In patients with incurable malignancy it is important to reduce the severity of the Cushing's syndrome using medical therapy (see above) or, if appropriate, bilateral adrenalectomy.

Therapeutic use of glucocorticoids

The remarkable anti-inflammatory properties of glucocorticoids have led to their use in a wide variety of clinical conditions, but the hazards are significant. Equivalent doses of commonly used glucocorticoids are listed in Box 20.42. Topical preparations (dermal, rectal and inhaled) can also be absorbed into the systemic circulation. Although this rarely occurs to a sufficient degree to produce clinical features of Cushing's syndrome, it can result in significant suppression of endogenous ACTH and cortisol secretion.

**20.42 Equivalent doses of glucocorticoids**

- Hydrocortisone: 20 mg
- Cortisone acetate: 25 mg
- Prednisolone: 5 mg
- Dexamethasone: 0.5 mg

Side-effects of glucocorticoids

The clinical features of glucocorticoid excess are illustrated in Figure 20.21 (p. 771). Adverse effects are related to dose, duration of therapy, and pre-existing conditions that might be worsened by corticosteroid therapy, such as diabetes mellitus or osteoporosis. Osteoporosis is a particularly important problem because, for a given bone mineral density, the fracture risk is greater in glucocorticoid-treated patients than in post-menopausal osteoporosis. Therefore, when systemic glucocorticoids are prescribed and the anticipated duration of steroid therapy is more than 3 months, bone-protective therapy should be considered, as detailed on page 1081. Rapid changes in glucocorticoid levels can also lead to marked mood disturbance, either depression or mania, and insomnia.

The anti-inflammatory effect of glucocorticoids may mask signs of disease. For example, perforation of a viscus may be masked and the patient may show no febrile response to an infection. Although there is debate about whether or not corticosteroids increase the risk of peptic ulcer when used alone, they act synergistically with NSAIDs, including aspirin, to increase the risk of serious gastrointestinal adverse effects. Latent tuberculosis may be reactivated and patients on corticosteroids should be advised to avoid contact with varicella zoster virus if they are not immune.

**20.43 Advice to patients on glucocorticoid replacement therapy****Intercurrent stress**

- Febrile illness: double dose of hydrocortisone

Surgery

- Minor operation: hydrocortisone 100 mg i.m. with pre-medication
- Major operation: hydrocortisone 100 mg 6-hourly for 24 hours, then 50 mg i.m. 6-hourly until ready to take tablets

Vomiting

- Patients must have parenteral hydrocortisone if unable to take it by mouth

Steroid card

- Patient should carry this at all times. It should give information regarding diagnosis, steroid, dose and doctor

Bracelet

- Patients should be encouraged to buy one of these and have it engraved with the diagnosis and a reference number for a central database

Management of glucocorticoid withdrawal

All glucocorticoid therapy, even if inhaled or applied topically, can suppress the HPA axis. In practice, this is only likely to result in a crisis due to adrenal insufficiency on withdrawal of treatment if glucocorticoids have been administered orally or systemically for longer than 3 weeks, if repeated courses have been prescribed within the previous year, or if the dose is higher than the equivalent of 7.5 mg prednisolone per day. In these circumstances, the drug, when it is no longer required for the underlying condition, must be withdrawn slowly at a rate dictated by the duration of treatment. If glucocorticoid therapy has been prolonged, then it may take many months for the HPA axis to recover. All patients must be advised to avoid sudden drug withdrawal. They should be issued with a steroid card and/or wear an engraved bracelet (Box 20.43).

Recovery of the HPA axis is aided if there is no exogenous glucocorticoid present during the nocturnal surge in ACTH secretion. This can be achieved by giving glucocorticoid in the morning. Giving ACTH to stimulate adrenal recovery is of no value as the pituitary remains suppressed.

In patients who have received glucocorticoids for longer than a few weeks, it is often valuable to confirm that the HPA axis is recovering during glucocorticoid withdrawal. Once the dose of glucocorticoid is reduced to a minimum (e.g. 4 mg prednisolone or 0.5 mg dexamethasone per day), then measure plasma cortisol at 0900 hrs before the next dose. If this is detectable, then perform an ACTH stimulation test (see Box 20.46) to confirm that glucocorticoids can be withdrawn completely. Even once glucocorticoids have been successfully withdrawn, short-term replacement therapy is often advised during significant intercurrent illness occurring in subsequent months, as the HPA axis may not be able to respond fully to severe stress.

Adrenal insufficiency

Adrenal insufficiency results from inadequate secretion of cortisol and/or aldosterone. It is potentially fatal

20.44 Causes of adrenocortical insufficiency

Secondary (↓ACTH)

- Withdrawal of suppressive glucocorticoid therapy
- Hypothalamic or pituitary disease

Primary (↑ACTH)

Addison's disease

Common causes

- Autoimmune
 - Sporadic
 - Polyglandular syndromes (p. 794)
- Tuberculosis
- HIV/AIDS
- Metastatic carcinoma
- Bilateral adrenalectomy

Rare causes

- Lymphoma
- Intra-adrenal haemorrhage (Waterhouse–Friedrichsen syndrome following meningococcal septicaemia)
- Amyloidosis
- Haemochromatosis

Corticosteroid biosynthetic enzyme defects

- Congenital adrenal hyperplasias
- Drugs
 - Metyrapone, ketoconazole, etomidate

and notoriously variable in its presentation. A high index of suspicion is therefore required in patients with unexplained fatigue, hyponatraemia or hypotension. Causes are shown in Box 20.44. The most common is ACTH deficiency (secondary adrenocortical failure), usually because of inappropriate withdrawal of chronic glucocorticoid therapy or a pituitary tumour (p. 785). Congenital adrenal hyperplasias and Addison's disease (primary adrenocortical failure) are rare.

Clinical assessment

The clinical features of adrenal insufficiency are shown in Box 20.45. In Addison's disease, either glucocorti-

coid or mineralocorticoid deficiency may come first, but eventually all patients fail to secrete both classes of corticosteroid.

Patients may present with chronic features and/or in acute circulatory shock. With a chronic presentation, initial symptoms are often misdiagnosed as chronic fatigue syndrome or depression. Adrenocortical insufficiency should also be considered in patients with hyponatraemia, even in the absence of symptoms (p. 435).

Features of an acute adrenal crisis include circulatory shock with severe hypotension, hyponatraemia, hyperkalaemia and, in some instances, hypoglycaemia and hypercalcaemia. Muscle cramps, nausea, vomiting, diarrhoea and unexplained fever may be present. The crisis is often precipitated by intercurrent disease, surgery or infection.

Vitiligo occurs in 10–20% of patients with autoimmune Addison's disease (p. 732).

Investigations

In patients presenting with chronic illness, investigations should be performed before any treatment. In patients with suspected acute adrenal crisis, treatment should not be delayed pending results. A random blood sample should be stored for measurement of cortisol. It may be appropriate to spend 30 minutes performing a short ACTH stimulation test (Box 20.46) before administering hydrocortisone, but investigations may need to be delayed until after recovery.

Assessment of glucocorticoids

Random plasma cortisol is usually low in patients with adrenal insufficiency, but it may be within the normal range, yet inappropriately low for a seriously ill patient. Random measurement of plasma cortisol cannot therefore be used to confirm or refute the diagnosis, unless the value is high (> 460 nmol/L (> 17 µg/dL)).

20.45 Clinical and biochemical features of adrenal insufficiency

20.46 How and when to do an ACTH stimulation test

Use
<ul style="list-style-type: none"> • Diagnosis of primary or secondary adrenal insufficiency • Assessment of HPA axis in patients taking suppressive glucocorticoid therapy • Relies on ACTH-dependent adrenal atrophy in secondary adrenal insufficiency, so may not detect acute ACTH deficiency (e.g. in pituitary apoplexy, p. 787)
Dose
<ul style="list-style-type: none"> • 250 µg ACTH₁₋₂₄ (Synacthen) by i.m. injection at any time of day
Blood samples
<ul style="list-style-type: none"> • 0 and 30 mins for plasma cortisol • 0 mins also for ACTH (on ice) if Addison's disease is being considered (i.e. patient not known to have pituitary disease or to be taking exogenous glucocorticoids)
Results
<ul style="list-style-type: none"> • Normal subjects plasma cortisol > 460 nmol/L (~17 µg/dL)* either at baseline or at 30 mins • Incremental change in cortisol is not a criterion
*The exact cortisol concentration depends on the cortisol assay being used.

More useful is the short ACTH stimulation test (also called the tetracosactrin or short Synacthen test) described in Box 20.46. Cortisol levels fail to increase in response to exogenous ACTH in patients with primary or secondary adrenal insufficiency. These can be distinguished by measurement of ACTH (which is low in ACTH deficiency and high in Addison's disease). If an ACTH assay is unavailable, then a long ACTH stimulation test can be used (1 mg depot ACTH i.m. daily for 3 days); in secondary adrenal insufficiency there is a progressive increase in plasma cortisol with repeated ACTH administration, whereas in Addison's disease, cortisol remains less than 700 nmol/L (25.4 µg/dL) at 8 hours after the last injection.

In a patient who is already receiving glucocorticoids, the short ACTH stimulation test can be performed first thing in the morning, more than 12 hours after the last dose of glucocorticoid, or the treatment can be changed to a synthetic steroid such as dexamethasone (0.75 mg daily), which does not cross-react in the plasma cortisol immunoassay.

Assessment of mineralocorticoids

Mineralocorticoid secretion in patients with suspected Addison's disease cannot be adequately assessed by electrolyte measurements since hyponatraemia occurs in both aldosterone and cortisol deficiency (see Box 20.45 and p. 435). Hyperkalaemia is common, but not universal, in aldosterone deficiency. Plasma renin activity and aldosterone should be measured in the supine position. In mineralocorticoid deficiency, plasma renin activity is high, with plasma aldosterone being either low or in the lower part of the normal range.

Assessment of adrenal androgens

This is not necessary in men because testosterone from the testes is the principal androgen. In women, dehydroepiandrosterone (DHEA) and androstenedione may be measured in a random specimen of blood, though levels are highest in the morning.

Other tests to establish the cause

Patients with unexplained secondary adrenocortical insufficiency should be investigated as described on page 785. In patients with elevated ACTH, further tests are required to establish the cause of Addison's disease. In those who have autoimmune adrenal failure, antibodies can often be measured against steroid-secreting cells (adrenal and gonad), thyroid antigens, pancreatic β cells and gastric parietal cells. Thyroid function tests, full blood count (to screen for pernicious anaemia), plasma calcium, glucose and tests of gonadal function (p. 753) should be performed. Other causes of adrenocortical disease are usually obvious clinically, particularly if health is not fully restored by corticosteroid replacement therapy. Tuberculosis causes adrenal calcification, visible on plain X-ray or ultrasound scan. A chest X-ray and early morning urine for culture should also be taken. An HIV test should be performed if risk factors for infection are present (p. 385). Imaging of the adrenals by CT or MRI to identify metastatic malignancy may also be appropriate.

Management

Patients with adrenocortical insufficiency always need glucocorticoid replacement therapy and usually, but not always, mineralocorticoid. Adrenal androgen replacement for women is controversial. Other treatments depend on the underlying cause. The emergency management of adrenal crisis is described in Box 20.47.

Glucocorticoid replacement

Hydrocortisone (cortisol) is the drug of choice. In someone who is not critically ill, hydrocortisone should be given by mouth, 15 mg on waking and 5 mg at around 1800 hrs. The dose may need to be adjusted for the individual patient but this is subjective. Excess weight gain usually indicates over-replacement, whilst persistent lethargy or hyperpigmentation may be due to an inadequate dose. Measurement of plasma cortisol levels is

20.47 Management of adrenal crisis

Correct volume depletion
<ul style="list-style-type: none"> • I.v. saline as required to normalise BP and pulse • In severe hyponatraemia (< 125 mmol/L) avoid increases of plasma Na > 10 mmol/L/day to prevent pontine demyelination (p. 435) • Fludrocortisone is not required during the acute phase of treatment
Replace glucocorticoids
<ul style="list-style-type: none"> • I.v. hydrocortisone succinate 100 mg stat • Continue parenteral hydrocortisone (50–100 mg i.m. 6-hourly) until the patient is well enough for reliable oral therapy
Correct other metabolic abnormalities
<ul style="list-style-type: none"> • Acute hypoglycaemia: i.v. 10% glucose • Hyperkalaemia: should respond to volume replacement, but occasionally requires specific therapy (Box 16.17, p. 441)
Identify and treat underlying cause
<ul style="list-style-type: none"> • Consider acute precipitant, e.g. infection • Consider adrenal or pituitary pathology (see Box 20.44)

unhelpful, because the dynamic interaction between cortisol and glucocorticoid receptors is not predicted by measurements such as the maximum or minimum plasma cortisol level after each dose. Advice to patients dependent on glucocorticoid replacement is given in Box 20.43. These are physiological replacement doses which should not cause Cushingoid side-effects.

Mineralocorticoid replacement

Fludrocortisone (9 α -fluoro-hydrocortisone) is administered in a dose 0.05–0.1 mg daily and adequacy of replacement may be assessed objectively by measurement of blood pressure, plasma electrolytes and plasma renin activity.

Androgen replacement

DHEA (approximately 50 mg/day) is sometimes given to women with primary adrenal insufficiency. Some trials have suggested that DHEA increases libido and sense of well-being, but complications include acne and hirsutism.

Incidental adrenal mass

It is not uncommon for a mass in the adrenal gland to be identified on a CT or MRI scan of the abdomen that has been performed for another indication. Such lesions are known as adrenal 'incidentalomas'. They are present in up to 10% of adults and the prevalence increases with age.

Eighty-five per cent of adrenal incidentalomas are non-functioning adrenal adenomas. The remainder includes functional tumours of the adrenal cortex (secreting cortisol, aldosterone or androgens), pheochromocytomas, primary and secondary carcinomas, hamartomas and other rare disorders including granulomatous infiltrations.

Clinical assessment and investigations

There are two key questions to be resolved: is the lesion secreting hormones, and is it benign or malignant?

Patients with an adrenal incidentaloma are usually asymptomatic. However, clinical signs and symptoms of excess glucocorticoids (p. 771), mineralocorticoids (see below), catecholamines (p. 779) and, in women, androgens (p. 759) should be sought. Investigations should include a 24-hour urine collection for metanephrines and urine free cortisol and, in women, measurement of serum testosterone, DHEA and androstenedione concentrations. Patients with hypertension should be investigated for mineralocorticoid excess as described below.

CT and MRI are equally effective in assessing the malignant potential of an adrenal mass, using the following parameters:

- **Size.** The larger the lesion, the greater the malignant potential. Around 90% of adrenocortical carcinomas are > 4 cm in diameter, but specificity is poor since only approximately 25% of such lesions are malignant.
- **Configuration.** Homogeneous and smooth lesions are more likely to be benign. The presence of metastatic lesions elsewhere increases the risk of malignancy, but as many as two-thirds of adrenal incidentalomas in patients with cancer are benign.

20.48 Glucocorticoids in old age

- **Adrenocortical insufficiency:** often insidious and difficult to spot.
- **Glucocorticoid therapy:** especially hazardous in older people, who are already relatively immunocompromised and susceptible to osteoporosis, diabetes, hypertension and other complications.
- **'Physiological' glucocorticoid replacement therapy:** increased risk of adrenal crisis, because compliance may be poor and there is a greater incidence of intercurrent illness. Patient and carer education with regular reinforcement of principles described in Box 20.43 is crucial.

- **Presence of lipid.** Adenomas are usually lipid-rich, resulting in an attenuation of < 10 Hounsfield Units (HU) on an unenhanced CT and in signal dropout on chemical shift MRI.
- **Enhancement.** Benign lesions demonstrate rapid washout of contrast, whereas malignant lesions tend to retain contrast.

Histology in a sample obtained by CT-guided biopsy is not useful in distinguishing an adrenal adenoma from an adrenal carcinoma, although it is occasionally helpful in confirming adrenal metastases from other cancers.

Management

Functional lesions and tumours > 5 cm in diameter should be removed by laparoscopic adrenalectomy. In patients with radiologically benign, non-functioning lesions < 5 cm in diameter, surgery is only required if serial imaging suggests tumour growth.

Primary hyperaldosteronism

Estimates of the prevalence of primary hyperaldosteronism vary according to the screening tests employed,

20.49 Causes of mineralocorticoid excess

With renin high and aldosterone high (secondary hyperaldosteronism)

- Inadequate renal perfusion, e.g. diuretic therapy, cardiac failure, liver failure, nephrotic syndrome, renal artery stenosis
- Renin-secreting renal tumour (very rare)

With renin low and aldosterone high (primary hyperaldosteronism)

- Adrenal adenoma secreting aldosterone (Conn's syndrome)
- Idiopathic bilateral adrenal hyperplasia
- Glucocorticoid-suppressible hyperaldosteronism (rare)

With renin low and aldosterone low (non-aldosterone-dependent activation of mineralocorticoid pathway)

- Ectopic ACTH syndrome
- Liquorice misuse (inhibition of 11 β -HSD2)
- Liddle's syndrome
- 11-deoxycorticosterone-secreting adrenal tumour
- Rare forms of congenital adrenal hyperplasia and 11 β -HSD2 deficiency

but it may occur in as many as 10% of people with hypertension. Indications to test for mineralocorticoid excess in hypertensive patients include hypokalaemia (including hypokalaemia induced by thiazide diuretics), poor control of blood pressure with conventional therapy, a family history of early-onset hypertension, or presentation at a young age.

Causes of excessive activation of mineralocorticoid receptors are shown in Box 20.49. It is important to differentiate primary hyperaldosteronism, caused by an intrinsic abnormality of the adrenal glands resulting in aldosterone excess, from secondary hyperaldosteronism, which is usually a consequence of enhanced activity of renin in response to inadequate renal perfusion and hypotension. Most individuals with primary hyperaldosteronism have bilateral adrenal hyperplasia (idiopathic hyperaldosteronism), while only a minority have an aldosterone-producing adenoma (APA; Conn's syndrome). Glucocorticoid-suppressible hyperaldosteronism is a rare autosomal dominant condition in which aldosterone is secreted 'ectopically' from the adrenal fasciculata/reticularis in response to ACTH. Rarely, the mineralocorticoid receptor pathway in the distal nephron is activated, even though aldosterone concentrations are low.

Clinical features

Individuals with primary hyperaldosteronism are usually asymptomatic, but they may have features of sodium retention or potassium loss. Sodium retention may cause oedema, while hypokalaemia may cause muscle weakness (or even paralysis, especially in Chinese), polyuria (secondary to renal tubular damage which produces nephrogenic diabetes insipidus) and occasionally tetany (because of associated metabolic alkalosis and low ionised calcium). Blood pressure is elevated but accelerated phase hypertension is rare.

Investigations

Biochemical

Routine bloods may show a hypokalaemic alkalosis. Sodium is usually at the upper end of the normal range in primary hyperaldosteronism, but is characteristically low in secondary hyperaldosteronism (because low plasma volume stimulates ADH release and high angiotensin II levels stimulate thirst). The key measurements are plasma renin and aldosterone (see Box 20.49). In many centres, the aldosterone:renin ratio (ARR) is employed as a screening test for primary hyperaldosteronism in hypertensive patients. Almost all antihypertensive drugs interfere with this ratio (β -blockers inhibit, whilst thiazide diuretics stimulate renin secretion). Thus, individuals with an elevated ARR require further testing after stopping interfering antihypertensive drugs for at least 2 weeks. If necessary, antihypertensive agents that have minimal effects on the renin-angiotensin system, such as calcium antagonists and α -blockers, may be substituted. Oral potassium supplementation may also be required, as hypokalaemia itself suppresses renin activity. If, on repeat testing, renin activity is low and aldosterone concentrations are elevated, then further investigation under specialist supervision may include suppression tests (sodium loading) and/or stimulation tests (captopril or furosemide administration) to differentiate angiotensin II-dependent aldosterone secretion in idiopathic hyperplasia from autonomous aldosterone

Fig. 20.23 Aldosterone-producing adenoma causing Conn's syndrome. **A** CT scan of left adrenal adenoma (arrow). **B** The tumour is 'canary yellow' because of intracellular lipid accumulation.

secretion typical of an aldosterone-producing adenoma (APA).

Imaging and localisation

Imaging with CT or MRI will identify most APAs (Fig. 20.23), but it is important to recognise the risk of false positives (non-functioning adrenal adenomas are common) and false negatives (imaging may have insufficient resolution to identify adenomas with diameter < 0.5 cm). If the imaging is inconclusive and there is an intention to proceed with surgery on the basis of strong biochemical evidence of an APA, then adrenal vein catheterisation with measurement of aldosterone (and cortisol to confirm positioning of the catheters) is required.

Management

Mineralocorticoid receptor antagonists are valuable in treating both hypokalaemia and hypertension in all forms of mineralocorticoid excess. Up to 20% of males develop gynaecomastia on spironolactone. Eplerenone or amiloride (10–40 mg/day), which blocks the epithelial sodium channel regulated by aldosterone, is an alternative.

In patients with an APA, medical therapy is usually given for a few weeks to normalise whole-body electrolyte balance before unilateral adrenalectomy. Laparoscopic surgery cures the biochemical abnormality but hypertension remains in as many as 70% of cases,

probably because of irreversible damage to the systemic microcirculation.

Phaeochromocytoma and paraganglioma

These are rare neuro-endocrine tumours that may secrete catecholamines (adrenaline/epinephrine, noradrenaline/norepinephrine) and are responsible for less than 0.1% of cases of hypertension. Approximately 80% of these tumours occur in the adrenal medulla (phaeochromocytomas), while 20% arise elsewhere in the body in sympathetic ganglia (paragangliomas). Most are benign but approximately 15% show malignant features. Around 25% of phaeochromocytomas are associated with inherited disorders, including neurofibromatosis (p. 1218), von Hippel–Lindau syndrome (p. 1219) and MEN type 2 (p. 793). Paragangliomas are particularly associated with mutations in the succinate dehydrogenase B, C and D genes.

Clinical features

These depend on the pattern of catecholamine secretion and are listed in Box 20.50.

Some patients present with a complication of hypertension, such as stroke, myocardial infarction, left ventricular failure, hypertensive retinopathy or accelerated phase hypertension. The apparent paradox of postural

hypotension between episodes is explained by 'pressure natriuresis' during hypertensive episodes so that intravascular volume is reduced. There may also be features of the familial syndromes associated with phaeochromocytoma.

Investigations

Excessive secretion of catecholamines can be confirmed by measuring metabolites in plasma and/or urine (metanephrine and normetanephrine). There is a high 'false positive' rate as misleading metanephrine concentrations may be seen in stressed patients (during acute illness or following vigorous exercise or severe pain) and following ingestion of some drugs such as tricyclic antidepressants. For this reason, a repeat sample should usually be requested if elevated levels are found, although as a rule the higher the concentration of metanephrines, the more likely the diagnosis of phaeochromocytoma/paraganglioma. Serum chromogranin A is often elevated and may be a useful tumour marker in patients with non-secretory tumours and/or metastatic disease. Genetic testing should be considered in individuals with other features of a genetic syndrome, with a family history of phaeochromocytoma/paraganglioma and in those presenting under the age of 50 years.

Localisation

Phaeochromocytomas are usually identified by abdominal CT or MRI (Fig. 20.24). Localisation of paragangliomas may be more difficult. Scintigraphy using meta-iodobenzyl guanidine (MIBG) can be useful, particularly if combined with CT. ^{18}F -deoxyglucose PET is a sensitive but not specific test, and is not universally available.

Management

Medical therapy is required to prepare the patient for surgery, preferably for a minimum of 6 weeks to allow restoration of normal plasma volume. The most useful drug in the face of very high circulating catecholamines is the α -blocker phenoxybenzamine (10–20 mg orally 6–8-hourly) because it is a non-competitive antagonist, unlike prazosin or doxazosin. If α -blockade produces a marked tachycardia, then a β -blocker (e.g. propranolol) or combined α - and β -antagonist (e.g. labetalol) can be

20.50 Clinical features of phaeochromocytoma

- Hypertension (usually paroxysmal; often postural drop of blood pressure)
- Paroxysms of:
 - Pallor (occasionally flushing)
 - Palpitations
 - Sweating
 - Headache
 - Anxiety (fear of death—*angor animi*)
- Abdominal pain, vomiting
- Constipation
- Weight loss
- Glucose intolerance

[A]

[B]

added. On no account should the β -antagonist be given before the α -antagonist, as it may cause a paradoxical rise in blood pressure due to unopposed α -mediated vasoconstriction.

During surgery sodium nitroprusside and the short-acting α -antagonist phentolamine are useful in controlling hypertensive episodes which may result from anaesthetic induction or tumour mobilisation. Post-operative hypotension may occur and require volume expansion and, very occasionally, noradrenaline (norepinephrine) infusion. This is uncommon if the patient has been prepared adequately with phenoxybenzamine.

Metastatic tumours may behave in an aggressive or a very indolent fashion. Management options include debulking surgery, radionuclide therapy with ^{131}I -MIBG, chemotherapy and (chemo)embolisation of hepatic metastases.

Congenital adrenal hyperplasia

Pathophysiology and clinical features

Inherited defects in enzymes of the cortisol biosynthetic pathway (see Fig. 20.20, p. 770) result in insufficiency of hormones 'distal' to the block, with impaired negative feedback and increased ACTH secretion. ACTH then stimulates the production of steroids 'proximal' to the enzyme block. This produces adrenal hyperplasia and a combination of clinical features that depend on the severity and site of the defect in biosynthesis. All of these enzyme abnormalities are inherited as autosomal recessive traits.

The most common enzyme defect is 21-hydroxylase deficiency. This results in impaired synthesis of cortisol and aldosterone and accumulation of 17OH-progesterone, which is then diverted to form adrenal androgens. In about one-third of cases this defect is severe and presents in infancy with features of glucocorticoid and mineralocorticoid deficiency (see Box 20.45, p. 775) and androgen excess (i.e. ambiguous genitalia in girls). In the other two-thirds, mineralocorticoid secretion is adequate, but there may be features of cortisol insufficiency and/or ACTH and androgen excess, including precocious pseudopuberty, which is distinguished from 'true' precocious puberty by low gonadotrophins. Sometimes the mildest enzyme defects are not apparent until adult life, when females may present with amenorrhoea and/or hirsutism (p. 759). This is called 'non-classical' or 'late-onset' congenital adrenal hyperplasia.

Defects of all the other enzymes in Figure 20.20 (p. 770) are rare. Both 17-hydroxylase and 11 β -hydroxylase deficiency may produce hypertension due to excess production of 11-deoxycorticosterone, which has mineralocorticoid activity.

Investigations

Circulating 17OH-progesterone levels are raised in 21-hydroxylase deficiency, but this may only be demonstrated after ACTH administration in late-onset cases. To avoid salt-wasting crises in infancy, 17OH-progesterone can be routinely measured in heel prick blood spot samples taken from all infants in the first week of life. Assessment is otherwise as described for adrenal insufficiency on page 775.

In siblings of affected children, antenatal genetic diagnosis can be made by amniocentesis or chorionic

villus sampling. This allows prevention of virilisation of affected female fetuses by administration of dexamethasone to the mother.

Management

The aim is to replace deficient corticosteroids and to suppress ACTH-driven adrenal androgen production. In contrast to glucocorticoid replacement therapy in other forms of cortisol deficiency (p. 776), it is usual to give 'reverse' treatment. This involves giving a larger dose of a long-acting synthetic glucocorticoid just before going to bed to suppress the early morning ACTH peak, and a smaller dose in the morning. A careful balance is required between adequate suppression of adrenal androgen excess and excessive glucocorticoid replacement resulting in features of Cushing's syndrome. In children, growth velocity is an important measurement, since either under- or over-replacement with glucocorticoids suppresses growth. In adults, clinical features (menstrual cycle, hirsutism, weight gain, blood pressure) and biochemical profiles (plasma renin activity, 17OH-progesterone and testosterone levels) provide a guide.

Women with late-onset 21-hydroxylase deficiency may not require corticosteroid replacement. If hirsutism is the main problem, anti-androgen therapy may be just as effective (p. 762).

THE ENDOCRINE PANCREAS AND GASTROINTESTINAL TRACT

A series of hormones are secreted from cells distributed throughout the gastrointestinal tract and pancreas. Functional anatomy and physiology are described in Chapters 21 and 22. Diseases associated with abnormalities of these hormones are listed in Box 20.51. Most are rare, with the exception of diabetes mellitus (Ch. 21).

20.51 Classification of endocrine diseases of the pancreas and gastrointestinal tract

	Primary	Secondary
Hormone excess	Insulinoma Gastrinoma (Zollinger–Ellison syndrome) Carcinoid syndrome (secretion of 5-HT) Glucagonoma VIPoma Somatostatinoma	Hypergastrinaemia of achlorhydria Hyperinsulinaemia after bariatric surgery
Hormone deficiency	Diabetes mellitus	
Hormone hypersensitivity	Rare, e.g. pseudoacromegaly	
Hormone resistance	Insulin resistance syndromes (e.g. type 2 diabetes mellitus, lipodystrophy, leprechaunism)	
Non-functioning tumours	Pancreatic carcinoma Pancreatic neuro-endocrine tumour	

Presenting problems in endocrine pancreas disease

Spontaneous hypoglycaemia

Hypoglycaemia most commonly occurs as a side-effect of treatment with insulin or sulphonylurea drugs in people with diabetes mellitus. In non-diabetic individuals, symptomatic hypoglycaemia is rare, but it is not uncommon to detect venous blood glucose concentrations below 3.0 mmol/L in asymptomatic patients. For this reason, and because the symptoms of hypoglycaemia are non-specific, a hypoglycaemic disorder should only be diagnosed if all three conditions of Whipple's triad are met (Fig. 20.25). There is no specific blood glucose concentration at which spontaneous hypoglycaemia can be said to occur, although the lower the blood glucose concentration, the more likely it is to have pathological significance.

Clinical assessment

The clinical features of hypoglycaemia are described in the section on insulin-induced hypoglycaemia on page 812. Individuals with chronic spontaneous hypoglycaemia often have attenuated autonomic responses, and may present with a wide variety of features of neuroglycopenia, including odd behaviour and convulsions. The symptoms are usually episodic and relieved by consumption of carbohydrate. Symptoms occurring while fasting (such as before breakfast) or following exercise are much more likely to be representative of pathological hypoglycaemia than those which develop after food (post-prandial or 'reactive' symptoms). Hypoglycaemia should be considered in all comatose patients, even if there is an apparently obvious cause, such as hemiplegic stroke or alcohol intoxication.

Investigations

Does the patient have a hypoglycaemic disorder?

Patients who present acutely with confusion, coma or convulsions should be tested for hypoglycaemia at the bedside with a capillary blood sample and an automated meter. While this is sufficient to exclude

hypoglycaemia, blood glucose meters are relatively inaccurate in the hypoglycaemic range and the diagnosis should always be confirmed by a laboratory-based glucose measurement. At the same time, a sample should be taken for later measurement, if necessary, of alcohol, insulin, C-peptide and sulphonylurea levels. Taking these samples during an acute presentation prevents subsequent unnecessary dynamic tests and is of medico-legal importance in cases where poisoning is suspected.

Patients who attend the outpatient clinic with episodic symptoms suggestive of hypoglycaemia present a more challenging problem. The main diagnostic test is the prolonged (72-hour) fast. If symptoms of hypoglycaemia develop during the fast, then blood samples should be taken to confirm hypoglycaemia and for later measurement of insulin and C-peptide. Hypoglycaemia is then corrected with oral or intravenous glucose and Whipple's triad completed by confirmation of the resolution of symptoms. The absence of clinical and biochemical evidence of hypoglycaemia during a prolonged fast effectively excludes the diagnosis of a hypoglycaemic disorder.

What is the cause of the hypoglycaemia?

In the acute setting, the underlying diagnosis is often obvious. In non-diabetic individuals, alcohol excess is the most common cause of hypoglycaemia in the UK, but other drugs, for example salicylates, quinine and pentamidine, may also be implicated. Hypoglycaemia is one of many metabolic derangements which occur in patients with hepatic failure, renal failure, sepsis or malaria.

Hypoglycaemia in the absence of insulin, or any insulin-like factor, in the blood indicates impaired gluconeogenesis and/or availability of glucose from glycogen in the liver. Hypoglycaemia associated with high insulin and low C-peptide concentrations is indicative of administration of exogenous insulin, either factitiously or feloniously. Adults with high insulin and C-peptide concentrations during an episode of hypoglycaemia are most likely to have an insulinoma, but sulphonylurea ingestion should also be considered (particularly in

Fig. 20.25 Differential diagnosis of spontaneous hypoglycaemia. Measurement of insulin and C-peptide concentrations during an episode is helpful in determining the underlying cause.

individuals with access to such medication, such as health-care professionals or family members of someone with type 2 diabetes). Insulinomas in the pancreas are usually small (< 5 mm diameter), but can usually be identified by CT, MRI or ultrasound (endoscopic or laparoscopic). Imaging should include the liver since around 10% of insulinomas are malignant. Rarely, large non-pancreatic tumours, such as sarcomas, may cause recurrent hypoglycaemia because of their ability to produce excess insulin-like growth factor-2.

Management

Treatment of acute hypoglycaemia should be initiated as soon as laboratory blood samples have been taken, and should *not* be deferred until the formal laboratory confirmation is obtained. Intravenous dextrose (5% or 10%) is effective in the short term in the obtunded patient, and should be followed on recovery with oral unrefined carbohydrate (starch). Continuous dextrose infusion may be necessary, especially in sulphonylurea poisoning. Intramuscular glucagon (1 mg) stimulates hepatic glucose release, but is ineffective in patients with depleted glycogen reserves such as alcohol excess, liver disease.

Chronic recurrent hypoglycaemia in insulin-secreting tumours can be treated by regular consumption of oral carbohydrate combined with agents that inhibit insulin secretion (diazoxide or somatostatin analogues). Insulinomas are resected when benign, providing the individual is fit enough to undergo surgery. Metastatic malignant insulinomas are incurable and are managed along the same lines as other metastatic neuro-endocrine tumours (see below).

20.52 Spontaneous hypoglycaemia in old age

- **Presentation:** may present with focal neurological abnormality. Blood glucose should be checked in all patients with acute neurological symptoms and signs, especially stroke, as these will reverse with early treatment of hypoglycaemia.

Gastroenteropancreatic neuro-endocrine tumours

Neuro-endocrine tumours (NETs) are a heterogeneous group derived from neuro-endocrine cells in many organs, including the gastrointestinal tract, lung, adrenals (phaeochromocytoma, p. 779) and thyroid (medullary carcinoma, p. 752). Most NETs occur sporadically, but a proportion are associated with genetic cancer syndromes such as MEN 1, MEN 2 and neurofibromatosis type 1 (pp. 793 and 1218). NETs may secrete hormones into the circulation.

Gastroenteropancreatic NETs arise in organs that are derived embryologically from the gastrointestinal tract. Most commonly they occur in the small bowel, but they can also arise elsewhere in the bowel, pancreas, thymus and bronchi. The term 'carcinoid' is often used when referring to non-pancreatic gastroenteropancreatic NETs, because when initially described they were thought to behave in an indolent fashion compared with conventional cancers. It is now recognised

that there is a wide spectrum of malignant potential for all NETs; some are benign (most insulinomas and appendiceal carcinoid tumours) while others have an aggressive clinical course with widespread metastases (small cell carcinoma of the lung). The majority of gastroenteropancreatic NETs behave in an intermediate manner with relatively slow growth, but a propensity to invade and metastasise to remote organs, especially the liver.

Clinical features

Gastroenteropancreatic NETs usually present with local mass effects, such as small bowel obstruction, appendicitis, and pain from hepatic metastases. Thymic and bronchial carcinoids occasionally present with ectopic ACTH syndrome (p. 771). Pancreatic NETs can also cause hormone excess (Box 20.53) but most are non-functional. The classic 'carcinoid syndrome' (Box 20.54) occurs when vasoactive hormones, such as serotonin (5-HT), reach the systemic circulation. In the case of gastrointestinal carcinoids, this invariably means that the tumour has metastasised to the liver, as hormones secreted by the primary tumour into the portal vein are metabolised and inactivated in the liver.

Investigations

A combination of imaging with ultrasound, CT, MRI and/or radiolabelled somatostatin analogue (Fig. 20.26) will usually identify the primary tumour and allow staging, which is crucial for determining prognosis. Biopsy of the primary tumour or a metastatic deposit is required to confirm the histological type. NETs demonstrate immunohistochemical staining for the proteins chromogranin A and synaptophysin, and the histological grade may also provide prognostic information.

Carcinoid syndrome is confirmed by measuring elevated concentrations of 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, in a 24-hour urine collection. False positives can occur, particularly if the individual has been eating certain foods, such as avocado and pineapple. Chromogranin A and synaptophysin can be measured in a fasting blood sample, along with the hormones listed in Box 20.53; these can be useful as tumour markers.

20.53 Pancreatic neuro-endocrine tumours

Tumour	Hormone	Effects
Gastrinoma	Gastrin	Peptic ulcer and steatorrhoea (Zollinger–Ellison syndrome)
Insulinoma	Insulin	Recurrent hypoglycaemia (see above)
VIPoma	Vasoactive intestinal peptide (VIP)	Watery diarrhoea and hypokalaemia
Glucagonoma	Glucagon	Diabetes mellitus, necrolytic migratory erythema
Somatostatinoma	Somatostatin	Diabetes mellitus and steatorrhoea

Fig. 20.26 Octreotide scintigraphy in a metastatic neuro-endocrine tumour. **A** Coronal CT scan showing hepatomegaly and a mass inferior to the liver (at the intersection of the horizontal and vertical red lines). **B** Octreotide scintigram showing patches of increased uptake in the upper abdomen. **C** When the octreotide and CT scans are superimposed, it shows that the areas of increased uptake are in hepatic metastases and in the tissue mass which may be lymph nodes or a primary tumour.

20.54 Clinical features of the carcinoid syndrome

- Episodic flushing, wheezing and diarrhoea
- Facial telangiectasia
- Cardiac involvement (tricuspid regurgitation, pulmonary stenosis, right ventricular endocardial plaques) leading to heart failure

Management

Treatment of solitary tumours is by surgical resection. If metastatic or multifocal primary disease is present, then surgery is usually not indicated, unless there is, for example, gastrointestinal obstruction. Diazoxide may reduce insulin secretion in insulinomas and high doses of proton pump inhibitors suppress acid production in gastrinomas. Somatostatin analogues are effective in reducing the symptoms of carcinoid syndrome and of excess glucagon and vasoactive intestinal peptide (VIP) production. The slow-growing nature of NETs means that conventional cancer therapies, such as chemotherapy and radiotherapy, have a limited role. Other treatments, such as interferon, targeted radionuclide therapy with ^{131}I -MIBG and radiolabelled somatostatin analogues (which may be taken up by NET metastases), and resection/embolisation of hepatic metastases, may have a role in the palliation of symptoms, but there is little evidence that they prolong life.

THE HYPOTHALAMUS AND THE PITUITARY GLAND

Diseases of the hypothalamus and pituitary are rare, with an annual incidence of approximately 1:50 000. The pituitary plays a central role in several major endocrine axes, so that investigation and treatment invariably involve several other glands.

Functional anatomy, physiology and investigations

The anatomical relationships of the pituitary are shown in Figure 20.27 and its numerous functions are shown

in Figure 20.2 (p. 735). The pituitary gland is enclosed in the sella turcica and bridged over by a fold of dura mater called the diaphragma sellae, with the sphenoidal air sinuses below and the optic chiasm above. The cavernous sinuses are lateral to the pituitary fossa and contain the 3rd, 4th and 6th cranial nerves and the internal carotid arteries. The gland is composed of two lobes, anterior and posterior, and is connected to the hypothalamus by the infundibular stalk, which has portal vessels carrying blood from the median eminence of the hypothalamus to the anterior lobe and nerve fibres to the posterior lobe.

Diseases of the hypothalamus and pituitary are classified in Box 20.55. By far the most common disorder is an adenoma of the anterior pituitary gland.

20.55 Classification of diseases of the pituitary and hypothalamus

	Primary	Secondary
Hormone excess		
Anterior pituitary	Prolactinoma Acromegaly Cushing's disease Rare TSH-, LH- and FSH-secreting adenomas	Disconnection hyperprolactinaemia
Hypothalamus and posterior pituitary	Syndrome of inappropriate antidiuretic hormone (SIADH; p. 436)	
Hormone deficiency		
Anterior pituitary	Hypopituitarism	GnRH deficiency (Kallmann's syndrome)
Hypothalamus and posterior pituitary	Cranial diabetes insipidus	
Hormone resistance	Growth hormone resistance (Laron dwarfism) Nephrogenic diabetes insipidus	
Non-functioning tumours	Pituitary adenoma Craniopharyngioma Metastatic tumours

Investigation of patients with pituitary disease

Although pituitary disease presents with diverse clinical manifestations (see below), the approach to investigation is similar in all cases (Box 20.56).

The approach to testing for hormone deficiency is outlined in Box 20.56. Details are given in the sections on individual glands elsewhere in this chapter. This approach has generally superseded the potentially hazardous 'combined pituitary function test', which involves simultaneous administration of thyrotrophin-releasing hormone (TRH), gonadotrophin-releasing hormone (GnRH) and insulin (to induce hypoglycaemic stress and stimulate ACTH and growth hormone secretion).

Tests for hormone excess vary according to the hormone in question. For example, prolactin is not secreted in pulsatile fashion, although it rises with significant psychological stress. Assuming that the patient was not distressed by venepuncture, a random measurement of serum prolactin is sufficient to diagnose hyperprolactinaemia. In contrast, growth hormone is secreted in a pulsatile fashion. A high random level does not confirm acromegaly; the diagnosis is only confirmed by failure of growth hormone to be suppressed (by the insulin-induced rise in insulin-like growth factor-1) during an oral glucose tolerance test. Similarly, in

suspected ACTH-dependent Cushing's disease (p. 772), random measurement of plasma cortisol is unreliable and the diagnosis is usually made by a dexamethasone suppression test.

The most common local complication of a large pituitary tumour is compression of the optic pathway. The resulting visual field defect can be documented using a Goldman's perimetry chart.

MRI reveals 'abnormalities' of the pituitary gland in as many as 10% of 'healthy' middle-aged people. It should therefore be performed only if there is a clear biochemical abnormality or in a patient who presents with clinical features of pituitary tumour (see below). A pituitary tumour may be classified as either a macroadenoma (> 10 mm diameter) or a microadenoma (< 10 mm diameter). Microadenomas are not associated with hypopituitarism or compression of local structures and are only treated if they are secreting excess hormones.

Surgical biopsy is usually only performed as part of a therapeutic operation. Conventional histology identifies tumours as chromophobe (usually non-functioning), acidophil (typically prolactin- or growth hormone-

secreting) or basophil (typically ACTH-secreting); immunohistochemistry may confirm their secretory capacity but is poorly predictive of growth potential of the tumour.

Presenting problems in hypothalamic and pituitary disease

The clinical features of pituitary disease are shown in Figure 20.28. Younger women with pituitary disease most commonly present with secondary amenorrhoea (p. 756) or galactorrhoea (in hyperprolactinaemia). Postmenopausal women and men of any age are less likely to report symptoms of hypogonadism and so are more likely to present late with larger tumours causing visual field defects. Nowadays, many patients present with the incidental finding of a pituitary tumour on a CT or MRI scan.

Hypopituitarism

Hypopituitarism describes combined deficiency of any of the anterior pituitary hormones. The clinical presentation is variable and depends on the underlying lesion and the pattern of resulting hormone deficiency. The most common cause is a pituitary macroadenoma but other causes are listed in Box 20.57.

Clinical assessment

The presentation is highly variable. With progressive lesions of the pituitary there is a characteristic sequence of loss of pituitary hormone secretion. Growth hormone secretion is often the earliest to be lost. In adults, this produces lethargy, muscle weakness and increased

fat mass, but these features are not obvious in isolation. Next, gonadotrophin (LH and FSH) secretion becomes impaired with, in the male, loss of libido and, in the female, oligomenorrhoea or amenorrhoea. Later, in the male there may be gynaecomastia and decreased frequency of shaving. In both sexes axillary and pubic hair eventually become sparse or even absent and the skin becomes characteristically finer and wrinkled. Chronic anaemia may also occur. The next hormone to be lost is usually ACTH, resulting in symptoms of cortisol insufficiency. In contrast to primary adrenal insufficiency (p. 774), angiotensin II-dependent zona glomerulosa function is not lost and hence aldosterone secretion maintains normal plasma potassium. However, there may be postural hypotension and a dilutional hyponatraemia for three reasons:

- Failure of vasoconstriction in the absence of cortisol results in pooling of blood in the legs on standing.
- Antidiuretic hormone (ADH) release is enhanced by hypotension and cortisol deficiency.
- Cortisol is required for normal water excretion by the kidney.

In contrast to the pigmentation of Addison's disease, a striking degree of pallor is usually present, principally because of lack of stimulation of melanocytes by β -lipotropic hormone (β -LPH, a fragment of the ACTH precursor peptide) in the skin. Finally, TSH secretion is lost with consequent secondary hypothyroidism. This contributes further to apathy and cold intolerance. In contrast to primary hypothyroidism, frank myxoedema is rare, presumably because the thyroid retains some autonomous function. The onset of all of the above symptoms is notoriously insidious. However, patients sometimes

present acutely unwell with glucocorticoid deficiency. This may be precipitated by a mild infection or injury, or may occur secondary to pituitary apoplexy (p. 787).

Other features of pituitary disease may be present (see Fig. 20.28).

Investigations

The strategy for investigation of pituitary disease is described in Box 20.56. In acutely unwell patients, the priority is to diagnose and treat cortisol deficiency (p. 774). Other tests can be undertaken later. Specific dynamic tests for diagnosing hormone deficiency are described in Boxes 20.46 (p. 776) and 20.58. More specialised biochemical tests, such as insulin tolerance tests (Box 20.59), GnRH and TRH tests, are rarely required. All patients with biochemical evidence of pituitary hormone deficiency should have an MRI or CT scan to identify pituitary or hypothalamic tumours. If a tumour is not identified, then further investigations are indicated to exclude infectious or infiltrative causes.

Management

Treatment of acutely ill patients is similar to that described for adrenocortical insufficiency on page 776, except that sodium depletion is not an important component to correct. Chronic hormone replacement therapies are described below. Once the cause of hypopituitarism is established, specific treatment—of a pituitary macroadenoma, for example (see below)—may be required.

Cortisol replacement

Hydrocortisone should be given if there is ACTH deficiency. Suitable doses are described in the section on adrenal disease on page 46. Mineralocorticoid replacement is not required.

Thyroid hormone replacement

Thyroxine 100–150 µg once daily should be given as described on page 742. Unlike in primary hypothyroidism, measuring TSH is not helpful in adjusting the replacement dose because patients with hypopituitarism often secrete glycoproteins which are measured in the TSH assays but are not bioactive. The aim is to maintain serum T₄ in the upper part of the reference

20.58 Tests of growth hormone secretion

GH levels are commonly undetectable, so a choice from the range of 'stimulation' tests is required*:

- 1 hour after going to sleep
- Frequent sampling during sleep
- Post-exercise
- Insulin-induced hypoglycaemia
- Arginine (may be combined with GHRH)
- Glucagon
- Clonidine

*In pre-pubertal patients, priming with sex steroid is required before 'stimulation' tests are performed.

20.59 How and when to do an insulin tolerance test

Use

- Assessment of the HPA axis
- Assessment of growth hormone deficiency
- Indicated when there is doubt after other tests in Box 20.56
- Usually performed in specialist centres, especially in children
- i.v. glucose and hydrocortisone must be available for resuscitation

Contraindications

- Ischaemic heart disease
- Epilepsy
- Severe hypopituitarism (0800 hrs plasma cortisol < 180 nmol/L (6.6 µg/dL))

Dose

- 0.15 U/kg body weight soluble insulin i.v.

Aim

- To produce adequate hypoglycaemia (tachycardia and sweating with blood glucose < 2.2 mmol/L (40 mg/dL))

Blood samples

- 0, 30, 45, 60, 90, 120 mins for blood glucose, plasma cortisol and growth hormone

Results

- Normal subjects GH > 6.7 µg/L (20 mU/L)*
- Normal subjects cortisol > 550 nmol/L (~20.2 µg/dL)*

*The precise cut-off figure for a satisfactory cortisol and GH response depends on the assay used and so varies between centres.

range. It is dangerous to give thyroid replacement to patients with adrenal insufficiency without first giving glucocorticoid therapy, since this may precipitate adrenal crisis.

Sex hormone replacement

This is indicated if there is gonadotrophin deficiency in men of any age and in women under the age of 50 to restore normal sexual function and to prevent osteoporosis (p. 1116).

Growth hormone replacement

Growth hormone (GH) is administered by daily subcutaneous self-injection to children and adolescents with GH deficiency and, until recently, was discontinued once the epiphyses had fused. However, although hypopituitary adults receiving 'full' replacement with hydrocortisone, thyroxine and sex steroids are usually much improved by these therapies, some individuals remain lethargic and unwell compared with a healthy population. Some of these patients feel better, and have objective improvements in their fat:muscle mass ratios and other metabolic parameters, if they are also given GH replacement. GH therapy may also help young adults to achieve a higher peak bone mineral density. The principal side-effect is sodium retention, manifest as peripheral oedema or carpal tunnel syndrome. For this reason, GH replacement should be started at a low dose, with monitoring of the response by measurement of serum insulin-like growth factor-1 (IGF-1) levels.

Pituitary tumour

Pituitary tumours produce a variety of mass effects, depending on their size and location, but also present as incidental findings on CT or MRI, or with hypopituitarism, as described above. A wide variety of disorders can present as mass lesions in or around the pituitary gland (see Box 20.57). Most intrasellar tumours are pituitary macroadenomas (most commonly non-functioning adenomas, Fig. 20.28), whereas the majority of suprasellar masses are craniopharyngiomas (see Fig. 20.32, p. 792). The most common cause of a parasellar mass is a meningioma.

Clinical assessment

Clinical features are shown in Figure 20.28. A common but non-specific presentation is with headache, which may be the consequence of stretching of the diaphragma sellae. Compression of the neural connections between the retina and occipital cortex may lead to a visual field defect. Although the classical abnormalities associated with compression of the optic chiasm are bitemporal hemianopia (see Fig. 20.29) or upper quadrantanopia, any type of visual field defect can result from suprasellar extension of a tumour because it may compress the optic nerve (unilateral loss of acuity or scotoma) or the optic tract (homonymous hemianopia). Optic atrophy may be apparent on ophthalmoscopy. Lateral extension of a sellar mass into the cavernous sinus with subsequent compression of the 3rd, 4th or 6th cranial nerves may cause diplopia and strabismus.

Occasionally, pituitary tumours infarct or there is bleeding into cystic lesions. This is termed 'pituitary apoplexy' and may result in sudden expansion with local compression symptoms and acute-onset

hypopituitarism. Non-haemorrhagic infarction can also occur in a normal pituitary gland; predisposing factors include obstetric haemorrhage (Sheehan's syndrome), diabetes mellitus and raised intracranial pressure.

Investigations

Patients suspected of having a pituitary tumour should undergo MRI or CT. Whilst some lesions have distinctive neuroradiological features, definitive diagnosis often requires biopsy which is usually done at the same time as operative treatment to resect or debulk a tumour that is compressing the optic chiasm. All patients with (para-) sellar space-occupying lesions should have pituitary function assessed as described in Box 20.56 (p. 784).

Management

Modalities of treatment of common pituitary and hypothalamic tumours are shown in Box 20.60. Associated hypopituitarism should be treated as described above.

Urgent treatment is required if there is evidence of pressure on visual pathways. The chances of recovery of a visual field defect are proportional to the duration of symptoms, with full recovery unlikely if the defect has been present for longer than 4 months. It is crucial that serum prolactin is measured before emergency surgery is performed. If the prolactin is > 5000 mU/L, then the lesion may be a macroprolactinoma and a therapeutic trial of a dopamine agonist for just a few days may successfully shrink the lesion and make surgery unnecessary (see Fig. 20.29).

Most operations on the pituitary are performed using the trans-sphenoidal approach via the nostrils, while transfrontal surgery via a craniotomy is reserved for suprasellar tumours. It is uncommon to be able to resect large lesions completely, particularly if there is lateral extension into the cavernous sinuses. All operations on the pituitary carry a risk of damaging normal endocrine function; this risk increases with the size of the primary lesion.

Pituitary function (see Box 20.56, p. 784) should be retested 4–6 weeks following surgery, primarily to detect the development of any new hormone deficits. Rarely, the surgical treatment of a sellar lesion can result in recovery of hormone secretion that was deficient pre-operatively.

Following surgery, imaging should be repeated, usually after a few months and, if there is any residual mass and the histology confirms a radiosensitive tumour, external radiotherapy may be given to reduce the risk of recurrence. Radiotherapy is not useful in patients requiring urgent therapy because it takes many months or years to be effective and there is a risk of acute swelling of the mass. Radiotherapy carries a life-long risk of hypopituitarism (50–70% in the first 10 years) and annual pituitary function tests are obligatory. There is also concern that radiotherapy might impair cognitive function, cause vascular changes and even induce primary brain tumours, but these side-effects have not been quantified reliably and are likely to be rare.

Non-functioning tumours should be followed up by repeated imaging at intervals that depend on the size of the lesion and on whether or not radiotherapy has been administered. For smaller lesions that are not causing mass effects, therapeutic surgery may not be indicated and the lesion may simply be monitored by serial

neuroimaging without a clear-cut diagnosis having been established.

Hyperprolactinaemia/galactorrhoea

Hyperprolactinaemia is a common abnormality which usually presents with hypogonadism and/or galactorrhoea (lactation in the absence of breastfeeding). Since prolactin stimulates milk secretion but not breast development, galactorrhoea rarely occurs in men and only does so if gynaecomastia has been induced by hypogonadism (p. 759). The differential diagnosis of hyperprolactinaemia is shown in Box 20.61. Many drugs, especially dopamine antagonists, elevate prolactin concentrations. Pituitary tumours can cause hyperprolactinaemia by directly secreting prolactin (prolactinomas, see below), or by compressing the infundibular stalk and thus interrupting the tonic inhibitory effect of hypothalamic dopamine on prolactin secretion ('disconnection' hyperprolactinaemia).

Prolactin usually circulates as a free (monomeric) hormone in plasma, but in some individuals prolactin becomes bound to an IgG antibody. This complex is known as macroprolactin and such patients have macroprolactinaemia (not to be confused with macroprolactinoma, a prolactin-secreting pituitary tumour > 1 cm in diameter). Since macroprolactin cannot cross blood vessel walls to reach prolactin receptors in target tissues it is of no pathological significance. Some commercial prolactin assays do not distinguish prolactin from macroprolactin and so macroprolactinaemia is a cause of spurious hyperprolactinaemia. Identification of macroprolactin requires gel filtration chromatography or polyethylene glycol precipitation techniques and one of these tests should be performed in all patients with hyperprolactinaemia, if the prolactin assay is known to cross-react.

Clinical assessment

In women, in addition to galactorrhoea, hypogonadism associated with hyperprolactinaemia causes secondary amenorrhoea and anovulation with infertility (p. 756). Important points in the history include drug use, recent pregnancy and menstrual history. The quantity of milk produced is variable, and it may be observed

only by manual expression. In men there is decreased libido, reduced shaving frequency and lethargy (p. 757). Unilateral galactorrhoea may be confused with nipple discharge, and careful breast examination to exclude malignancy or fibrocystic disease is important. Further assessment should address the features in Figure 20.28 (p. 785).

Investigations

Pregnancy should first be excluded before further investigations are performed in women of child-bearing potential. The upper limit of normal for many assays of serum prolactin is approximately 500 mU/L (14 ng/mL). In non-pregnant and non-lactating patients, monomeric prolactin concentrations of 500–1000 mU/L are likely to be induced by stress or drugs, and a repeat measurement is indicated. Levels between 1000 and 5000 mU/L are likely to be due to either drugs, a microprolactinoma or 'disconnection' hyperprolactinaemia. Levels above 5000 mU/L are highly suggestive of a macroprolactinoma.

Patients with prolactin excess should have tests of gonadal function (p. 753), and T_4 and TSH measured to exclude primary hypothyroidism causing TRH-induced prolactin excess. Unless the prolactin falls after withdrawal of relevant drug therapy, a serum prolactin of > 1000 mU/L is an indication for MRI or CT scan of the hypothalamus and pituitary. Patients with a macroadenoma also need tests for hypopituitarism (see Box 20.56).

Management

If possible, the underlying cause should be corrected (for example, cessation of offending drugs and giving thyroxine replacement in primary hypothyroidism). If this is not possible, then in almost all cases of hyperprolactinaemia, dopamine agonist therapy (see Box 20.62) will normalise prolactin levels with return of gonadal function. If gonadal function does not return despite effective lowering of prolactin, then there may be associated gonadotrophin deficiency or, in the female, the onset of the menopause. Troublesome physiological galactorrhoea can also be treated with dopamine agonists. Management of prolactinomas is described below.

Prolactinoma

Most prolactinomas in pre-menopausal women are microadenomas because the symptoms of prolactin excess usually result in early presentation. In men and post-menopausal women, however, the presentation is often much more insidious and due to mass effects rather than hyperprolactinaemia, with the result that these tumours are almost invariably macroadenomas at the time of diagnosis. Prolactin-secreting cells of the anterior pituitary share a common lineage with growth hormone-secreting cells, so occasionally prolactinomas can secrete excess growth hormone and cause acromegaly. In prolactinomas there is a relationship between prolactin concentration and tumour size: the higher the level, the bigger the tumour. Some macroprolactinomas can elevate prolactin concentrations > 100 000 mU/L. The investigation of prolactinomas is the same as for other pituitary tumours (see above).

Management

As shown in Box 20.60, several therapeutic modalities can be employed in the management of prolactinomas.

Medical

Dopamine agonist drugs are first-line therapy for the majority of patients (Box 20.62). They usually reduce serum prolactin concentrations and cause significant

tumour shrinkage (Fig. 20.29). It is possible to withdraw dopamine agonist therapy without recurrence of hyperprolactinaemia after a few years of treatment in some patients with a microadenoma. Also, after the menopause, suppression of prolactin is only required in microadenomas if galactorrhoea is troublesome, since hypogonadism is then physiological and tumour growth unlikely. In patients with macroadenomas, drugs can only be withdrawn after curative surgery or radiotherapy and under close supervision.

Ergot-derived dopamine agonists (bromocriptine and cabergoline) can bind to 5-HT_{2B} receptors in the heart and elsewhere and have been associated with fibrotic reactions, particularly tricuspid valve regurgitation, in

Fig. 20.29 Visual field defect in a patient with a macroprolactinoma and shrinkage of tumour following treatment with a dopamine agonist. **[A]** Goldmann visual field chart showing normal visual fields (black) and bitemporal hemianopia (red) in a patient with hyperprolactinaemia. **[B]** MRI scan showing a pituitary macroadenoma (T) compressing the optic chiasm (C). **[C]** MRI scan of the same tumour following treatment with a dopamine agonist. The macroadenoma, which was a prolactinoma, has decreased in size substantially and is no longer compressing the optic chiasm.

20.62 Dopamine agonist therapy: drugs used to treat prolactinomas

	Oral dose*	Advantages	Disadvantages
Bromocriptine	2.5–15 mg/day 8–12-hourly	Available for parenteral use Short half-life; useful in treating infertility Proven long-term efficacy	Ergotamine-like side-effects (nausea, headache, postural hypotension, constipation) Frequent dosing so poor compliance Rare reports of fibrotic reactions in various tissues
Cabergoline	250–1000 µg/week 2 doses/week	Long-acting, so missed doses less important Reported to have fewer ergotamine-like side-effects	Limited data on safety in pregnancy Associated with cardiac valvular fibrosis in Parkinson's disease
Quinagolide	50–150 µg/day Once daily	A non-ergot with few side-effects in patients intolerant of the above	Untested in pregnancy

*Tolerance develops for the side-effects. All of these agents, especially bromocriptine, must be introduced at low dose and increased slowly. If several doses of bromocriptine are missed, the process must start again.

patients with Parkinson's disease and, less commonly, prolactinoma. At the relatively low doses used in prolactinomas it is uncertain whether systematic screening for cardiac fibrosis is required, but if dopamine agonist therapy is prolonged many authorities recommend periodic screening by echocardiography or use of non-ergot agents (quinagolide).

Surgery and radiotherapy

Surgical decompression is usually only necessary when a macroprolactinoma has failed to shrink sufficiently with dopamine agonist therapy and this may be because the tumour has a significant cystic component. Surgery may also be performed in patients who are intolerant of dopamine agonists. Microadenomas can be removed selectively by trans-sphenoidal surgery with a cure rate of about 80%; the cure rate for surgery in macroadenomas is substantially lower.

External irradiation may be required for some macroadenomas to prevent regrowth if dopamine agonists are stopped.

Pregnancy

Hyperprolactinaemia often presents with infertility, so dopamine agonist therapy may be followed by pregnancy. Patients with microadenomas should be advised to withdraw dopamine agonist therapy as soon as pregnancy is confirmed. In contrast, macroprolactinomas may enlarge rapidly under oestrogen stimulation and these patients should continue dopamine agonist therapy and need measurement of prolactin levels and visual fields during pregnancy. All patients should be advised to report headache or visual disturbance promptly.

Acromegaly

Acromegaly is caused by growth hormone (GH) secretion from a pituitary tumour, usually a macroadenoma.

Clinical features

If GH hypersecretion occurs before puberty then the presentation is with gigantism. More commonly, GH excess occurs in adult life and presents with acromegaly. If hypersecretion starts in adolescence and persists into adult life, then the two conditions may be combined. The clinical features are shown in Figure 20.30.

The most common complaints are headache and sweating. Additional features include those of any pituitary tumour (see Fig. 20.28, p. 785).

Investigations

The clinical diagnosis must be confirmed by measuring GH levels during an oral glucose tolerance test (Fig. 20.31). In normal subjects, plasma GH suppresses to below 0.5 µg/L (approximately 2 mU/L). In acromegaly, GH does not suppress and in about 50% of patients there is a paradoxical rise. The rest of pituitary function should be investigated as described in Box 20.56 (p. 784). Prolactin concentrations are elevated in about 30% of patients due to co-secretion of prolactin from the tumour.

The diagnosis of acromegaly is more difficult in patients with insulin deficiency, either type 1 or longstanding type 2 diabetes mellitus. GH may fail to suppress following a glucose load in these patients because inadequate insulin secretion results in failure of glucose to stimulate IGF-1 from the liver. It is IGF-1 that, in turn, suppresses GH secretion. This is important because acromegaly can cause diabetes mellitus by exacerbating insulin resistance. However, measuring IGF-1 usually resolves matters; in diabetic patients without acromegaly, IGF-1 concentrations are low, while in acromegalic patients IGF-1 levels are high.

Additional tests in acromegaly may include screening for colonic neoplasms with colonoscopy.

Management

This is summarised in Box 20.60.

Surgical

Trans-sphenoidal surgery is usually the first line of treatment and may result in cure of GH excess, especially in patients with microadenomas. More often, surgery serves to debulk the tumour and further second-line therapy is required, according to post-operative imaging and glucose tolerance test results.

Radiotherapy

External radiotherapy is usually employed as second-line treatment if acromegaly persists after surgery, to stop tumour growth and lower GH levels. However, GH levels fall slowly (over many years) and there is a risk of hypopituitarism.

Fig. 20.30 Clinical features of acromegaly. (IGT = impaired glucose tolerance)

Fig. 20.31 Oral glucose tolerance tests in a normal subject and a patient with acromegaly with measurement of blood glucose and plasma growth hormone. Note the suppression of growth hormone secretion to $< 0.5 \mu\text{g/L}$ in the normal subject, and failure to suppress (sometimes accompanied by paradoxical elevation) in acromegaly. Glucose tolerance may also be impaired in acromegaly. (To convert GH in $\mu\text{g/L}$ to mU/L multiply by 3. To convert glucose in mmol/L to mg/dL multiply by 18.)

Medical

In patients with persisting acromegaly after surgery, medical therapy is usually employed to lower GH levels to $< 1.5 \mu\text{g/L}$ (approximately $< 5 \text{ mU/L}$) and to normalise IGF-1 concentrations. Medical therapy may be discontinued after several years in patients who have received radiotherapy. Somatostatin analogues (such as octreotide or lanreotide) can be administered as slow-release injections every few weeks. Somatostatin analogues can also be used as primary therapy for acromegaly either as an alternative or in advance of surgery, given evidence that they can induce modest tumour shrinkage in a proportion of patients. Dopamine agonists are less potent in lowering GH but may be helpful, especially in patients with associated prolactin excess. Pegvisomant is a peptide GH receptor antagonist which is administered by daily self-injection and may be indicated in some patients whose GH and IGF-1 concentrations fail to suppress sufficiently following somatostatin analogue therapy.

Craniopharyngioma

Craniopharyngiomas are benign tumours that develop in cell rests of Rathke's pouch, and may be located within the sella turcica, or commonly in the suprasellar

Fig 20.32 Craniopharyngioma. **A** This developmental tumour characteristically presents in younger patients; it is often cystic and calcified, as shown in this MRI scan (arrows). **B** Pathology specimen. **C** Hypothalamic damage is manifest as diabetes insipidus and loss of satiety, leading to relentless weight gain, as in this young woman following successful surgical resection and irradiation of her craniopharyngioma.

space. They are often cystic with a solid component that may or may not be calcified (Fig. 20.32). In young people, they are diagnosed more commonly than pituitary adenomas. They may present with pressure effects on adjacent structures, hypopituitarism and/or cranial diabetes insipidus. In addition, other clinical features that are directly related to hypothalamic damage may also occur. These include hyperphagia and obesity (see Fig. 20.32C), loss of the sensation of thirst and disturbance of temperature regulation.

Craniopharyngiomas can rarely be reached by the trans-sphenoidal route and so surgery may involve a craniotomy, with a relatively high risk of hypothalamic damage and other complications. If the tumour has a large cystic component it may be safer to place in the cyst cavity a drain which is attached to a subcutaneous access device, rather than attempt a resection. Whatever form it takes, surgery is unlikely to be curative and radiotherapy is usually given, although there is uncertainty about its efficacy. Unfortunately, craniopharyngiomas often recur, requiring repeated surgery. They often cause considerable morbidity, usually from hypothalamic obesity, water balance problems and/or visual failure.

Diabetes insipidus

This uncommon disorder is characterised by the persistent excretion of excessive quantities of dilute urine and by thirst. Diabetes insipidus is classified into two types:

- cranial diabetes insipidus, in which there is deficient production of ADH by the hypothalamus
- nephrogenic diabetes insipidus, in which the renal tubules are unresponsive to ADH.

The underlying causes are listed in Box 20.63.

20.63 Causes of diabetes insipidus

Cranial

Structural hypothalamic or high stalk lesion

- See Box 20.57

Idiopathic

Genetic defect

- Dominant (AVP gene mutation)
- Recessive (DIDMOAD syndrome—association of diabetes insipidus with diabetes mellitus, optic atrophy, deafness)

Nephrogenic

Genetic defect

- V2 receptor mutation
- Aquaporin-2 mutation
- Cystinosis

Metabolic abnormality

- Hypokalaemia
- Hypercalcaemia

Drug therapy

- Lithium
- Demeclocycline

Poisoning

- Heavy metals

Chronic kidney disease

- Polycystic kidney disease
- Sickle-cell anaemia
- Infiltrative disease

Clinical features

The most marked symptoms are polyuria and polydipsia. The patient may pass 5–20 L or more of urine in 24 hours. This is of low specific gravity and osmolality. If the patient has an intact thirst mechanism, is conscious and has access to oral fluids, then he or she can maintain adequate fluid intake. However, in an unconscious patient or a patient with damage to the hypothalamic thirst centre, diabetes insipidus is potentially lethal. If there is associated cortisol deficiency, then diabetes insipidus may not be manifest until glucocorticoid replacement therapy is given. The most common differential diagnosis is primary polydipsia, caused by drinking excessive amounts of fluid in the absence of a defect in ADH or thirst control.

Investigations

Diabetes insipidus can be confirmed if serum ADH is undetectable or the urine is not maximally concentrated (i.e. is < 600 mOsm/kg) in the presence of increased plasma osmolality (i.e. > 300 mOsm/kg). Sometimes, the diagnosis can be confirmed or refuted by random simultaneous samples of blood and urine, but more often a dynamic test is required. The water deprivation test described in Box 20.64 is widely used, but an alternative is to infuse hypertonic (5%) saline and measure ADH secretion in response to increasing plasma osmolality. Thirst can also be assessed during these tests on a visual analogue scale. Anterior pituitary function and suprasellar anatomy should be assessed in patients with cranial diabetes insipidus as indicated in Box 20.56 (p. 784).

20.64 How and when to do a water deprivation test

Use

- To establish a diagnosis of diabetes insipidus, and differentiate cranial from nephrogenic causes

Protocol

- No coffee, tea or smoking on the test day
- Free fluids until 0730 hrs on the morning of the test, but discourage patients from 'stocking up' with extra fluid in anticipation of water deprivation
- No fluids from 0730 hrs
- Attend at 0830 hrs for body weight, plasma and urine osmolality
- Record body weight, urine volume, urine and plasma osmolality and thirst score on a visual analogue scale every 2 hrs for up to 8 hrs
- Stop the test if the patient loses 3% of body weight
- If plasma osmolality reaches > 300 mOsm/kg and urine osmolality < 600 mOsm/kg, then administer DDAVP (see text) 2 µg i.m.

Interpretation

- Diabetes insipidus is confirmed by a plasma osmolality > 300 mOsm/kg with a urine osmolality < 600 mOsm/kg
- Cranial diabetes insipidus is confirmed if urine osmolality rises by at least 50% after DDAVP
- Nephrogenic diabetes insipidus is confirmed if DDAVP does not concentrate the urine
- Primary polydipsia is suggested by low plasma osmolality at the start of the test

20.65 The pituitary and hypothalamus in old age

- **Late presentation:** often with large tumours causing visual disturbance, because early symptoms such as amenorrhoea and sexual dysfunction do not occur or are not recognised.
- **Coincidentally discovered pituitary tumours:** may not require surgical intervention if the visual apparatus is not involved, because of slow growth. Radiotherapy alone is sometimes employed simply to prevent further growth.
- **Hyperprolactinaemia:** less impact in post-menopausal women who are already 'physiologically' hypogonadal. Macroprolactinomas, however, require treatment because of their potential to cause mass effects.

In primary polydipsia, the urine may be excessively dilute because of chronic diuresis which 'washes out' the solute gradient across the loop of Henle, but plasma osmolality is low rather than high. DDAVP (see below) should not be administered to patients with primary polydipsia, since it will prevent excretion of water and risks severe water intoxication if the patient continues to drink fluid to excess.

In nephrogenic diabetes insipidus appropriate further tests include plasma electrolytes, calcium and investigation of the renal tract (Chs 16 and 17).

Management

Treatment of cranial diabetes insipidus is with desamino-des-aspartate-arginine vasopressin (desmopressin, DDAVP), an analogue of ADH which has a longer half-life. DDAVP is usually administered intranasally. An oral formulation is also available but bioavailability is low and rather unpredictable. In sick patients, DDAVP should be given by intramuscular injection. The dose of DDAVP should be adjusted on the basis of serum sodium concentrations and/or osmolality. The principal hazard should be excessive treatment resulting in water intoxication and hyponatraemia. Conversely, inadequate treatment results in thirst and polyuria. The ideal dose prevents nocturia but allows a degree of polyuria from time to time before the next dose (e.g. DDAVP nasal dose 5 µg in the morning and 10 µg at night).

The polyuria in nephrogenic diabetes insipidus is improved by thiazide diuretics (e.g. bendroflumethiazide 5–10 mg/day), amiloride (5–10 mg/day) and NSAIDs (e.g. indometacin 15 mg 8-hourly), although the last of these carries a risk of reducing glomerular filtration rate.

DISEASES AFFECTING MULTIPLE ENDOCRINE GLANDS

Multiple endocrine neoplasia (MEN)

These rare autosomal dominant syndromes are characterised by hyperplasia and formation of adenomas or malignant tumours in multiple glands. They fall into two groups, as shown in Box 20.66. Some other genetic diseases also have an increased risk of endocrine tumours; for example, pheochromocytoma is associated with von Hippel-Lindau syndrome (p. 1219) and neurofibromatosis type 1 (p. 1218).

i	20.66 Multiple endocrine neoplasia (MEN) syndromes
MEN 1 (Werner's syndrome)	
<ul style="list-style-type: none"> • Primary hyperparathyroidism • Pituitary tumours • Pancreatic neuro-endocrine tumours (insulinoma, gastrinoma) 	
MEN 2 (Sipple's syndrome)	
<ul style="list-style-type: none"> • Primary hyperparathyroidism • Medullary carcinoma of thyroid • Pheochromocytoma <p>In addition, in MEN 2b syndrome there are phenotypic changes (including marfanoid habitus, skeletal abnormalities, abnormal dental enamel, multiple mucosal neuromas)</p>	

MEN syndromes should be considered in all patients with two or more endocrine tumours and in patients with solitary tumours who report other endocrine tumours in their family. MEN 1 results from inactivating mutations in *MEN1*, a tumour suppressor gene on chromosome 11, whereas MEN 2 is caused by mutations in the *RET* proto-oncogene on chromosome 10. This causes constitutive activation of the membrane-associated tyrosine kinase RET, which controls the development of cells that migrate from the neural crest. Different mutations causing loss of function of the RET kinase are associated with Hirschsprung's disease (p. 914). Genetic testing can be performed on relatives of affected individuals, after appropriate counselling (p. 64).

Individuals who carry mutations associated with MEN should be entered into a surveillance programme. In MEN 1, this typically involves annual history, examination and measurements of serum calcium, gastrointestinal hormones (see Box 20.53, p. 782) and prolactin; MRI of the pituitary is performed at less frequent intervals. In individuals with MEN 2, annual history, examination and measurement of serum calcium and urinary catecholamine metabolites should be performed. Because the penetrance of medullary carcinoma of the thyroid is 100% in individuals with a *RET* mutation, prophylactic thyroidectomy should be performed in early childhood.

Autoimmune polyendocrine syndromes (APS)

Two distinct autoimmune polyendocrine syndromes are known: APS types 1 and 2.

The most common is APS type 2 (Schmidt's syndrome) which typically presents in women between the ages of 20 and 60. It is usually defined as the occurrence in the same individual of two or more autoimmune endocrine disorders, some of which are listed in Box

i	20.67 Autoimmune polyendocrine syndromes (APS)*
Type 1 (APECED)	
<ul style="list-style-type: none"> • Addison's disease • Hypoparathyroidism • Type 1 diabetes • Primary hypothyroidism • Chronic mucocutaneous candidiasis • Nail dystrophy • Dental enamel hypoplasia 	
Type 2 (Schmidt's syndrome)	
<ul style="list-style-type: none"> • Addison's disease • Primary hypothyroidism • Graves' disease • Pernicious anaemia • Primary hypogonadism • Type 1 diabetes • Vitiligo • Coeliac disease • Myasthenia gravis 	
*In both types of APS, the precise pattern of disease varies between affected individuals.	

20.67. The mode of inheritance is autosomal dominant with incomplete penetrance and there is a strong association with HLA-DR3 and CTLA-4. APS type 2 may be further subdivided, depending on the precise combination of endocrine disorders observed, but this is of limited value.

APS type 1, which is also termed autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), is much rarer and is inherited in an autosomal recessive fashion. It is caused by mutations in the autoimmune regulator gene (*AIRE*). *AIRE* is responsible for the presentation of self-antigens to thymocytes in utero, which is essential for the deletion of thymocyte clones that react against self-antigens and hence for the development of immune tolerance (Ch. 4). The most common clinical features are described in Box 20.67, although the pattern of presentation is variable and other autoimmune disorders are often observed.

The diabetic foot 833

Diabetes can affect every system in the body. In routine clinical practice, examination of the patient with diabetes is focused on ① hands, ③ blood pressure, ⑦ eyes, ⑧ insulin injection sites and ⑪ feet.

⑦ Examination of the eyes

Visual acuity

- Distance vision using Snellen chart at 6 metres
- Near vision using standard reading chart

Impaired visual acuity may indicate diabetic eye disease, including maculopathy, and serial decline suggests development or deterioration

Lens opacification

- Look for the red reflex using the ophthalmoscope held 30 cm from the eye

Fundal examination

- Dilate pupils with a mydriatic (e.g. tropicamide) and examine with ophthalmoscope in a darkened room
- Note features of diabetic retinopathy (p. 826), including photocoagulation scars from previous laser treatment

Background retinopathy.

Proliferative retinopathy.

① Examination of the hands

Several abnormalities are more common in diabetes:

- Limited joint mobility ('cheiroarthropathy') causes painless stiffness in the hands, and occasionally affects the wrists and shoulders. The inability to extend (to 180°) the metacarpophalangeal or interphalangeal joints of at least one finger bilaterally can be demonstrated in the 'prayer sign'
- Dupuytren's contracture (p. 1070) causes nodules or thickening of the skin and knuckle pads
- Carpal tunnel syndrome (p. 1228) presents with wrist pain radiating into the hand
- Trigger finger (flexor tenosynovitis)
- Muscle-wasting/sensory changes may be present as features of a peripheral sensorimotor neuropathy, although this is more common in the lower limbs

⑧ Insulin injection sites

Main areas used

- Anterior abdominal wall
- Upper thighs/buttocks
- Upper outer arms

Inspection

- Bruising
- Lumps (lipodystrophy)
- Subcutaneous fat deposition (lipohypertrophy)
- Subcutaneous fat loss (lipoatrophy; associated with injection of unpurified animal insulins—now rare)
- Erythema, infection (rare)

Lipohypertrophy.

⑪ Examination of the feet

Inspection

- Look for evidence of callus formation on weight-bearing areas, clawing of the toes (a feature of neuropathy), loss of the plantar arch, discoloration of the skin (ischaemia), localised infection and the presence of ulcers
- Deformity may be present, especially in Charcot neuroarthropathy
- Fungal infection may affect skin between toes, and nails

Charcot neuroarthropathy.

Circulation

- Peripheral pulses, skin temperature and capillary refill may be abnormal

Sensation

- Abnormal in stocking distribution in typical peripheral sensorimotor neuropathy
- Light touch: use monofilaments
- Vibration sense: use 128 Hz tuning fork over big toe/malleoli
- Pin-prick: use pin
- Pain: pressure over Achilles tendon
- Proprioception: test position of big toe

Monofilaments.

Reflexes

- Loss of ankle reflexes in typical sensorimotor neuropathy
- Test plantar and ankle reflexes

Diabetes mellitus is a clinical syndrome characterised by hyperglycaemia caused by absolute or relative deficiency of insulin. Hyperglycaemia has many causes (see Box 21.7, p. 804) but is most commonly due to type 1 or type 2 diabetes. Lack of insulin affects the metabolism of carbohydrate, protein and fat, and can cause significant disturbance of water and electrolyte homeostasis; death may result from acute metabolic decompensation. Long-standing metabolic derangement is associated with functional and structural changes in many organs, particularly those of the vascular system, which lead to the clinical 'complications' of diabetes. These characteristically affect the eye, the kidney and the nervous system.

The distribution of blood glucose concentration in populations is unimodal, with no clear division between people with normal and abnormal values. Hyperglycaemia represents an independent risk factor for disease of both small and large blood vessels. Diagnostic criteria for diabetes (pp. 805–806) have been selected to identify those who have a degree of hyperglycaemia which, if untreated, is associated with a significant risk of microvascular disease, and in particular diabetic retinopathy. Less severe hyperglycaemia is called 'impaired glucose tolerance'. This is not associated with substantial risk of microvascular disease, but is associated with increased risk of large vessel disease (e.g. atheroma leading to myocardial infarction) and with a greater risk of developing diabetes in future. The implication of these criteria is that there is no such thing as 'mild' diabetes not requiring effective treatment.

The incidences of both type 1 and type 2 diabetes are rising; it is estimated that, in the year 2000, 171 million people had diabetes, and this is expected to double by 2030 (Fig. 21.1). This global pandemic principally involves type 2 diabetes and is associated with greater longevity, obesity, unsatisfactory diet, sedentary lifestyle and increasing urbanisation. Many cases of type 2 diabetes remain undetected. However, the prevalence of both types of diabetes varies considerably around the world, and is related to differences in genetic and environmental factors. The prevalence of known diabetes in

Fig. 21.1 World-wide estimated number of adults with diabetes by age group and year.

i

21.1 The current cost of diabetes in the UK

- 10–30% reduction in life expectancy
- Most common cause of blindness in age group 20–65 years
- 1000 patients per annum reach end-stage renal failure
- Lower limb amputation rate increased 25-fold
- Use of hospital beds increased sixfold
- 7% of total National Health Service budget

the UK is around 4%, but is higher in the Middle and Far East (e.g. > 12% in urban areas of the Indian sub-continent). A pronounced rise in the prevalence of type 2 diabetes occurs in migrant populations to industrialised countries, as in Asian and Afro-Caribbean immigrants to the UK. Type 2 diabetes is now being observed in children and adolescents, particularly in some ethnic groups, such as Hispanics and Afro-Americans.

Type 1 diabetes is more common in Caucasian populations, and in northern Europe its prevalence in children has doubled in the last 20 years, with a particular increase in children under 5 years of age.

Diabetes is a major burden upon health-care facilities in all countries. Estimated costs in the UK are shown in Box 21.1.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Normal glucose and fat metabolism

Blood glucose is tightly regulated and maintained within a narrow range. A balance is preserved between the entry of glucose into the circulation from the liver, supplemented by intestinal absorption after meals, and glucose uptake by peripheral tissues, particularly skeletal muscle. A continuous supply of glucose is essential for the brain, which cannot oxidise free fatty acids and relies upon glucose as its principal metabolic fuel.

When intestinal glucose absorption declines between meals, hepatic glucose output is increased in response to low insulin levels and increased levels of the counter-regulatory hormones, glucagon and epinephrine (adrenaline). The liver produces glucose by gluconeogenesis and glycogen breakdown. The main substrates for gluconeogenesis are glycerol and amino acids, as shown in Figure 21.2.

After meals, blood insulin levels rise. Insulin is an anabolic hormone with profound effects on the metabolism of carbohydrate, fat and protein (Box 21.2). Insulin is secreted from pancreatic β cells into the portal circulation, with a brisk increase in response to a rise in blood glucose (Fig. 21.3). A number of other factors can augment insulin release, including amino acids and hormones, such as glucagon-like peptide 1 (GLP-1), released from the gut following food intake (p. 822). Insulin lowers blood glucose by suppressing hepatic glucose production and stimulating glucose uptake in skeletal muscle and fat, mediated by the glucose transporter, GLUT 4.

Adipocytes (and the liver) synthesise triglyceride from non-esterified ('free') fatty acids (FFAs) and glycerol. Insulin stimulates lipogenesis and inhibits lipolysis,

Fig. 21.2 Major metabolic pathways of fuel metabolism and the actions of insulin. ⊕ indicates stimulation and ⊖ indicates suppression by insulin. In response to a rise in blood glucose, e.g. after a meal, insulin is released, suppressing gluconeogenesis and promoting glycogen synthesis and storage. Insulin promotes the peripheral uptake of glucose, particularly in skeletal muscle, and encourages storage (as muscle glycogen). It also promotes protein synthesis and lipogenesis, and suppresses lipolysis. The release of intermediate metabolites, including amino acids (glutamine, alanine), 3-carbon intermediates in oxidation (lactate, pyruvate) and free fatty acids (FFAs), is controlled by insulin. In the absence of insulin, e.g. during fasting, these processes are reversed and favour gluconeogenesis in liver from glycogen, glycerol, amino acids and other 3-carbon precursors.

i 21.2 Metabolic actions of insulin	
Increase (anabolic effects)	Decrease (anticatabolic effects)
Carbohydrate metabolism	
Glucose transport (muscle, adipose tissue)	Gluconeogenesis
Glucose phosphorylation	Glycogenolysis
Glycogenesis	
Glycolysis	
Pyruvate dehydrogenase activity	
Pentose phosphate shunt	
Lipid metabolism	
Triglyceride synthesis	Lipolysis
Fatty acid synthesis (liver)	Lipoprotein lipase (muscle)
Lipoprotein lipase activity (adipose tissue)	Ketogenesis
	Fatty acid oxidation (liver)
Protein metabolism	
Amino acid transport	Protein degradation
Protein synthesis	

promoting triglyceride accumulation. Lipolysis is stimulated by catecholamines and liberates FFAs which can be oxidised by many tissues. Their partial oxidation in the liver provides energy to drive gluconeogenesis and also produces ketone bodies (acetoacetate, which can be reduced to 3-hydroxybutyrate or decarboxylated to acetone) which are generated in hepatocyte mitochondria. Ketone bodies are organic acids which, when formed in small amounts, are oxidised and utilised as metabolic fuel. However, the rate of utilisation of ketone bodies by peripheral tissues is limited, and when the rate of production by the liver exceeds their removal, hyperketonaemia results. This occurs physiologically during starvation, when low insulin levels and high catecholamine levels increase lipolysis and delivery of FFAs to the liver.

Aetiology and pathogenesis of diabetes

In both of the common types of diabetes, environmental factors interact with genetic susceptibility to determine which people develop the clinical syndrome,

Fig. 21.3 Pancreatic structure and endocrine function. **A** The normal adult pancreas contains about 1 million islets which are scattered throughout the exocrine parenchyma. Histology is shown in Figure 21.4. **B** The core of each islet consists of β cells that produce insulin, and is surrounded by a cortex of endocrine cells that produce other hormones including glucagon (α cells), somatostatin (δ cells) and pancreatic polypeptide (PP cells). **C** Pro-insulin in the pancreatic β cell is cleaved to release insulin and equimolar amounts of inert C-peptide (connecting peptide). Measurement of C-peptide can be used to assess endogenous insulin secretory capacity. **D** An acute first phase of insulin secretion occurs in response to an elevated blood glucose, followed by a sustained second phase.

and the timing of its onset. However, the underlying genes, precipitating environmental factors and pathophysiology differ substantially between type 1 and type 2 diabetes. Type 1 diabetes was previously termed 'insulin-dependent diabetes mellitus' (IDDM) and is invariably associated with profound insulin deficiency requiring replacement therapy. Type 2 diabetes was previously termed 'non-insulin-dependent diabetes mellitus' (NIDDM) because patients retain the capacity to secrete some insulin but exhibit impaired sensitivity to insulin (insulin resistance) and initially can usually be treated without insulin replacement therapy. However, 20% or more of patients with type 2 diabetes will ultimately develop profound insulin deficiency requiring replacement therapy so that IDDM and NIDDM were misnomers.

Type 1 diabetes

Pathology

Type 1 diabetes is a T cell-mediated autoimmune disease (p. 85) involving destruction of the insulin-secreting β cells in the pancreatic islets which takes place over many years. Hyperglycaemia accompanied by the classical symptoms of diabetes occurs only when 70–90% of β cells have been destroyed.

The pathology in the pre-diabetic pancreas in type 1 diabetes is characterised by:

- 'insulinitis' (Fig. 21.4): infiltration of the islets with mononuclear cells containing activated macrophages, helper cytotoxic and suppressor T lymphocytes, natural killer cells and B lymphocytes
- initial patchiness of this lesion with, until a very late stage, lobules containing heavily infiltrated islets seen adjacent to unaffected lobules
- β -cell specificity of the destructive process, with the glucagon and other hormone-secreting cells in the islet remaining intact.

Islet cell antibodies can be detected before the clinical development of type 1 diabetes, but have a variable predictive value as a marker of disease, and disappear with increasing duration of diabetes (see Fig. 21.4). These antibodies are generally not suitable for screening or diagnostic purposes. However, glutamic acid decarboxylase (GAD) antibodies may have a role in identifying late-onset type 1 diabetes in middle-aged people (latent autoimmune diabetes in adults, LADA) in whom type 2 diabetes might otherwise be presumed.

Type 1 diabetes is associated with other autoimmune disorders (Ch. 4), including thyroid disease (p. 736), coeliac disease (p. 879), Addison's disease (p. 775), pernicious anaemia (p. 1021) and vitiligo (p. 1253).

Genetic predisposition

Genetic factors account for about one-third of the susceptibility to type 1 diabetes, the inheritance of which

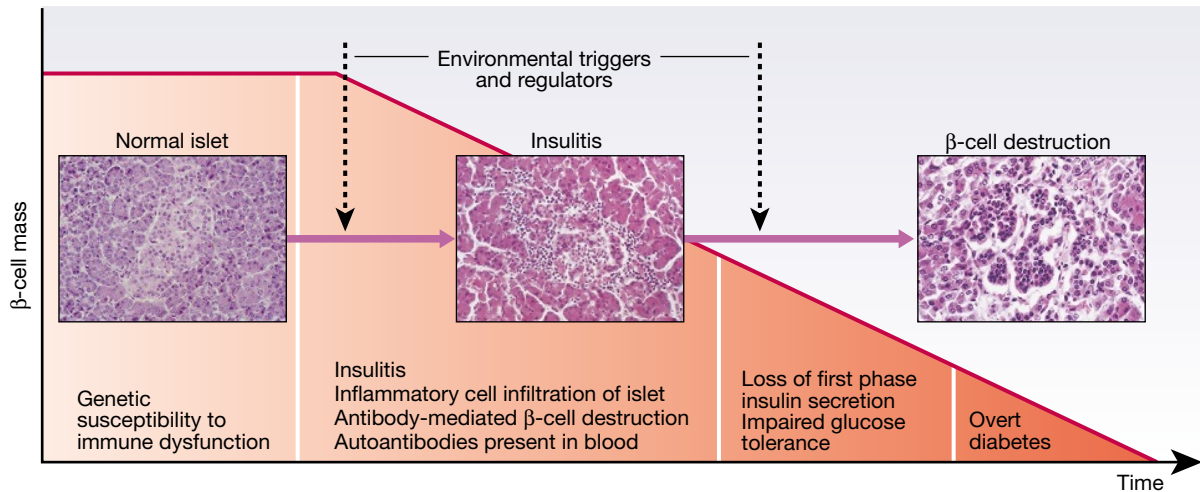

Fig. 21.4 Pathogenesis of type 1 diabetes. Proposed sequence of events in the development of type 1 diabetes. Environmental triggers are described in the text.

21.3 Risk of developing type 1 diabetes in an individual who has a first-degree relative with type 1 diabetes	
Relative with type 1 diabetes	% overall risk
Identical twin	35
Non-identical twin	20
HLA-identical sibling	16
Non-HLA-identical sibling	3
Father	9
Mother	3
Both parents	Up to 30

is polygenic (Box 21.3). Over 20 different regions of the human genome show some linkage with type 1 diabetes but most interest has focused on the human leucocyte antigen (HLA) region within the major histocompatibility complex on the short arm of chromosome 6; this locus is designated IDDM 1. The HLA haplotypes *DR3* and/or *DR4* are associated with increased susceptibility to type 1 diabetes in Caucasians and are in 'linkage disequilibrium', i.e. they tend to be transmitted together, with the neighbouring alleles of the *HLA-DQA1* and *DQB1* genes. The latter may be the main determinants of the genetic susceptibility, since these HLA class II genes code for proteins on the surface of cells which present foreign and self antigens to T lymphocytes (p. 85). Candidate gene and genome-wide association studies have also implicated other genes in type 1 diabetes, e.g. *CD25*, *PTPN22*, *IL2RA*, which are involved in immune recognition of pancreatic islet antigens, T cell development and immune regulation. The genes associated with type 1 diabetes overlap with those for other autoimmune disorders such as coeliac disease and thyroid disease, consistent with clustering of these conditions in individuals or families.

Environmental factors

Although genetic susceptibility appears to be a prerequisite for type 1 diabetes, the concordance rate between monozygotic twins is less than 40% (see Box 21.3), and environmental factors have an important role in promoting clinical expression of the disease. Although

hypotheses abound, the nature of these environmental factors is uncertain.

One proposal is that reduced exposure to microorganisms in early childhood limits maturation of the immune system and increases susceptibility to autoimmune disease (the 'hygiene hypothesis'). Another is that viral infection in the pancreas alters β cells' immunogenicity; several viruses have been implicated, including mumps, Coxsackie B4, retroviruses, rubella (in utero), cytomegalovirus and Epstein-Barr virus. Stress may precipitate type 1 diabetes by stimulating the secretion of counter-regulatory hormones and possibly by modulating immune activity. Dietary factors may also be important. Various nitrosamines (found in smoked and cured meats) and coffee have been proposed as potentially diabetogenic toxins. Bovine serum albumin (BSA), a major constituent of cow's milk, has been implicated, since children who are given cow's milk early in infancy are more likely to develop type 1 diabetes than those who are breastfed. BSA may cross the neonatal gut and raise antibodies which cross-react with a heat-shock protein expressed by β cells.

Metabolic disturbances in type 1 diabetes

Patients with type 1 diabetes present when progressive β -cell destruction has crossed a threshold at which adequate insulin secretion and normal blood glucose levels can no longer be sustained. Above a certain level, high glucose levels may be toxic to the remaining β cells so that profound insulin deficiency rapidly ensues. Severe insulin deficiency is associated with the metabolic sequelae shown in Figure 21.5. Hyperglycaemia leads to glycosuria and dehydration, which in turn induces secondary hyperaldosteronism (p. 433). Unrestrained lipolysis and proteolysis result in weight loss, increased gluconeogenesis and ketogenesis. Ketoacidosis occurs when generation of ketone bodies exceeds the capacity for their metabolism. Elevated blood H^+ ions drive K^+ out of the intracellular compartment, while secondary hyperaldosteronism encourages urinary loss of K^+ . Thus patients usually present with a short history (typically a few weeks) of hyperglycaemic symptoms (thirst, polyuria, nocturia and fatigue), infections and weight loss, and may have developed ketoacidosis (p. 809).

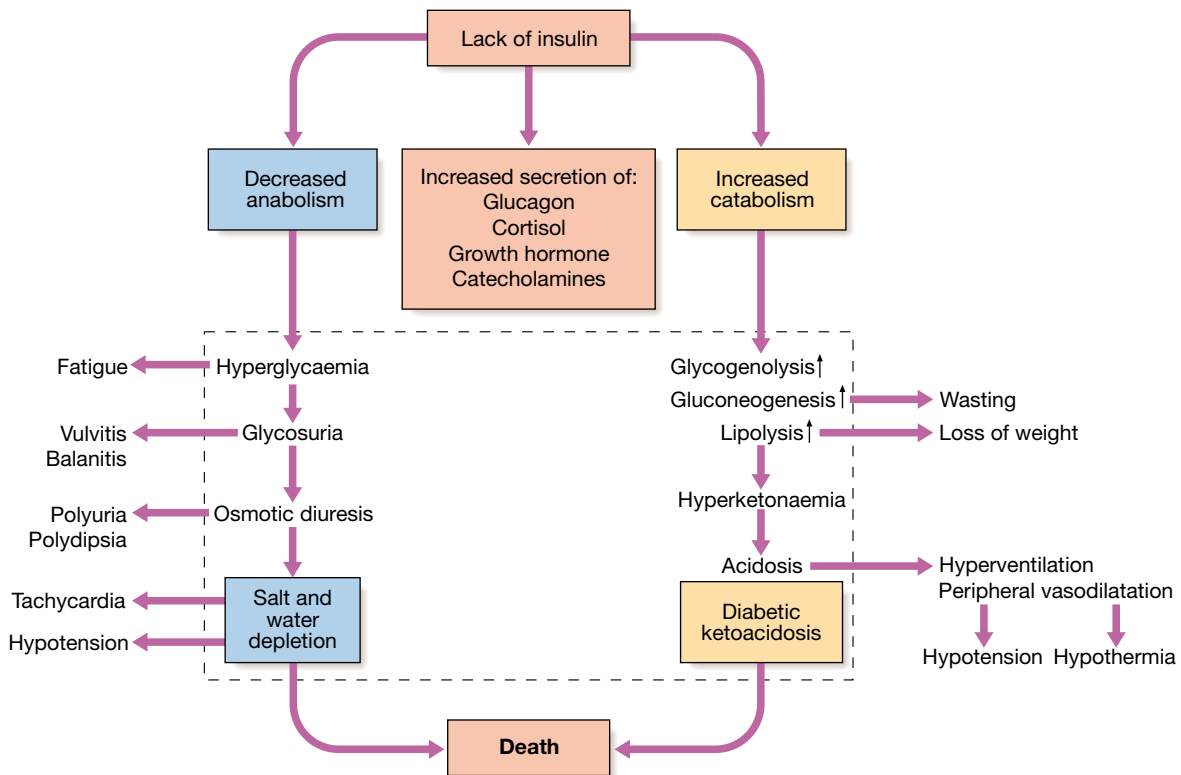

Fig. 21.5 Pathophysiological basis of the symptoms and signs of uncontrolled diabetes mellitus.

Type 2 diabetes

Pathology

Type 2 diabetes is a more complex condition than type 1 diabetes because there is a combination of resistance to the actions of insulin in liver and muscle together with impaired pancreatic β -cell function leading to 'relative' insulin deficiency. The natural history is shown in Figure 21.6. Insulin resistance appears to come first, and leads to elevated insulin secretion in order to maintain normal blood glucose levels. However, in susceptible individuals the pancreatic β cells are unable to sustain the increased demand for insulin and a slowly progressive insulin deficiency develops.

Insulin resistance

Type 2 diabetes, or its antecedent impaired glucose tolerance, is often associated with other disorders, particularly central (visceral) obesity, hypertension and dyslipidaemia (characterised by elevated levels of small dense low-density lipoprotein (LDL) cholesterol and triglycerides, and a low level of high-density lipoprotein (HDL) cholesterol) (Box 21.4). It has been suggested that coexistence of this cluster of conditions, all of which predispose to cardiovascular disease, is a specific entity (the 'insulin resistance syndrome' or 'metabolic syndrome'), with insulin resistance being the primary defect and the presence of obesity being a powerful amplifier of the insulin resistance.

The primary cause of insulin resistance remains unclear. Intra-abdominal 'central' adipose tissue is metabolically active, and releases large quantities of FFAs which may induce insulin resistance because they

compete with glucose as a fuel supply for oxidation in peripheral tissues such as muscle. In addition, adipose tissue releases a number of hormones (including a variety of peptides, called 'adipokines' because they are structurally similar to immunological 'cytokines') which act on specific receptors to influence sensitivity to insulin in other tissues. Because visceral adipose tissue drains into the portal vein, central obesity may have a particularly potent influence on insulin sensitivity in the liver, and thereby adversely affect gluconeogenesis and hepatic lipid metabolism.

Physical activity is another important determinant of insulin sensitivity. Inactivity is associated with down-regulation of insulin-sensitive kinases and may promote accumulation of FFAs within skeletal muscle. Sedentary

21.4 Features of the insulin resistance (metabolic) syndrome*

- Hyperinsulinaemia
- Type 2 diabetes or impaired glucose tolerance
- Hypertension
- Low HDL cholesterol; elevated triglycerides
- Central (visceral) obesity
- Microalbuminuria
- Increased fibrinogen
- Increased plasminogen activator inhibitor-1
- Increased C-reactive protein (CRP)
- Elevated plasma uric acid

*This constellation of features has also been called Reaven's syndrome and syndrome X. It describes the co-segregation in the population of a group of risk factors for atherosclerosis, manifested by macrovascular disease (coronary, cerebral, peripheral) and an excess mortality. It is not a discrete clinical disorder. Additional associations include polycystic ovary syndrome (p. 760) and non-alcoholic fatty liver disease (NAFLD, p. 956).

Fig. 21.6 Natural history of type 2 diabetes. **A** In the early stage of the disorder the response to progressive insulin resistance is an increase in insulin secretion by the pancreatic cells, causing hyperinsulinaemia. Eventually the β cells are unable to compensate adequately and blood glucose rises, producing hyperglycaemia. With further β -cell failure (type 2 diabetes) glycaemic control deteriorates and treatment requirements escalate. **B** Progressive pancreatic β -cell failure in patients in the United Kingdom Prospective Diabetes Study (UKPDS). β -cell function was estimated using the homeostasis model assessment (HOMA) and was already $< 50\%$ at the time of diagnosis. Thereafter, long-term increments in fasting plasma glucose were accompanied by progressive β -cell dysfunction. By extrapolating the slope of this progression, it appears that pancreatic dysfunction may have been developing for many years before diagnosis of diabetes.

people are therefore more insulin-resistant than active people with the same degree of obesity. Moreover, physical activity allows non-insulin-dependent glucose uptake into muscle, reducing the 'demand' on the pancreatic β cells to produce insulin.

Additional disorders have been associated more recently with insulin resistance. Deposition of fat in the liver is a common association with central obesity and is exacerbated by insulin resistance and/or deficiency. Many patients with type 2 diabetes have evidence of fatty infiltration of the liver (non-alcoholic fatty liver disease (NAFLD), p. 956). This condition may improve with effective treatment of the diabetes and dyslipidaemia, but despite this a few patients progress to non-alcoholic steatohepatitis (NASH) (p. 957) and cirrhosis.

Pancreatic β -cell failure

In the early stages of type 2 diabetes, reduction in the total mass of pancreatic islet tissue is modest. At the time of diagnosis, around 50% of β -cell function has been lost and this declines progressively with time (see Fig. 21.6B). Some pathological changes are typical of type 2 diabetes, the most consistent of which is deposition of amyloid. In addition, elevated plasma glucose and FFAs exert toxic effects on pancreatic β cells to impair insulin secretion. However, while β -cell numbers are reduced, α -cell mass is unchanged and glucagon secretion is increased, which may contribute to the hyperglycaemia.

Genetic predisposition

Genetic factors are important in type 2 diabetes, as shown by marked differences in susceptibility in different ethnic groups and by studies in monozygotic twins where concordance rates for type 2 diabetes approach 100%. However, many genes are involved and the chance of developing diabetes is also influenced very powerfully by environmental factors (Box 21.5). Genome-wide association studies have identified over 20 genes or gene

21.5 Risk of developing type 2 diabetes for siblings of probands with type 2 diabetes

Age at onset of type 2 diabetes in proband	Age-corrected risk of type 2 diabetes for siblings (%)
25–44	53
45–54	37
55–64	38
65–80	31

regions that are associated with type 2 diabetes, each exerting a small effect. The largest effect is seen with variation in *TCF7L2*; the 10% of the population with two copies of the risk variant for this gene have a nearly two-fold increase in risk of developing type 2 diabetes. Most of the genes known to contribute to risk of type 2 diabetes are involved in β -cell function or in regulation of cell cycling and turnover, suggesting that altered regulation of β -cell mass is a primary predisposing factor.

Environmental and other risk factors

Diet and obesity

Epidemiological studies show that type 2 diabetes is associated with overeating, especially when combined with obesity and underactivity. Middle-aged people with diabetes eat significantly more and are fatter and less active than their non-diabetic siblings. The risk of developing type 2 diabetes increases tenfold in people with a body mass index (BMI) $> 30 \text{ kg/m}^2$ (p. 115). However, although the majority of patients with type 2 diabetes are obese, only a minority of obese people develop diabetes. Obesity probably acts as a diabetogenic factor (through increasing resistance to the action of insulin) only in those who are genetically predisposed both to insulin resistance and to β -cell failure.

In addition to the effect of total calorie content on obesity, the constituents of the diet and the style of eating may be important. Sweet foods rich in refined carbohydrate consumed frequently may increase the demand for insulin secretion, while high-fat foods may increase FFAs and exacerbate insulin resistance.

Age

Type 2 diabetes is more common in the middle-aged and elderly (Box 21.6). In the UK, it affects 10% of the population over 65, and over 70% of all cases of diabetes occur after the age of 50 years.

21.6 Diagnosis of diabetes mellitus in old age

- **Prevalence:** increases with age, affecting ~10% of people over 65 years. Half of these people are undiagnosed. Impaired β -cell function and exaggerated insulin resistance with ageing both contribute.
- **Glycosuria:** the renal threshold for glucose rises with age, so glycosuria may not develop until the blood glucose concentration is markedly raised.
- **Pancreatic carcinoma:** may present in old age with the development of diabetes, in association with weight loss and diminished appetite.

Pregnancy

During normal pregnancy, insulin sensitivity is reduced through the action of placental hormones and this affects glucose tolerance. The insulin-secreting cells of the pancreatic islets may be unable to meet this increased demand in women genetically predisposed to develop diabetes. The term 'gestational diabetes' refers to hyperglycaemia occurring for the first time during pregnancy (p. 815). Repeated pregnancy increases the likelihood of developing irreversible diabetes, particularly in obese women; 80% of women with gestational diabetes ultimately develop permanent diabetes.

Metabolic disturbances in type 2 diabetes

Patients with type 2 diabetes have a slow onset of 'relative' insulin deficiency. Relatively small amounts of insulin are required to suppress lipolysis, and some glucose uptake is maintained in muscle, so that, in contrast with type 1 diabetes, lipolysis and proteolysis are not unrestrained and weight loss and ketoacidosis seldom occur. The severity of the classical 'osmotic' symptoms of polyuria and polydipsia is related to the degree of glycosuria. In type 2 diabetes, hyperglycaemia develops slowly over months or years and there is a rise in the renal threshold for glucose (the capacity of renal tubules to reabsorb glucose from the glomerular filtrate), so that glycosuria is limited and osmotic symptoms are usually mild. This is one reason that many cases of type 2 diabetes are discovered coincidentally and a large number are undetected. Thus, patients are often asymptomatic and usually present with a long history (typically many months) of fatigue, with or without osmotic symptoms.

In some patients with type 2 diabetes, presentation is late and pancreatic β -cell failure has reached an advanced stage of insulin deficiency (see type 1 diabetes, p. 801). These patients may present with weight loss but ketoacidosis is uncommon.

Intercurrent illness, e.g. with infections, increases the production of counter-regulatory hormones such as cortisol, growth hormone and catecholamines. This can precipitate an acute exacerbation of insulin resistance and insulin deficiency, and result in more severe hyperglycaemia and dehydration (see hyperosmolar non-ketotic coma, p. 812).

Other forms of diabetes

Other causes of diabetes are shown in Box 21.7. In most cases there is an obvious cause of destruction of pancreatic β cells. Some acquired disorders, notably other endocrine diseases such as acromegaly (p. 790) or Cushing's syndrome (p. 770), can precipitate type 2 diabetes in susceptible individuals.

A number of unusual genetic diseases are associated with diabetes. In rare families, diabetes is caused by single gene defects with autosomal dominant inheritance. These subtypes constitute less than 5% of all cases of diabetes and typically present as 'maturity-onset diabetes of the young' (MODY), i.e. non-insulin-requiring diabetes presenting before the age of 25 years (Box 21.8).

21.7 Aetiological classification of diabetes mellitus

Type 1 diabetes

- Immune-mediated
- Idiopathic

Type 2 diabetes

Other specific types

- Genetic defects of β -cell function (see Box 21.8)
- Genetic defects of insulin action (e.g. leprechaunism, lipodystrophies)
- Pancreatic disease (e.g. pancreatitis, pancreatectomy, neoplastic disease, cystic fibrosis, haemochromatosis, fibrocalculous pancreatopathy)
- Excess endogenous production of hormonal antagonists to insulin (e.g. growth hormone—acromegaly; glucocorticoids—Cushing's syndrome; glucagon—glucagonoma; catecholamines—phaeochromocytoma; thyroid hormones—thyrotoxicosis)
- Drug-induced (e.g. corticosteroids, thiazide diuretics, phenytoin)
- Viral infections (e.g. congenital rubella, mumps, Coxsackie virus B)
- Uncommon forms of immune-mediated diabetes
- Associated with genetic syndromes (e.g. Down's syndrome; Klinefelter's syndrome; Turner's syndrome; DIDMOAD (Wolfram's syndrome)—diabetes insipidus, diabetes mellitus, optic atrophy, nerve deafness; Friedreich's ataxia; myotonic dystrophy)

Gestational diabetes

INVESTIGATIONS

Urine testing

Glucose

Testing the urine for glucose with dipsticks is a common screening procedure for detecting diabetes. If pos-

21.8 Monogenic diabetes mellitus: maturity onset diabetes of the young (MODY)

Functional defect	Main type*	Gene mutated*
β-cell glucose sensing	MODY2	<i>GCK</i>
The set point for basal insulin release is altered, causing a high fasting glucose, but sufficient insulin is released after meals. As a result the HbA_{1c} is often normal and microvascular complications are rare. Treatment is only rarely required		
β-cell transcriptional regulation	MODY3	<i>HNF-1α</i>
	MODY5	<i>HNF-1β</i>
	MODY1	<i>HNF-4α</i>
Diabetes develops during adolescence/early adulthood and can be managed with diet and tablets for many years, but ultimately insulin treatment is required. The HNF-1 α and 4 α forms respond particularly well to sulphonylurea drugs. All types are associated with microvascular complications. HNF-1 β mutations also cause renal cysts and renal failure		
*Other gene mutations have been found in rare cases. For further information, see http://projects.exeter.ac.uk/diabetesgenes/mody/		

sible, testing should be performed on urine passed 1–2 hours after a meal to maximise sensitivity. Glycosuria always warrants further assessment by blood testing (see below). The greatest disadvantage of urinary glucose measurement is the individual variation in renal threshold for glucose. The most common cause of glycosuria is a low renal threshold, which is common during pregnancy and in young people; 'renal glycosuria' is a benign condition unrelated to diabetes. Some drugs may interfere with urine glucose tests.

Ketones

Ketone bodies can be identified by the nitroprusside reaction, which measures acetoacetate, using either tablets or dipsticks. Ketonuria may be found in normal people who have been fasting or exercising strenuously for long periods, who have been vomiting repeatedly, or who have been eating a diet high in fat and low in carbohydrate. Ketonuria is therefore not pathognomonic of diabetes but, if associated with glycosuria, the diagnosis of diabetes is highly likely. In diabetic ketoacidosis (p. 809), ketones can also be detected in plasma using dipsticks.

Protein

Standard dipstick testing for albumin detects urinary albumin at concentrations > 300 mg/L, but smaller amounts (microalbuminuria, Box 17.21, p. 480) can only be measured using specific albumin dipsticks or by quantitative biochemical laboratory measurement. Microalbuminuria or proteinuria, in the absence of urinary tract infection, is an important indicator of the development of diabetic nephropathy and/or increased risk of macrovascular disease (see Box 21.44, p. 830).

Blood testing

Glucose

Laboratory glucose testing in blood relies upon an enzymatic reaction (glucose oxidase) and is cheap, usually

automated and highly reliable. However, variation in blood glucose depends on whether the patient has eaten recently, so it is important to consider the circumstances in which the blood sample was taken.

Blood glucose can also be measured with colorimetric or other testing sticks, which are often read with a portable electronic meter. These are used for capillary (fingerprick) testing to monitor diabetes treatment (p. 808). To make the diagnosis of diabetes, the blood glucose concentration should be estimated using an accurate laboratory method rather than a portable technique.

Glucose concentrations are lower in venous than in arterial or capillary (fingerprick) blood. Whole blood glucose concentrations are lower than plasma concentrations because red blood cells contain relatively little glucose. In general, venous plasma values are the most reliable for diagnostic purposes (Boxes 21.9 and 21.10).

Glycated haemoglobin

Glycated haemoglobin provides an accurate and objective measure of glycaemic control over a period of weeks to months. This allows assessment of glycaemic control by repeated measurements every few months in patients with known diabetes, but current assays may not be sufficiently sensitive to make a diagnosis of diabetes and are usually within the normal range in patients with impaired glucose tolerance.

In diabetes, the slow non-enzymatic covalent attachment of glucose to haemoglobin (glycation) increases the amount in the HbA_1 (HbA_{1c}) fraction relative to non-glycated adult haemoglobin (HbA_0). These fractions can be separated by chromatography; laboratories may report glycated haemoglobin as total glycated haemoglobin (GHb), HbA_1 or HbA_{1c} . In most countries HbA_{1c} is the preferred measurement. The rate of formation of HbA_{1c} is directly proportional to the ambient blood glucose concentration; a rise of 1% in HbA_{1c} corresponds to an approximate average increase of 2 mmol/L (36 mg/dL) in blood glucose. Although HbA_{1c} concentration reflects the integrated blood glucose control over the lifespan of the erythrocyte (120 days), half of the erythrocytes are replaced in 60 days and HbA_{1c} is most sensitive to changes in glycaemic control occurring in the month before measurement.

Various assay methods are used to measure HbA_{1c} , but most laboratories have been reporting HbA_{1c} values (as %) aligned with the reference range that was used in the Diabetes Control and Complications Trial (DCCT). To allow world-wide comparisons of HbA_{1c} values, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) has developed a standard method; IFCC-standardised HbA_{1c} values are reported in mmol/mol. The equivalent of typical DCCT HbA_{1c} targets of 6.5% and 7.5% (p. 809) are 48 and 59 mmol/mol using the IFCC assay. In some countries, including the USA, DCCT-aligned HbA_{1c} is reported along with the estimated average blood glucose value (eAG) that is represented by the HbA_{1c} measurement. However, the clinical applicability of this eAG measurement is uncertain.

HbA_{1c} estimates may be erroneously diminished in anaemia or during pregnancy, and may be difficult to interpret with some assay methods in patients who have uraemia or a haemoglobinopathy.

21.9 Diagnosis of diabetes¹

Patient complains of symptoms suggesting diabetes

- Test urine for glucose and ketones
- Measure random or fasting venous blood glucose. Diagnosis confirmed by²:
Fasting plasma glucose ≥ 7.0 mmol/L (126 mg/dL)
Random plasma glucose ≥ 11.1 mmol/L (200 mg/dL)

Indications for oral glucose tolerance test (see Box 21.10)

- Fasting plasma glucose 6.1–7.0 mmol/L (110–126 mg/dL)
- Random plasma glucose 7.8–11.0 mmol/L (140–198 mg/dL)

¹The use of HbA_{1c} for diagnosis is uncertain.

²In asymptomatic patients two samples are required to confirm diabetes.

21.10 How to perform an oral glucose tolerance test (OGTT)

Preparation before the test

- Unrestricted carbohydrate diet for 3 days
- Fasted overnight for at least 8 hrs
- Rest for 30 mins
- Remain seated for the duration of the test, with no smoking

Sampling

- Plasma glucose is measured before and 2 hrs after a 75 g oral glucose drink

Interpretation (venous plasma glucose)

	Fasting	2 hrs after glucose load
Fasting hyperglycaemia	6.1–6.9 mmol/L (110–125 mg/dL)	< 7.8 mmol/L (< 140 mg/dL)
Impaired glucose tolerance	< 7.0 mmol/L (< 126 mg/dL)	7.8–11.0 mmol/L (140–199 mg/dL)
Diabetes	≥ 7.0 mmol/L (≥ 126 mg/dL)	≥ 11.1 mmol/L (≥ 200 mg/dL)

PRESENTING PROBLEMS IN DIABETES MELLITUS

Newly discovered hyperglycaemia

Hyperglycaemia is a very common biochemical abnormality. It is frequently detected on routine biochemical analysis of asymptomatic patients, following routine dipstick testing of urine showing glycosuria, or during severe illness ('stress hyperglycaemia'). Alternatively, hyperglycaemia may present with the chronic symptoms described in Box 21.11. Occasionally, patients present as an emergency with acute metabolic decompensation (see below). The key goals are to establish whether the patient has diabetes, what type of diabetes it is and how it should be treated.

Establishing the diagnosis of diabetes

When diabetes is suspected, the diagnosis may be confirmed by a random plasma glucose concentration greater than 11.0 mmol/L (199 mg/dL) (see Box 21.9). When random plasma glucose values are elevated but are not diagnostic of diabetes, glucose tolerance is usually assessed either by a fasting plasma glucose estimation or by an oral glucose tolerance test (OGTT) (see Box 21.10).

21.11 Symptoms of hyperglycaemia

- Thirst, dry mouth
- Polyuria
- Nocturia
- Tiredness, fatigue, lethargy
- Noticeable change in weight (usually weight loss)
- Blurring of vision
- Pruritus vulvae, balanitis (genital candidiasis)
- Nausea; headache
- Hyperphagia; predilection for sweet foods
- Mood change, irritability, difficulty in concentrating, apathy

The diagnostic criteria for diabetes mellitus (and normality) recommended by the World Health Organization (WHO) in 2000 are shown in Boxes 21.9 and 21.10, and Figure 21.7. The values are based on the threshold for risk of developing vascular disease. Patients who do not meet the criteria for diabetes may have 'impaired glucose tolerance' (IGT, Box 21.10 and Fig. 21.7) or 'fasting hyperglycaemia' (sometimes called 'impaired fasting glucose', when the fasting glucose is between 6.1 and 6.9 mmol/L (110–125 mg/dL)). These patients have increased risks of progression to frank diabetes with time and of macrovascular atheromatous disease. Lowering the cut-off defining impaired fasting glucose to 5.6 mmol/L has been proposed; this would triple the prevalence of this condition.

In some people, an abnormal blood glucose result is observed under conditions which impose a burden on the pancreatic β cells, e.g. during pregnancy, infection, myocardial infarction or other severe stress, or during treatment with diabetogenic drugs such as corticosteroids. This 'stress hyperglycaemia' usually disappears after the acute illness has resolved. However, blood glucose should be remeasured and an OGTT will often show persistence of impaired glucose tolerance.

The diagnostic criteria for diabetes in pregnancy are more stringent than those recommended for non-pregnant subjects. Pregnant women with abnormal glucose tolerance should be referred urgently to a specialist unit for full evaluation.

When a diagnosis of diabetes is confirmed, other investigations should include plasma urea, creatinine and electrolytes, lipids, liver and thyroid function tests, and urine testing for ketones, protein or microalbuminuria.

Clinical assessment and classification

Hyperglycaemia causes a wide variety of symptoms (see Box 21.11). The clinical features of the two main types of diabetes are compared in Box 21.12. The classical symptoms of thirst, polyuria, nocturia and rapid weight loss are prominent in type 1 diabetes, but are often absent in patients with type 2 diabetes, many of whom are asymptomatic or have non-specific complaints such as chronic fatigue and malaise. Uncontrolled diabetes is associated with an increased susceptibility to infection and patients may present with skin sepsis (boils) or genital candidiasis, and complain of pruritus vulvae or balanitis. A history of pancreatic disease (see Box 21.7, p. 804), particularly in patients with a history of alcohol excess, makes insulin deficiency more likely, although such patients may develop incidental classical type 2 diabetes.

Plasma glucose (mmol/L)

Fig. 21.7 Glucose tolerance tests: venous plasma glucose after 75 g glucose by mouth. The dotted lines indicate the 'renal threshold', i.e. the blood glucose concentration above which glycosuria occurs. (To convert glucose in mmol/L to mg/dL, multiply by 18.)

21.12 Comparative features of type 1 and type 2 diabetes

	Type 1	Type 2
Typical age at onset	< 40 yrs	> 50 yrs
Duration of symptoms	Weeks	Months to years
Body weight	Normal or low	Obese
Ketonuria	Yes	No
Rapid death without treatment with insulin	Yes	No
Autoantibodies	Yes	No
Diabetic complications at diagnosis	No	25%
Family history of diabetes	Uncommon	Common
Other autoimmune disease	Common	Uncommon

While the distinction between type 1 and type 2 diabetes is usually obvious, overlap occurs particularly in age at onset, duration of symptoms and family history. A few young people have a form of diabetes designated 'maturity-onset diabetes of the young' (MODY; see Box 21.8, p. 805); they usually have a remarkably strong family history of early-onset diabetes. Classical type 2 diabetes is developing increasingly in obese sedentary young people, including children. Some middle-aged and elderly people present with typical autoimmune type 1 diabetes. Others with apparent type 2 diabetes have evidence of autoimmune activity against pancreatic β cells, and may have a slowly evolving variant of type 1 diabetes (latent autoimmune diabetes in adults (LADA)). Some patients with type 2 diabetes have advanced pancreatic β -cell failure at the time of presentation and require treatment with insulin. For these reasons, the definitive diagnosis of the type of diabetes may sometimes be unclear until the natural history or responsiveness to different therapies becomes apparent with time.

The physical signs in patients with type 2 diabetes at diagnosis depend on the mode of presentation. In Western populations more than 80% are overweight, and the obesity is often central (truncal or abdominal). Obesity is much less evident in Asians. Hypertension is present in at least 50% of patients with type 2 diabetes. Although dyslipidaemia is also common, skin lesions such as xanthelasma and eruptive xanthomas are rare. An increasing number of patients now present with non-alcoholic fatty liver disease, usually identified by their elevated blood transaminase values, but they may also have non-tender hepatomegaly.

Management

The methods of treatment of diabetes are: dietary/lifestyle modification, oral anti-diabetic drugs and injected therapies. These are described in detail on pages 818–824. In patients with suspected type 1 diabetes, urgent treatment with insulin is required and prompt referral to a specialist is usually needed. In patients with suspected type 2 diabetes, the first line of therapy involves advice about dietary and lifestyle modification. Oral anti-diabetic drugs are added in those who do not achieve glycaemic targets as a result, or who have severe symptomatic hyperglycaemia at diagnosis and a high HbA_{1c} .

In parallel with treatment of hyperglycaemia, other risk factors for complications of diabetes need to be addressed, including treatment of hypertension (p. 606) and dyslipidaemia (p. 454), and advice on smoking cessation (p. 98).

Educating patients

It is essential that people with diabetes understand their disorder and learn to handle all aspects of their management as comprehensively and quickly as possible. Ideally, this can be achieved by a multidisciplinary team (doctor, dietitian, specialist nurse and podiatrist) in the outpatient setting. However, patients commencing insulin need daily advice at first and admission to hospital may sometimes be necessary.

Those requiring insulin need to learn how to measure doses of insulin accurately with an insulin syringe or pen device, how to inject, and how to adjust the dose on the basis of blood glucose values and in relation to factors such as exercise, illness and episodic hypoglycaemia. They must therefore acquire a working knowledge of diabetes, be familiar with the symptoms of hypoglycaemia (Box 21.21, p. 812), and have ready access to medical advice when the need arises. Information should be provided about driving (national statutory regulations and practical safety measures, Box 21.13). Providing this education is time-consuming but essential if patients are to undertake normal activities safely while maintaining good control.

It is a sensible precaution for those who are taking insulin or oral anti-diabetic medications to carry a card stating their name and address, the fact that they have diabetes, the nature and dose of any insulin or other drugs they may be taking, and the contact details of their family doctor and any specialist diabetes clinic that they attend.

Self-assessment of glycaemic control

Urine testing to assess blood glucose control has major limitations, particularly in people with type 1 diabetes, but also in those with type 2 diabetes in whom a raised renal threshold for glucose may mask persistent hyperglycaemia. Negative urine tests fail to distinguish between normal and low blood glucose levels, which is a serious disadvantage since the aim of treatment is a normal blood glucose level while avoiding hypoglycaemia. However, semi-quantitative urine glucose testing with visually read strips is very cheap and may suffice for many people with type 2 diabetes treated with diet alone or in those taking oral therapy who have stable glycaemic control.

Many patients (particularly those treated with insulin) should be taught to perform capillary blood glucose measurements using blood glucose test strips, read either visually or with a glucose meter (Box 21.14). The principal advantage of self-monitoring of blood glucose is that information is available immediately and permits

21.14 Blood glucose (BG) testing and diabetes

Treatment with insulin

- Regular BG monitoring should be performed by all patients to adjust the insulin dose and detect hypoglycaemia
- Daily pre-prandial and bedtime measurements are usually recommended
- Target BG levels are typically 5–8 mmol/L (~90–144 mg/dL), although target ranges may be lower (e.g. in gestational diabetes) or higher (e.g. in impaired awareness of hypoglycaemia)

Treatment with anti-diabetic drugs

- BG monitoring is optional in many patients with stable type 2 diabetes; patient preference usually decides
- BG monitoring is most useful in patients taking sulphonylureas (risk of hypoglycaemia), during intercurrent illness and prescription of corticosteroids, and during changes in therapy
- BG is usually measured before breakfast (typical target 4–7 mmol/L (~72–126 mg/dL)) and 2 hrs after food (typical target 4–10 mmol/L (~72–180 mg/dL))

the well-informed and motivated patient to make appropriate adjustments in treatment (particularly in insulin dose) on a day-to-day basis. Thus changes in routine can be accommodated, ketoacidosis avoided, compliance with diet encouraged and near-normal metabolism achieved while avoiding frequent and disabling hypoglycaemia. Blood glucose monitoring involves a significant cost and may not be justified in many patients with type 2 diabetes. Single random blood glucose estimations obtained at routine clinic visits are of limited value and profiles measured in hospital may be unrepresentative of normal circumstances. Continuous blood glucose monitoring methodology is available but is costly and not yet applicable to routine monitoring.

Advice to patients with IGT

These patients have an increased risk both of progression to type 2 diabetes and of developing macrovascular disease. There is evidence that the lifestyle advice recommended for patients with type 2 diabetes will reduce the risk of progression in IGT. Patients with IGT should be monitored annually by measurement of fasting blood glucose. Other cardiovascular risk factors should be treated aggressively.

Long-term supervision of diabetes

Diabetes is a complex disorder which progresses in severity with time, so people with diabetes should be seen at regular intervals for the remainder of their lives, either at a specialist diabetic clinic or in primary care where facilities are available and staff are trained in diabetes care. A checklist for follow-up visits is given in Box 21.15. The frequency of visits is very variable, ranging from weekly during pregnancy to annually in the case of patients with well-controlled type 2 diabetes.

Therapeutic goals

The aims of treatment are to relieve the symptoms of hyperglycaemia and to achieve as near normal

21.13 Diabetes and driving

- Licensing regulations vary considerably between countries. In the UK, diabetes requiring insulin therapy or any complication that could affect driving should be declared to the Driver and Vehicle Licensing Agency; ordinary driving licences are 'period-restricted' for insulin-treated drivers, and vocational licences (large goods vehicles and public service vehicles) are generally refused unless very strict criteria can be met
- The main risk to driving performance is hypoglycaemia. Visual impairment and other complications may occasionally cause problems
- Insulin-treated diabetic drivers should be advised to:
 - Check blood glucose before driving and 2-hourly during long journeys
 - Keep an accessible supply of fast-acting carbohydrate in the vehicle
 - Take regular snacks or meals during long journeys
 - Stop driving if hypoglycaemia develops
 - Refrain from driving until at least 45 mins after treatment of hypoglycaemia (delayed recovery of cognitive function)
 - Carry identification in case of injury

21.15 How to review a patient in the diabetes clinic

Body weight and BMI

Urinalysis

- Analyse fasting specimen for glucose, ketones, albumin (both macro- and microalbuminuria)

Biochemistry

- Lipid profile and renal, liver and thyroid function

Glycaemic control

- Glycated haemoglobin (HbA_{1c})
- Inspection of home blood glucose monitoring record

Hypoglycaemic episodes

- Number and cause of severe (requiring assistance for treatment) events and frequency of mild (self-treated) episodes
- Time of day when 'hypos' are experienced
- Nature and intensity of symptoms
- Ability to identify onset (awareness)

Blood pressure

Smoking

Eye examination

- Visual acuities (near and distance)
- Ophthalmoscopy (with pupils dilated) or digital photography

Lower limbs and feet

- Peripheral pulses
- Tendon reflexes
- Perception of vibration sensation, light touch and proprioception
- Callus indicating pressure areas
- Nails
- Deformity
- Ulceration
- Need for podiatry

metabolism as is practicable, while avoiding hypoglycaemia and therapeutic side-effects. The nearer the body weight approaches the ideal level and the closer the blood glucose is kept to normal, the more the total metabolic profile is improved and the lower the incidence of vascular disease and of specific diabetic complications. Excellent glycaemic control may also slow the progression of pancreatic β -cell failure.

The recommended target HbA_{1c} is 7% or less, to minimise the risk of vascular complications. However, this may be difficult to achieve and to maintain, particularly with increasing duration of diabetes. Type 2 diabetes progresses in severity with time, with evidence of a gradual rise in HbA_{1c} despite escalation in treatment (Fig. 21.8). Strict glycaemic control in type 1 diabetes increases the risk of hypoglycaemia. Glycaemic targets should therefore be appropriate to the age and physical condition of the patient; strict control may be inappropriate in the very young, the elderly, people with several comorbidities or cancer, and those with advanced diabetic complications or cardiovascular disease. Blood glucose targets depend similarly on individual requirements, but fasting blood glucose values below 6 mmol/L (108 mg/dL) are desirable in type 2 diabetes. Preprandial values between 5 and 8 mmol/L would be ideal in patients with type 1 diabetes, in whom values below

Fig. 21.8 Time course of changes in HbA_{1c} during the United Kingdom Prospective Diabetes Study (UKPDS). In the UKPDS there was loss of glycaemic control with time in patients receiving monotherapy, independently of their randomisation to conventional or intensive glycaemic control, consistent with progressive decline in β -cell function (see Fig. 21.6, p. 803).

4 mmol/L should be avoided. The importance of routinely measuring post-prandial glucose is debatable, and multiple daily measurements (> 4/day) are seldom practical or tolerated.

In people with type 2 diabetes, treatment of coexisting hypertension and dyslipidaemia is usually required. This can be determined by assessment of cardiovascular risk and targets are adjusted to individual circumstances. The target for blood pressure is usually < 140/80 mmHg. The target levels for lipids are usually a total cholesterol < 5.0 mmol/L (approximately 190 mg/dL) and LDL cholesterol < 3.0 mmol/L (approximately 115 mg/dL). Similar targets would be appropriate in type 1 diabetes, with modification depending on age and the presence of microalbuminuria.

Diabetic ketoacidosis

Ketoacidosis is a major medical emergency and remains a serious cause of morbidity, principally in people with type 1 diabetes. A significant number of newly diagnosed diabetic patients present in ketoacidosis. In established diabetes a common course of events is that patients develop an intercurrent infection, lose their appetite, and either stop or reduce their dose of insulin in the mistaken belief that under these circumstances less insulin is required. Any form of stress, particularly that produced by infection, may precipitate severe ketoacidosis, even in patients with type 2 diabetes. No obvious precipitating cause can be found in many cases.

The average mortality in developed countries is 5–10% and is higher in the elderly. Although some deaths from ketoacidosis are associated with severe medical conditions such as acute myocardial infarction or septicemia, others are the consequence of delays in diagnosis and management errors.

Pathogenesis

A clear understanding of the biochemical basis and pathophysiology of diabetic ketoacidosis is essential for its efficient treatment. The cardinal biochemical features are:

- hyperglycaemia
- hyperketonaemia
- metabolic acidosis.

The hyperglycaemia causes a profound osmotic diuresis leading to dehydration and electrolyte loss, particularly of sodium and potassium. Potassium loss is exacerbated by secondary hyperaldosteronism as a result of reduced renal perfusion. Ketosis results from insulin deficiency, exacerbated by elevated catecholamines and other stress hormones, resulting in unrestrained lipolysis and supply of FFAs for hepatic ketogenesis (see Fig. 21.5, p. 802). When this exceeds the capacity to metabolise acidic ketones, these accumulate in blood. The resulting metabolic acidosis forces hydrogen ions into cells, displacing potassium ions.

The average loss of fluid and electrolytes in moderately severe diabetic ketoacidosis in an adult is shown in Box 21.16. About half the deficit of total body water is derived from the intracellular compartment and occurs comparatively early in the development of acidosis with relatively few clinical features; the remainder represents loss of extracellular fluid sustained largely in the later stages, when marked contraction of the size of the extracellular space occurs, with haemoconcentration, a decreased blood volume, and finally a fall in blood pressure with associated renal ischaemia and oliguria.

 21.16 Average loss of fluid and electrolytes in adult diabetic ketoacidosis of moderate severity					
<ul style="list-style-type: none"> • Water: 6 L • Sodium: 500 mmol • Chloride: 400 mmol • Potassium: 350 mmol 	<table> <tr> <td>3 L extracellular</td><td>—replace with saline</td></tr> <tr> <td>3 L intracellular</td><td>—replace with dextrose</td></tr> </table>	3 L extracellular	—replace with saline	3 L intracellular	—replace with dextrose
3 L extracellular	—replace with saline				
3 L intracellular	—replace with dextrose				

Every patient in diabetic ketoacidosis is potassium-depleted, but the plasma concentration of potassium gives very little indication of the total body deficit. Plasma potassium may even be raised initially due to disproportionate loss of water, catabolism of protein and glycogen, and displacement of potassium from the intracellular compartment by H^+ ions. However, soon after insulin treatment is started there is likely to be a precipitous fall in the plasma potassium due to dilution of extracellular potassium by administration of intravenous fluids, the movement of potassium into cells induced by insulin, and the continuing renal loss of potassium.

The magnitude of the hyperglycaemia does not correlate with the severity of the metabolic acidosis; moderate elevation of blood glucose may be associated with life-threatening ketoacidosis. In some cases, hyperglycaemia predominates and acidosis is minimal, with patients presenting in a hyperosmolar state (p. 812).

Clinical assessment

The clinical features of ketoacidosis are listed in Box 21.17. In the fulminating case the striking features are those of salt and water depletion, with loss of skin turgor, furred tongue and cracked lips, tachycardia, hypotension and reduced intra-ocular pressure. Breathing may be deep and sighing, the breath is usually fetid, and the sickly-sweet smell of acetone may be apparent. Mental apathy, confusion or a reduced conscious level may be present. The state of consciousness is very variable in patients with diabetic ketoacidosis; coma is uncommon. A patient with dangerous ketoacidosis requiring urgent

21.17 Clinical features of diabetic ketoacidosis

Symptoms	
<ul style="list-style-type: none"> • Polyuria, thirst • Weight loss • Weakness • Nausea, vomiting 	<ul style="list-style-type: none"> • Leg cramps • Blurred vision • Abdominal pain
Signs	
<ul style="list-style-type: none"> • Dehydration • Hypotension (postural or supine) • Cold extremities/peripheral cyanosis • Tachycardia 	<ul style="list-style-type: none"> • Air hunger (Kussmaul breathing) • Smell of acetone • Hypothermia • Confusion, drowsiness, coma (10%)

treatment may walk into the consulting room. For this reason the term 'diabetic ketoacidosis' is to be preferred to 'diabetic coma', which implies that there is no urgency until unconsciousness supervenes. In fact, it is imperative that energetic treatment is started at the earliest possible stage.

Abdominal pain is sometimes a feature of diabetic ketoacidosis, particularly in children. Serum amylase may be elevated but rarely indicates coexisting pancreatitis. In infected patients, pyrexia may not be present initially because of vasodilatation secondary to acidosis.

Investigations

The following are important but should not delay the institution of intravenous fluid and insulin replacement:

- *Venous blood:* for urea and electrolytes, glucose, bicarbonate.
- *Arterial blood gases* to assess the severity of acidosis. (The severity of ketoacidosis can be assessed rapidly by measuring the venous plasma bicarbonate; less than 12 mmol/L indicates severe acidosis. The hydrogen ion concentration gives a more precise measure but requires arterial blood.)
- *Urinalysis for ketones.* (A meter is available to quantify ketones in plasma, and a test strip can be used as a semi-quantitative guide to the plasma concentration of acetoacetate and acetone.)
- *ECG.*
- *Infection screen:* full blood count, blood and urine culture, C-reactive protein, chest X-ray. Although leucocytosis invariably occurs, this represents a stress response and does not necessarily indicate infection.

Management

Diabetic ketoacidosis is a medical emergency which should be treated in hospital, preferably in a high-dependency area. Regular clinical and biochemical review is essential, particularly during the first 24 hours of treatment (Box 21.18). Guidelines for the management of ketoacidosis are shown in Box 21.19.

The principal components of treatment are:

- the administration of short-acting (soluble) insulin
- fluid replacement
- potassium replacement
- the administration of antibiotics if infection is present.

21.18 Monitoring in diabetic ketoacidosis ¹							
Laboratory	Baseline	1 hr	2 hr	3 hr	6 hr	12 hr	24 hr
Glucose ²	✓	✓	✓	✓	✓	✓	✓
Urea, electrolytes	✓	✓	✓	✓	✓	✓	✓
Creatinine	✓				✓	✓	✓
Bicarbonate	✓	✓	✓	✓	✓	✓	✓
Blood gases	(✓)		✓ ³		✓ ³		

¹The following should be monitored hourly: pulse, blood pressure, respiratory rate, urine output, capillary blood glucose.

²A capillary blood glucose measurement of > 17 mmol/L (approximately 300 mg/dL) using a meter or visually read glucose strips can be very misleading since the actual blood glucose concentration is often considerably higher when measured precisely in the laboratory; therefore an accurate measurement should be made at an early stage.

³If no clinical improvement. Blood gases at baseline are not necessary if plasma bicarbonate is > 15 mmol/L.

21.19 Management of diabetic ketoacidosis	
Fluid replacement	
<ul style="list-style-type: none"> 0.9% saline (NaCl) i.v. <ul style="list-style-type: none"> 1 L over 30 mins 1 L over 1 hr 1 L over 2 hrs 1 L over next 2–4 hrs When blood glucose < 15 mmol/L (270 mg/dL) <ul style="list-style-type: none"> Switch to 5% dextrose, 1 L 8-hourly If still dehydrated, continue 0.9% saline and add 5% dextrose, 1 L per 12 hrs Typical requirement is 6 L in first 24 hrs but avoid fluid overload in elderly patients Subsequent fluid requirement should be based on clinical response including urine output 	
Insulin	
<ul style="list-style-type: none"> 50 U soluble insulin in 50 mL 0.9% saline i.v. via infusion pump <ul style="list-style-type: none"> 6 U/hr initially 3 U/hr when blood glucose < 15 mmol/L (270 mg/dL) 2 U/hr if blood glucose < 10 mmol/L (180 mg/dL) Check blood glucose hourly initially; if no reduction in first hour, rate of insulin infusion should be increased Aim for fall in blood glucose of 3–6 mmol/L (approximately 55–110 mg/dL) per hour 	
Potassium	
<ul style="list-style-type: none"> None in first L of i.v. fluid unless plasma potassium < 3.0 mmol/L When < 3.5 mmol/L, give 20 mmol/hr When plasma potassium is 3.5–5.0 mmol/L, give 10 mmol/hr 	
Additional procedures	
<ul style="list-style-type: none"> Catheterisation if no urine passed after 3 hrs Nasogastric tube to keep stomach empty in unconscious or semiconscious patients, or if vomiting is protracted Central venous line if cardiovascular system compromised, to allow fluid replacement to be adjusted accurately Plasma expander if systolic BP is < 90 mmHg or does not rise with i.v. saline Antibiotic if infection demonstrated or suspected ECG monitoring in severe cases 	

Insulin

If an intravenous infusion of insulin (see Box 21.19) is not possible, soluble insulin can be given by intramuscular injection (loading dose of 10–20 U followed by 5 U hourly) or, alternatively, a fast-acting insulin analogue can be given hourly by subcutaneous injection (initially 0.3 U/kg body weight, then 0.1 U/kg hourly). The blood glucose concentration should fall by 3–6 mmol/L (approximately 55–110 mg/dL) per hour. A more rapid fall in blood glucose should be avoided, as hypoglycaemia can be precipitated and the serious complication of cerebral oedema may develop, particularly in children. If blood glucose does not fall within 1 hour of commencing treatment, the dose of insulin should be increased until a satisfactory response is obtained. Ketosis, dehydration, acidemia, infection and stress combine to produce severe insulin resistance in some cases but most will respond to a low-dose insulin regimen. When the blood glucose concentration has fallen to 10–15 mmol/L (180–270 mg/dL) the dose of insulin should be reduced to 1–4 U hourly. The half-life of intravenous insulin is short (2.5 mins) so the insulin infusion should not be interrupted.

Restoration of the usual insulin regimen, by subcutaneous injection, should not be instituted until the patient is able to eat and drink normally. 'Sliding scales' of subcutaneous insulin administration (in which insulin is prescribed according to blood glucose levels immediately before injection) should not be used.

Fluid replacement

Intravenous fluid replacement is required since, even when the patient is able to swallow, fluids given by mouth may be poorly absorbed. The extracellular fluid deficit should be replenished by infusing isotonic saline (0.9% NaCl). Early and rapid rehydration is essential; otherwise the administered insulin will not reach the poorly perfused tissues. If the plasma sodium is greater than 155 mmol/L, 0.45% saline may be given initially.

The intracellular water deficit must be replaced by using 5% or 10% dextrose and not by more saline. Dextrose is best given when the blood glucose concentration approaches normal. An accurate record of fluid balance must be maintained.

Potassium

As the plasma potassium is often high at presentation, treatment with intravenous potassium chloride should be started cautiously (see Box 21.19) and carefully monitored. Sufficient should be given to maintain a normal plasma concentration and large amounts may be required (100–300 mmol in the first 24 hours). Cardiac rhythm should be monitored in severe cases because of the risk of electrolyte-induced cardiac arrhythmia.

Bicarbonate

In patients who are severely acidotic ($[H^+] > 100$ nmol/L, pH < 7.0) the infusion of sodium bicarbonate (300 mL 1.26% over 30 mins into a large vein) should be considered, with the simultaneous administration of potassium. Its use is controversial, however, and should only be considered in exceptional circumstances. Complete correction of the acidosis should not be attempted.

21.20 Complications of diabetic ketoacidosis

- Cerebral oedema
May be caused by very rapid reduction of blood glucose, use of hypotonic fluids and/or bicarbonate
High mortality
Treat with mannitol, oxygen
- Acute respiratory distress syndrome (p. 187)
- Thromboembolism
- Disseminated intravascular coagulation (rare)
- Acute circulatory failure

Antibiotics

Infections must be carefully sought and vigorously treated since it may not be possible to abolish ketosis until they are controlled. The management of diabetic ketoacidosis may be complicated by the development of other conditions (Box 21.20) which require active therapy.

Non-ketotic hyperosmolar diabetic coma

This condition is characterised by severe hyperglycaemia ($> 50 \text{ mmol/L}$ (900 mg/dL)) without significant hyperketonaemia or acidosis. Severe dehydration and pre-renal uraemia are common. It usually affects elderly patients, many with previously undiagnosed type 2 diabetes. Mortality is high (40%). Treatment differs from ketoacidosis in two main respects. Firstly, these patients are usually relatively sensitive to insulin and approximately half the dose of insulin recommended for the treatment of ketoacidosis should usually be employed (3 U/hr). Secondly, the plasma osmolality should be measured or, less accurately, calculated using the following formula based on plasma values in mmol/L :

$$\text{Plasma osmolality} = 2[\text{Na}^+] + 2[\text{K}^+] + [\text{glucose}] + [\text{urea}]$$

The normal value is $280\text{--}290 \text{ mmol/kg}$ and the conscious level is depressed when it is high ($> 340 \text{ mmol/kg}$). The patient should be given 0.45% saline until the osmolality approaches normal, when isotonic (0.9%) saline should be substituted. The rate of fluid replacement should be adjusted on the basis of the central venous pressure, and plasma sodium concentration checked frequently. Thromboembolic complications are common, and prophylactic subcutaneous low molecular weight heparin is recommended.

Lactic acidosis

In coma due to lactic acidosis the patient is likely to be taking metformin for type 2 diabetes and is very ill and overbreathing but not as profoundly dehydrated as is usual in coma due to ketoacidosis. The patient's breath does not smell of acetone, and ketonuria is mild or even absent, yet plasma bicarbonate is reduced and the anion gap and H^+ are increased (p. 441). The diagnosis is confirmed by a high (usually $> 5.0 \text{ mmol/L}$) concentration of lactic acid in the blood. Treatment is with intravenous sodium bicarbonate sufficient to reduce H^+ below 60 nmol/L ($\text{pH } 7.2$), along with insulin and glucose.

Despite energetic treatment, the mortality in this condition is over 50%. Sodium dichloroacetate may be given to lower blood lactate.

Hypoglycaemia

When hypoglycaemia (blood glucose $< 3.5 \text{ mmol/L}$ (63 mg/dL)) occurs in a person with diabetes it is a result of treatment and not a manifestation of the disease itself. It occurs often in those treated with insulin, occasionally in those taking oral insulin secretagogues such as a sulphonylurea drug, and rarely with other anti-diabetic drugs. When hypoglycaemia develops in non-diabetic people, it is called 'spontaneous' hypoglycaemia, the causes and investigation of which are described on page 781. The risk of hypoglycaemia is the most important single factor limiting the attainment of near-normal glycaemia; fear of severe hypoglycaemia is common among patients and their relatives.

Clinical assessment

Symptoms of hypoglycaemia (Box 21.21) comprise two main groups: those related to acute activation of the autonomic nervous system and those secondary to glucose deprivation of the brain (neuroglycopenia). Symptoms of hypoglycaemia are idiosyncratic and differ with age. The ability to recognise their onset is an important aspect of the initial education of diabetic patients treated with insulin. The severity of hypoglycaemia is defined by ability to self-treat; 'mild' episodes are self-treated, while 'severe' require assistance for recovery.

Circumstances of hypoglycaemia

Nocturnal hypoglycaemia in patients with type 1 diabetes is probably common and under-recognised. As hypoglycaemia does not usually waken a person who is asleep and the usual warning symptoms are not perceived, it is often undetected. However, on direct questioning, patients may admit to poor quality of sleep, morning headaches, 'hangover', chronic fatigue and vivid dreams or nightmares. Sometimes a partner may observe profuse sweating, restlessness, twitching or even

21.21 Most common symptoms of hypoglycaemia

Autonomic

- Sweating
- Trembling
- Pounding heart
- Hunger
- Anxiety

Neuroglycopenic

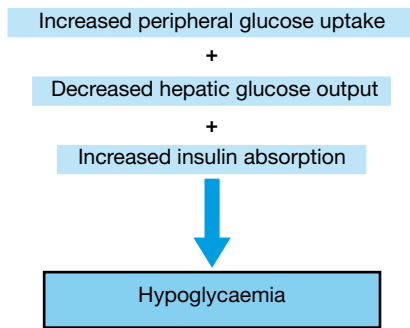

- Confusion
- Drowsiness
- Speech difficulty
- Inability to concentrate
- Incoordination
- Irritability, anger

Non-specific

- Nausea
- Tiredness
- Headache

N.B. Symptoms differ with age; children exhibit behavioural changes (such as naughtiness or irritability), while elderly people experience more prominent neurological symptoms such as visual disturbance and ataxia.

A

Well-controlled: hyperinsulinaemic

B

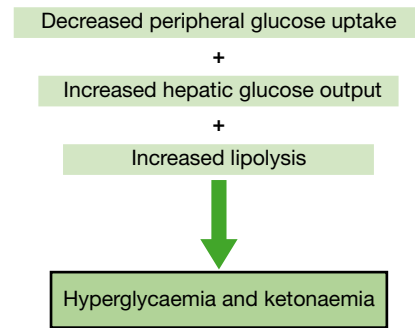

Decompensated: hypoinsulinaemic

Fig. 21.9 The potential effects of exercise in diabetic patients being treated with insulin. **A** Well-controlled hyperinsulinaemic patients. **B** Decompensated hypoinsulinaemic patients.

seizures. The only reliable way to identify this problem is to measure the blood glucose during the night.

Exercise-induced hypoglycaemia (Fig. 21.9) occurs in people with well-controlled, insulin-treated diabetes because of hyperinsulinaemia and the absence of the capacity to suppress secretion of endogenous insulin, a key factor in the normal adaptation to exercise.

Risk factors and causes of hypoglycaemia in patients taking insulin or sulphonylurea drugs are listed in Box 21.22. Severe hypoglycaemia can have serious morbidity (Box 21.23) and has a recognised mortality of up to 4% in insulin-treated patients. The unrecognised mortality

21.22 Hypoglycaemia: common causes and risk factors

Causes of hypoglycaemia

- Missed, delayed or inadequate meal
- Unexpected or unusual exercise
- Alcohol
- Errors in oral anti-diabetic agent(s) or insulin dose/schedule/administration
- Poorly designed insulin regimen, particularly if predisposing to nocturnal hyperinsulinaemia
- Lipohypertrophy at injection sites causing variable insulin absorption
- Gastroparesis due to autonomic neuropathy
- Malabsorption, e.g. coeliac disease
- Unrecognised other endocrine disorder, e.g. Addison's disease
- Factitious (deliberately induced)
- Breastfeeding by diabetic mother

Risk factors for severe hypoglycaemia

- Strict glycaemic control
- Impaired awareness of hypoglycaemia
- Age (very young and elderly)
- Increasing duration of diabetes
- Sleep
- C-peptide negativity (indicating complete insulin deficiency)
- History of previous severe hypoglycaemia
- Renal impairment
- Genetic, e.g. angiotensin-converting enzyme (ACE) genotype

21.23 Morbidity of severe hypoglycaemia in diabetic patients

CNS

- Impaired cognitive function
- Coma
- Convulsions
- Intellectual decline
- Transient ischaemic attack, stroke
- Brain damage (rare)
- Focal neurological lesions (rare)

Heart

- Cardiac arrhythmias
- Myocardial ischaemia

Eye

- Vitreous haemorrhage
- ? Worsening of retinopathy

Other

- Accidents (including road traffic accidents) with injury
- Hypothermia

may be higher. Occasionally, sudden death occurs during sleep in otherwise healthy young patients with type 1 diabetes ('dead-in-bed syndrome'); hypoglycaemia-induced cardiac arrhythmia has been implicated. Severe hypoglycaemia is very disruptive and impinges on many aspects of the patient's life, including employment, driving (see Box 21.13, p. 808), travel, sport and personal relationships.

Awareness of hypoglycaemia

In most instances patients have no difficulty in recognising the symptoms of hypoglycaemia and can take appropriate remedial action. In certain circumstances (e.g. during sleep, lying supine or when distracted by other activities) warning symptoms are not always perceived, so that appropriate action is not taken and neuroglycopenia with reduced consciousness ensues.

If short-acting insulin is administered to a non-diabetic person, symptoms of hypoglycaemia are usually experienced when the venous or capillary blood glucose falls to 2.5–3.0 mmol/L (45–54 mg/dL). In diabetic patients who are chronically hyperglycaemic the same symptoms may develop at a higher blood glucose level. Conversely,

patients who have strict glycaemic control (HbA_{1c} within the non-diabetic range) may not experience any symptoms even when the blood glucose is well below 2.5 mmol/L. In patients exposed to frequent hypoglycaemia, cerebral adaptation lowers the glycaemic thresholds for the onset of symptoms and counter-regulatory hormonal secretion, resulting in impaired awareness of hypoglycaemia. The prevalence of impaired perception of the onset of symptoms of hypoglycaemia increases with the duration of insulin treatment, and it affects around 20–25% of people with type 1 diabetes and < 10% with insulin-treated type 2 diabetes.

Counter-regulatory responses may also be impaired. In response to a falling blood glucose, there is normally suppression of endogenous insulin secretion (absent in type 1 diabetes) and a brisk secretion of counter-regulatory hormones, such as glucagon and epinephrine (adrenaline), which antagonise the blood glucose-lowering effect of insulin. Hypoglycaemia-induced secretion of glucagon becomes impaired in most people within 5 years of developing type 1 diabetes and many also develop a defective adrenaline response to hypoglycaemia so that glucose recovery may be seriously compromised. Both autonomic neuropathy and impaired central activation of counter-regulation following exposure to recurrent hypoglycaemia may contribute. Counter-regulatory deficiency is closely associated with impaired awareness of hypoglycaemia, and has been described as 'hypoglycaemia-associated autonomic failure'.

Management

Acute treatment of hypoglycaemia

Treatment of acute hypoglycaemia depends on its severity and on whether the patient is conscious and able to swallow (Box 21.24). Oral carbohydrate usually suffices if hypoglycaemia is recognised early. If parenteral therapy is required, then as soon as the patient is able to swallow, glucose should be given orally. Full recovery may not occur immediately and reversal of cognitive impairment may not be complete until 60 minutes after normoglycaemia is restored. Further, when hypoglycaemia has occurred in a patient treated with a long- or

intermediate-acting insulin or a long-acting sulphonylurea, such as glibenclamide, the possibility of recurrence should be anticipated; to prevent this, infusion of 10% dextrose, titrated to the patient's blood glucose, may be necessary.

If the patient fails to regain consciousness after blood glucose is restored to normal, then cerebral oedema and other causes of impaired consciousness, such as alcohol intoxication, a post-ictal state or cerebral haemorrhage, should be considered. Cerebral oedema has a high mortality and morbidity, and requires urgent treatment with mannitol and high-dose oxygen.

Following recovery, it is important to try to identify a cause and make appropriate adjustments to the patient's therapy. Unless the reason for a hypoglycaemic episode is clear, the patient should reduce the next dose of insulin by 10–20% and seek medical advice about further adjustments in dose.

The management of self-poisoning with oral anti-diabetic agents is given on page 214.

Prevention of hypoglycaemia

Patient education on the potential causes and risks of inducing hypoglycaemia and on its treatment, including the need to have an accessible supply of glucose (and glucagon) and to perform regular blood glucose monitoring, is fundamental to the prevention of this potentially dangerous side-effect of treatment. If strenuous or protracted exercise is anticipated, the preceding dose of insulin should be reduced (the degree of reduction varying widely between individuals but often being substantial) and extra carbohydrate ingested. Advice for during travel is shown in Box 21.25.

Relatives and friends also need to be familiar with the symptoms and signs of hypoglycaemia and should be instructed as to how this should be managed (including how to inject glucagon).

Unfortunately, many insulin regimens in current use produce inappropriate nocturnal hyperinsulinaemia. With a basal-bolus regimen (pp. 822–823) the times of maximum risk of hypoglycaemia are between 2300 and 0200 hrs and between 0500 and 0700 hrs. When an intermediate-acting insulin such as isophane (pp. 822–823) is taken before the main evening meal between 1700 and 1900 hrs, its peak action will coincide with the period of maximum sensitivity to insulin, namely 2300–0200 hrs. Short-acting insulin administered before a late evening meal (after 2000 hrs) can cause hypoglycaemia after retiring to bed. To reduce the risk of nocturnal

21.24 Emergency treatment of hypoglycaemia

Mild (self-treated)

- Oral fast-acting carbohydrate (10–15 g) is taken as glucose drink or tablets or confectionery
- This should be followed with a snack containing complex carbohydrate

Severe (external help required)

- If patient is semiconscious or unconscious, parenteral treatment is required:
I.v. 75 mL 20% dextrose (=15 g; give 0.2 g/kg in children)*
or
I.m. glucagon (1 mg; 0.5 mg in children)
- If patient is conscious and able to swallow:
Give oral refined glucose as drink or sweets (=25 g)
or
Apply glucose gel or jam or honey to buccal mucosa

*Use of 50% dextrose is no longer recommended.

21.25 Measures for avoidance and treatment of hypoglycaemia during travel

- Carry a supply of fast-acting carbohydrate (non-perishable, in suitable containers)
Screwtop plastic bottles for glucose drinks
Packets of powdered glucose (for use in hot, humid climates)
Confectionery (foil-wrapped in hot climates)
- Companions should carry additional oral carbohydrate, and glucagon
- Perform frequent blood glucose testing (carry spare meter, visually read strips)
- Use fast-acting insulin analogues for long-distance air travel

hypoglycaemia, administration of the evening dose of depot intermediate-acting insulin can be deferred until bedtime (after 2300 hrs) or a fast-acting insulin analogue used for the evening meal. A long-acting insulin analogue should be taken with breakfast instead of at bedtime, so that its action is then waning during the night. It is a sensible precaution for patients to measure their blood glucose before they retire to bed and to eat a carbohydrate snack if the reading is less than 6.0 mmol/L (approximately 110 mg/dL).

In patients with impaired awareness of hypoglycaemia the risk of severe hypoglycaemia is greatly increased. The usual therapeutic goals need to be modified and frequent self-monitoring of blood glucose is mandatory. Therapy-induced impaired awareness of hypoglycaemia is usually reversible if glycaemic control is relaxed and hypoglycaemia avoided completely.

Diabetes in pregnancy

Maternal glucose metabolism changes during normal pregnancy to meet the nutritional demands of the developing fetus. Pregnant women develop marked insulin resistance, particularly in the second half of pregnancy. Fasting plasma glucose decreases slightly, while post-prandial blood glucose may be increased. The renal threshold for glycosuria (p. 805) is reduced in pregnancy.

Gestational diabetes

Gestational diabetes is defined as diabetes with first onset or recognition during pregnancy. While this definition will include a small number of women with pre-existing (and previously clinically undetected) type 1 or type 2 diabetes, the majority of women can expect to return to normal glucose tolerance immediately after pregnancy. Risk factors for gestational diabetes are shown in Box 21.26.

Controversy surrounds the precise glucose levels at which gestational diabetes should be diagnosed and the most appropriate screening method for its detection. A number of factors have led to this difficulty. Firstly, a continuous relationship exists between maternal blood glucose and risk of adverse perinatal outcomes, with no easily definable 'threshold' of increased risk. Secondly, labelling a woman as having gestational diabetes may increase certain adverse outcomes such as caesarean section as doctors respond to a perceived increased risk. Finally, the risk of gestational diabetes and adverse outcomes varies widely between populations due to differing prevalences of underlying risk factors (see Box 21.26); this variation affects the sensitivity and specificity of screening programmes (p. 5). Screening practice varies between countries, although the WHO suggests that all women who meet the criteria for impaired glucose tolerance or diabetes after a 75g OGTT (see Box 21.10, p. 806) should be classified as having gestational diabetes.

Implications for the mother

Gestational diabetes is managed where possible by dietary modification, particularly by reducing consumption of refined carbohydrates (see Box 21.26). Blood glucose is monitored closely and insulin is introduced if glycaemic control is unsatisfactory. In certain cases metformin or glibenclamide (the only sulphonylurea that

21.26 Diabetes in pregnancy

Gestational diabetes

- **Glucose metabolism:** insulin resistance occurs in normal pregnancy, particularly in the second half. Gestational diabetes develops when the pancreas is unable to secrete sufficient insulin to compensate for the insulin resistance.
- **Risk factors:** include obesity, ethnicity (South Asian, black, Hispanic, Native American), family history of type 2 diabetes, previous glucose abnormalities during pregnancy and previous macrosomia.
- **Treatment:** strict glycaemic control is required, if possible by dietary modification, particularly reducing consumption of refined carbohydrates. Metformin can be useful. Insulin is often required.
- **Monitoring:** as below for established diabetes in pregnancy, except for items marked *.
- **Inadequate control:** risks increasing fetal size and perinatal morbidity.

Pregnancy in women with established diabetes

- **Glucose metabolism:** insulin doses must be increased substantially to overcome physiological insulin resistance.
- **Pre-conception preparation:** strict glycaemic control very early in pregnancy prevents fetal malformations. Pregnancy should be planned: folic acid supplementation is introduced before conception and patients with type 2 diabetes should usually be converted to insulin therapy. If possible, use basal-bolus insulin regimens.
- **Monitoring:**
 - Frequent self-monitoring of blood glucose, including post-prandial measurements, plus HbA_{1c}.
 - Maintain strict glycaemic control, i.e. HbA_{1c} close to the non-diabetic range. Do not strive for normoglycaemia at the expense of hypoglycaemia.
 - Check blood glucose periodically during the night.
 - Check overnight sample of urine for ketones regularly; increase intake of carbohydrate and dose of insulin to eliminate ketonuria.
 - Microalbuminuria* and retinal screening* should be performed on three occasions during the pregnancy.
 - Regular monitoring of fetal size, and screening for fetal abnormalities*.
- **Inadequate control:** early risks are congenital malformations and later risks are increased fetal size, neonatal hypoglycaemia and increased perinatal morbidity.

does not cross the placenta) is used. Other oral hypoglycaemic drugs are not used in pregnancy.

Gestational diabetes is associated with an increased risk of later development of type 2 diabetes in the mother. The risk is as high as 50% at 5 years in certain ethnic groups such as Hispanic women in the USA but is lower in Caucasian populations. Women with gestational diabetes should have glucose tolerance re-assessed after pregnancy (generally at 6 weeks post-partum or later). If post-partum glucose tolerance has returned to normal (fasting glucose < 6.1 mmol/L (110 mg/dL) and 2 hour glucose < 7.8 mmol/L (140 mg/dL)) advice on lifestyle changes should be given to minimise the long-term risk of developing type 2 diabetes. When glucose intolerance persists after pregnancy in a patient with a strong family history of diabetes, the presence of one of the rare autosomal dominant forms of diabetes (MODY, p. 805) should be considered.

Implications for the fetus

A clear relationship exists between maternal blood glucose and perinatal morbidity for the baby. Maternal glucose crosses the placenta and is an important fuel for the developing fetus. An elevated maternal blood glucose promotes fetal insulin production and hence stimulates fetal growth (macrosomia), which may complicate labour and delivery, resulting in a higher caesarean section rate. Fetal hyperinsulinaemia may also result in neonatal hypoglycaemia. Reduction of maternal blood glucose by insulin therapy can reduce fetal growth.

Pregnancy in women with established diabetes

Historically, pregnancy in patients with type 1 diabetes was associated with a very high incidence of morbidity for mother and child. In the 1940s and 1950s perinatal mortality rates were of the order of 40–50% and maternal mortality could be as high as 5%. Dramatic improvements in these outcomes for mother and child have been driven by the introduction of home monitoring of blood glucose, dietetic advice, modern intensive regimens for insulin delivery using either multiple injections or infusion pumps, improved obstetrical management and the support of a multidisciplinary team.

Type 2 diabetes in pregnancy used to be rare, but the increased prevalence of obesity and the emergence of type 2 diabetes in younger patients have increased its occurrence in women of reproductive age in most populations. The risk of complications and adverse outcomes in women with type 2 diabetes appears to be as high as those for women with type 1 diabetes.

Maternal hyperglycaemia early in pregnancy (during the first 6 weeks of development) has teratogenic effects. These include cardiac, renal and skeletal malformations, of which the caudal regression syndrome is the most characteristic. All women with diabetes should, if possible, be offered pre-pregnancy counselling and encouraged to achieve excellent glycaemic control before becoming pregnant (see Box 21.26). Later in pregnancy maternal hyperglycaemia is associated with macrosomia and neonatal hypoglycaemia, as described above for gestational diabetes.

Ideally, mothers should attempt to maintain near-normal glycaemia while avoiding hypoglycaemia in advance of conception and throughout all of pregnancy (see Box 21.26), but this is often difficult to achieve. Pregnancy is also associated with an increased potential for ketosis, particularly, but not exclusively, in women with type 1 diabetes. Ketoacidosis during pregnancy is dangerous for the mother and is associated with a high rate (10–35%) of fetal mortality.

Pregnancy is also associated with a worsening of diabetic complications, most notably retinopathy and nephropathy, so careful monitoring of eyes and kidneys is required throughout pregnancy.

While the outlook for mother and child has been vastly improved, pregnancy outcomes are still not equivalent to those of non-diabetic mothers. Perinatal mortality rates remain 3–4 times those of the non-diabetic population (at around 30–40 per 1000 pregnancies) and the rate of congenital malformation is increased 5–6-fold.

Hyperglycaemia in acute myocardial infarction

Hyperglycaemia is often found in patients who have sustained an acute myocardial infarction. In some, this represents stress hyperglycaemia (p. 806), some have previously undiagnosed diabetes, and many have established diabetes. Many patients with stress hyperglycaemia will have impaired glucose tolerance on a subsequent glucose tolerance test. There is much that can be done to reduce mortality from myocardial infarction in those with diabetes (Box 21.27). Hyperglycaemia should be treated with insulin and, in patients with type 2 diabetes, oral anti-diabetic drugs should be stopped in the peri-infarct period. Studies have suggested that good glycaemic control using insulin therapy for type 2 diabetes in patients with acute myocardial infarction may reduce their long-term mortality from coronary heart disease.

21.27 Treatments to reduce mortality from myocardial infarction in people with diabetes

Primary prevention of myocardial infarction

- Strict glycaemic control
- Aggressive control of hypertension
- Cholesterol reduction with a statin

Immediate measures in acute myocardial infarction

- Primary angioplasty or thrombolysis/fibrinolysis
- Aspirin and clopidogrel
- ACE inhibitor
- β -blocker
- ? Intravenous insulin

Secondary prevention of myocardial infarction

- Aspirin
- β -blocker
- ACE inhibitor
- Cholesterol reduction with high-dose statin
- Intensive subcutaneous insulin or anti-diabetic medication

Surgery and diabetes

Surgery, whether performed electively or in an emergency, causes catabolic stress and secretion of counter-regulatory hormones both in normal and in diabetic subjects. This results in increased glycogenolysis, gluconeogenesis, lipolysis, proteolysis and insulin resistance. In the non-diabetic person these metabolic effects lead to a secondary increase in the secretion of insulin, which exerts a restraining and controlling influence. In diabetic patients either there is absolute deficiency of insulin (type 1 diabetes) or insulin secretion is delayed and impaired (type 2 diabetes), so that in untreated or poorly controlled diabetes the uptake of metabolic substrate is significantly reduced, catabolism is increased and ultimately metabolic decompensation in the form of diabetic ketoacidosis may develop in both types of diabetes. Starvation exacerbates this process by increasing lipolysis. In addition, hyperglycaemia impairs phagocytic function (leading to reduced resistance to infection) and wound healing.

Thus surgery must be carefully planned and managed in the diabetic patient, with particular emphasis on good metabolic control and avoidance of hypoglycaemia, which is especially dangerous in the unconscious or semiconscious patient.

Pre-operative assessment

Careful pre-operative assessment is mandatory (Box 21.28). Much of this can be done as an outpatient but, if cardiovascular or renal function is impaired, there are signs of neuropathy (particularly autonomic), diabetic control is poor or alterations need to be made to the patient's usual treatment, then admission to hospital some days before operation is required.

21.28 How to assess diabetic patients pre-operatively

- Assess cardiovascular and renal function
- Check for features of neuropathy, particularly autonomic
- Assess glycaemic control
 - Measure HbA_{1c}
 - Monitor pre-prandial and bedtime blood glucose
- Review treatment of diabetes
 - Modify insulin regimen if necessary; use intermediate and short-acting insulins
 - Stop metformin and long-acting sulphonylureas; replace with insulin if necessary

Perioperative management

The management of diabetic patients undergoing surgery requiring general anaesthesia is summarised in Figure 21.10. Post-operatively, a glucose/insulin/potassium infusion should be continued until the patient's intake of food is adequate, when the normal insulin or tablet regimen can be resumed. If the intravenous infusion has to be continued for more than 24 hours, plasma electrolytes and urea should be measured and urinary ketones checked daily. If the infusion is prolonged, the concentration of potassium may require adjustment, and if dilutional hyponatraemia occurs, a parallel saline infusion may be necessary. If fluids need to be restricted, e.g. in patients with cardiovascular or renal disease, the rate of infusion can be halved by using a 20% dextrose solution and doubling the concentration of insulin and potassium. The insulin requirement is likely to be higher than that indicated in Figure 21.10 in patients with hepatic disease, obesity or sepsis and in those being treated with corticosteroids or undergoing cardiopulmonary bypass surgery.

Surgical emergencies

If the patient is significantly hyperglycaemic and/or ketoacidotic, this should be corrected first with an intravenous infusion of saline and/or dextrose plus insulin, 6 U/hour, with potassium as required. Subsequent treatment is as described in Figure 21.10.

Diabetes management if emergency surgery is required in a patient with well-controlled insulin-treated

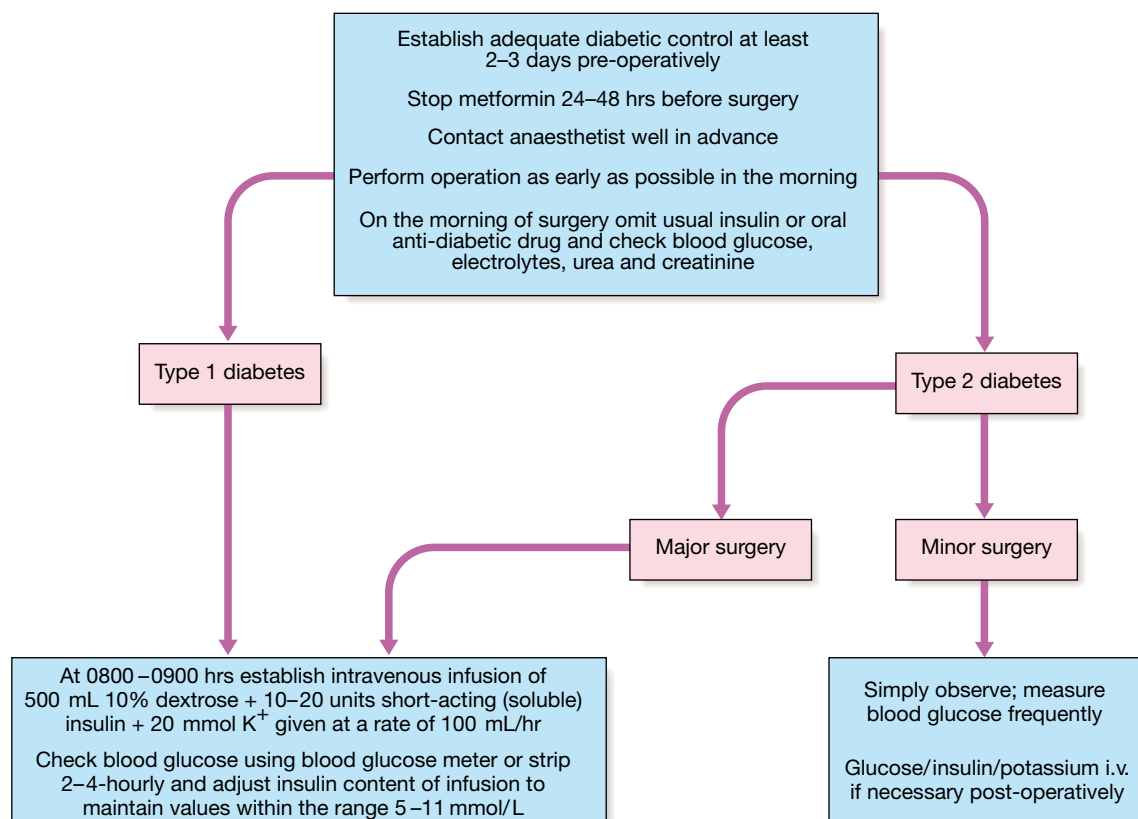

Fig. 21.10 Management of diabetic patients undergoing surgery and general anaesthesia. (Glucose of 5–11 mmol/L \approx 90–199 mg/dL.)

diabetes depends on when the last subcutaneous injection of insulin was given. If this was recent, an infusion of dextrose alone may be sufficient, but frequent monitoring is essential.

Children, adolescents and young adults with diabetes

Children and teenagers generally have type 1 diabetes, but more cases of type 2 diabetes in obese children are now appearing, and the possibility of a diagnosis of MODY (p. 805) should also be considered. The management of diabetes in children and adolescents presents particular challenges which should be addressed in specialised paediatric clinics. Insulin therapy and diet require modification to accommodate the physiological changes associated with growth and puberty and the physical and emotional challenges of adolescence. Adherence to prescribed treatment may be erratic, and glycaemic control often deteriorates during adolescence.

Wide fluctuations in blood glucose and frequent metabolic emergencies occur in a few adolescents and young adults, but use of the term 'brittle diabetes' should be discouraged, as this is not considered to be a pathological entity. The problem (mostly affecting young women) is usually associated with persistent manipulation of therapy (stopping insulin or taking excessive doses) to induce recurrent diabetic ketoacidosis or severe hypoglycaemia requiring hospital admission. This

attention-seeking behaviour may be a manifestation of psychological disturbance (p. 251).

Complications of diabetes

Patients with long-standing diabetes are at risk of developing a variety of complications of the disorder (Box 21.29). Moreover, as many as 25% of people with type 2 diabetes have evidence of diabetic complications at the time of initial diagnosis. Thus, diabetes may be first suspected when a patient visits an optometrist or podiatrist, or presents with hypertension or a vascular event such as an acute myocardial infarction or stroke. Blood glucose should therefore be checked in all patients presenting with such pathology. The detailed investigation and management of diabetic complications are described on pages 824–834.

MANAGEMENT OF DIABETES

In new cases of diabetes, adequate glycaemic control can be obtained by diet and lifestyle advice alone in approximately 50%, 20–30% will need oral anti-diabetic medication, and 20–30% will require insulin. Regardless of aetiology, the choice of treatment is determined by the adequacy of residual β -cell function. However, this cannot be determined easily by measurement of circulating plasma insulin concentration because a level which is adequate in one patient may be inadequate in another, depending upon sensitivity to insulin. Consideration of the features in Box 21.12 (p. 807), and in particular the age and weight of the patient at diagnosis, usually indicate the type of treatment required. However, in each individual the regimen adopted is effectively a therapeutic trial and should be reviewed regularly.

The ideal management for diabetes would allow the person to lead a completely normal life, to remain not only symptom-free but in good health, to achieve a normal metabolic state and to escape the long-term complications of diabetes. This is achievable to a variable degree. Setting individual goals for each patient is discussed on page 809.

Patients whose glycaemic control deteriorates after a period of satisfactory control are not a homogeneous group; they include some with late-onset type 1 diabetes who develop an absolute deficiency of insulin, some with type 2 diabetes whose β -cell failure is advanced, and others who are not adhering to the recommended diet. The most common precipitant of deteriorating glycaemic control is decreasing care with diet, usually associated with weight gain. Weight loss suggests worsening β -cell function. During continuing follow-up many patients will require combinations of anti-diabetic drugs to obtain satisfactory glycaemic control.

Diet and lifestyle

The importance of lifestyle changes such as undertaking regular physical activity, observing a healthy diet and reducing alcohol consumption should not be underestimated in improving glycaemic control, but many people, particularly the middle-aged and elderly, find

21.29 Complications of diabetes	
Microvascular/neuropathic	
Retinopathy, cataract	
• Impaired vision

Cerebral circulation	
• Transient ischaemic attack	• Stroke
Peripheral circulation	
• Claudication	• Ischaemia

21.30 Aims of dietary management

- Achieve good glycaemic control
- Reduce hyperglycaemia and avoid hypoglycaemia
- Assist with weight management:
 - Weight maintenance for type 1 diabetes and non-obese type 2 diabetes
 - Weight loss for overweight and obese type 2 diabetes
- Reduce the risk of micro- and macrovascular complications
- Ensure adequate nutritional intake
- Avoid 'atherogenic' diets or those that aggravate complications, e.g. high protein intake in nephropathy

them difficult to sustain. Patients should also be encouraged to stop smoking.

Dietary measures are required in the treatment of all people with diabetes. The aims are shown in Box 21.30. People with diabetes should have access to dietitians at diagnosis, review and at times of treatment change. Nutritional advice should be tailored to individuals and take account of their age and lifestyle. Structured education programmes are available for both common types of diabetes.

Composition of the diet

Recommended dietary composition is summarised in Box 21.31 (see also p. 107). Consumption of fruit and vegetables should be encouraged as components of a healthy diet.

Carbohydrate

Traditionally, people with diabetes, especially type 1 diabetes, have been advised to maintain a regular intake of carbohydrate in meals throughout the day. The development of modern insulin regimens, particularly using insulin analogues or continuous subcutaneous insulin infusion (CSII), has allowed greater flexibility in the timing and choice of carbohydrate intake. It is now possible to match the amount of carbohydrate in a meal with a dose of short-acting insulin using methods such as DAFNE (dose adjustment for normal eating), although this is demanding and requires extensive patient education. This approach enables motivated individuals with type 1 diabetes to achieve and maintain good glycaemic control, while avoiding post-prandial hyper- and hypoglycaemia.

21.31 Recommended composition of diet for people with diabetes

Dietary constituent	Percentage of energy intake
Carbohydrate	45–60%
Sucrose	Up to 10%
Fat (total)	< 35%
n-6 Polyunsaturated	< 10%
n-3 Polyunsaturated	Eat 1 portion (140g) oily fish once or twice weekly
Monounsaturated	10–20%
Saturated	< 10%
Protein	10–15% (do not exceed 1 g/kg body weight)
Fruit/vegetables	5 portions daily

Fig. 21.11 A 'plate model' for meal planning. The plate is divided into three sections. The smallest section (one-fifth of total area) is for the meat, fish, eggs or cheese, and the remainder divided in roughly equal proportions between the staple food (rice, pasta, potatoes, bread etc.) and vegetables or fruit.

For people with type 2 diabetes, limitation of refined carbohydrate and restriction of total caloric intake is important, and a 'plate model' (Fig. 21.11) can provide a simple visual aid to show the proportions of carbohydrate and other food groups for selection at mealtimes.

Both the amount and source of carbohydrate determine post-prandial glucose (p. 109). The glycaemic index (GI) of a carbohydrate-containing food is a measure of the change in blood glucose following its ingestion. Different foods can be ranked by their effect on post-prandial glycaemia. Consumption of foods with a low GI is encouraged because they produce a slow, gradual rise in blood glucose. Examples include starchy foods such as basmati rice, spaghetti, porridge, noodles, granary bread, and beans and lentils. However, different methods of food processing and preparation can influence the GI of foods, as can the ripeness of some foods and differences in strains of rice. In addition, GI is limited to assessing the effect of consuming types of carbohydrate, and does not address the total amount consumed.

Fat

The intake of total fat should be restricted to less than 35% of energy intake, with less than 10% as saturated fat, and 10–20% from monounsaturated fat through consumption of oils and spreads made from olive, rapeseed or groundnut oils (see Box 21.31). The influence of dietary fats on plasma lipid profile and cardiovascular disease is discussed on page 110.

Diabetic foods and sweeteners

Low-calorie and sugar-free drinks are useful for patients with diabetes. These drinks usually contain non-nutritive sweeteners. Many 'diabetic foods' contain sorbitol, are expensive and high in calories, and may cause gastrointestinal side-effects. As a result, these foods are not recommended as part of the diabetic diet.

Salt

People with diabetes should follow the advice given to the general population: namely, to reduce sodium intake to no more than 6g daily.

Weight management

In patients with diabetes, weight management is a key factor, as a high percentage of people with type 2 diabetes are overweight or obese, and many anti-diabetic drugs including insulin encourage weight gain. Obesity, particularly central obesity with increased waist circumference, also predicts insulin resistance and cardiovascular risk.

Management of obesity is described on pages 118–121. Weight loss can be achieved through a reduction in energy intake and an increase in energy expenditure through physical activity. Some people find group motivation in a slimming club to be helpful when attempting to lose weight and this is appropriate for most patients with type 2 diabetes. Patients on oral anti-diabetic drugs, and especially those on insulin, may need to adjust their therapy when changing their diet.

Exercise

Diabetic patients should be strongly encouraged to take regular physical activity, in the form of walking, gardening, swimming or cycling, for approximately 30 minutes daily, as this improves insulin sensitivity and the lipid profile and lowers blood pressure.

Alcohol

Alcohol can be consumed in moderation unless there is a coexisting medical problem that requires abstinence. As alcohol suppresses gluconeogenesis, it can precipitate or protract hypoglycaemia, particularly in patients taking insulin or sulphonylureas. In the UK the weekly recommended limits are a maximum of 14U for women and 21 U for men, a unit being defined as half a pint of beer/lager, a measure of spirits or a small glass of wine. Drinks containing alcohol can be a substantial (and often overlooked) source of calories and total intake may have to be reduced to assist weight reduction.

Anti-diabetic drugs

Various drugs are effective in reducing hyperglycaemia in patients with type 2 diabetes (Fig. 21.12). Although their mechanisms of action are different, most depend upon a supply of endogenous insulin and therefore have little

hypoglycaemic effect in patients with type 1 diabetes. Metformin and sulphonylureas have been the mainstay of treatment for many years and have the strongest evidence of preventing complications of diabetes. However, newer agents include the α -glucosidase inhibitors, the thiazolidinediones and the dipeptidyl peptidase 4 inhibitors. These drugs may be used as monotherapy or in combinations as dual or triple therapy, but adherence to prescribed medication is best when few drugs are used, preferably with once-daily administration. The effects of these drugs are compared in Box 21.32.

Biguanides

Metformin is the only biguanide available. Its long-term benefits were shown in the UKPDS (p. 826), and it is now widely used as first-line therapy for type 2 diabetes, irrespective of body weight. Metformin is also used increasingly as an adjunct to insulin therapy in obese patients with type 1 diabetes. However, it is less well tolerated than sulphonylureas because of a higher incidence of side-effects, particularly gastrointestinal symptoms.

Mechanism of action

The mechanism of action of metformin has not been precisely defined. It has no hypoglycaemic effect in non-diabetic individuals, but in diabetes, insulin sensitivity and peripheral glucose uptake are increased, possibly through inhibition of mitochondrial respiration and activation of AMP-regulated kinase (AMPK) in muscle. There is some evidence that it also impairs glucose absorption by the gut and inhibits hepatic gluconeogenesis. Although secretion of some endogenous insulin is mandatory for its glucose-lowering action, it does not increase insulin secretion and seldom causes hypoglycaemia.

Indications for use

Administration of metformin is not associated with a rise in body weight and it may be beneficial for the overweight or obese patient. In addition, as the glucose-lowering effect of metformin is synergistic with that of sulphonylureas, the two can be combined when either alone has proved inadequate. It can also be given in combination with most other anti-diabetic medications. Metformin is given with food, usually starting with

Fig. 21.12 Principal modes and sites of action of pharmacological treatments for type 2 diabetes.

21.32 Effects of anti-diabetic drugs used in the treatment of type 2 diabetes

	Insulin	Sulphonylureas and meglitinides	Metformin	Acarbose	Thiazolidinediones	Incretin-based therapies
Reduce basal glycaemia	Yes	Yes	Yes	Slightly	Yes	Yes

Tolerability	Good	Good	Moderate	Moderate	Good	Moderate

500 mg 12-hourly, gradually increased as required to a maximum of 1 g 8-hourly.

Metformin can increase susceptibility to lactic acidosis. Its use is contraindicated in patients with impaired renal or hepatic function and in those who drink alcohol in excess in whom the risk of lactic acidosis is significantly increased. It should be discontinued, at least temporarily, if any other serious medical condition develops, especially one causing severe shock or hypoxaemia. In such circumstances, treatment with insulin should be substituted.

Sulphonylureas

Mechanism of action

Sulphonylureas are 'insulin secretagogues' that act through a specific receptor which is linked to a K^+ channel on the surface of pancreatic β cells. K^+ transport triggers insulin secretion.

Indications for use

Sulphonylureas are valuable in the treatment of non-obese patients with type 2 diabetes who fail to respond to dietary measures alone. Although sulphonylureas will lower the blood glucose concentration of obese patients with type 2 diabetes, such patients should be treated energetically in the first instance by dietary measures with or without metformin, since treatment with sulphonylureas is often associated with an increase in weight which will exacerbate insulin resistance.

The main differences between the individual compounds lie in their potency, duration of action and cost. Tolbutamide, the mildest of the first-generation sulphonylureas, is very well tolerated. Its duration of action is relatively short, it is usually administered 8- or 12-hourly, and it is a useful drug in the elderly in whom the risk and the consequences of inducing hypoglycaemia are greater. Chlorpropamide has a biological half-life of about 36 hours and is taken once daily, but may cause severe and prolonged hypoglycaemia and is rarely used.

Of the second-generation sulphonylureas, gliclazide and glipizide cause few side-effects, but glibenclamide is prone to induce severe hypoglycaemia and should be avoided in the elderly. Newer long-acting preparations

such as glimepiride and a modified-release form of glipizide can be administered once daily with no apparent increased risk of hypoglycaemia. The dose-response of all sulphonylureas is steepest at low doses; little additional hypoglycaemic benefit is obtained when the dose is increased to maximal levels. Several drugs can potentiate the hypoglycaemic effect of sulphonylureas by displacing them from their plasma protein-binding sites, e.g. salicylates, phenylbutazone and antifungal agents.

Meglitinides

These insulin secretagogues are called prandial glucose regulators. Repaglinide directly stimulates endogenous insulin secretion through the sulphonylurea receptor and is taken immediately before food. It is less likely to cause hypoglycaemia than sulphonylureas. Nateglinide has a similar mode of action, restores first-phase insulin secretion, and can be prescribed with metformin.

Alpha-glucosidase inhibitors

The α -glucosidase inhibitors delay carbohydrate absorption in the gut by selectively inhibiting disaccharidases. Acarbose and miglitol are available and are taken with each meal. Both lower post-prandial blood glucose and modestly improve overall glycaemic control. They can be combined with a sulphonylurea. The main side-effects are flatulence, abdominal bloating and diarrhoea. They are used widely in the Far East but infrequently in the UK.

Thiazolidinediones

Mechanism of action

These drugs (also called TZD drugs, 'glitazones' or PPAR γ agonists) bind and activate peroxisome proliferator-activated receptor- γ , a nuclear receptor present mainly in adipose tissue that regulates the expression of several genes involved in metabolism. TZDs enhance the actions of endogenous insulin, partly directly (in the adipose cells) and partly indirectly (by altering release of 'adipokines' such as adiponectin and resistin which alter insulin sensitivity in the liver). Plasma insulin concentrations are not increased and hypoglycaemia does not occur.

Indications for use

Pioglitazone or rosiglitazone are usually prescribed as second-line therapy with metformin, or as third-line therapy in combination with sulphonylurea and metformin (known as 'triple therapy'). However, their use as monotherapy and in combination with insulin is increasing.

TZDs are most likely to be effective in patients with pronounced insulin resistance (e.g. in abdominal obesity) and redistribute fat away from the abdominal stores and into subcutaneous depots. However, body weight and total body fat are increased by TZDs.

A clinical study and meta-analysis have shown that pioglitazone reduces myocardial infarctions and strokes, so may benefit patients with cardiovascular disease. However, rosiglitazone may slightly increase acute ischaemic events, so should be avoided in patients with coronary heart disease.

TZDs have significant side-effects. The first drug of this class, troglitazone, had to be withdrawn because of hepatotoxicity and newer TZDs are avoided in patients with liver dysfunction, but it appears that this effect was specific to troglitazone. An important side-effect of all TZDs is sodium and fluid retention, which is aggravated if they are combined with insulin. TZDs must be avoided in patients with cardiac failure. They also increase upper limb fractures, mainly in women.

Incretin-based therapies

The secretion of insulin in response to a rise in blood glucose is greater when glucose is given by mouth than by intravenous infusion. In part this is caused by secretion of gut hormones, or incretins, which potentiate glucose-induced insulin secretion. Glucagon-like peptide (GLP-1) is an incretin hormone which stimulates insulin secretion in a glucose-dependent manner; thus hypoglycaemia does not occur. In addition, GLP-1 suppresses glucagon secretion, delays gastric emptying, reduces appetite and encourages weight loss.

As GLP-1 is rapidly degraded by the enzyme, dipeptidyl peptidase 4, inhibitors of this enzyme can be used to prolong its biological effect. The DPP-4 inhibitors or gliptins (sitagliptin, vildagliptin and saxagliptin) are oral agents which act in this manner. They are weight-neutral and have few side-effects.

Synthetic GLP-1 receptor antagonists with longer therapeutic action include exenatide (synthetic exendin-4) and liraglutide but, although they have the advantage of inducing weight loss in most patients, they have to be given daily by subcutaneous injection and may cause nausea. Pancreatitis is a rare complication of treatment with exenatide. Long-acting GLP-1 receptor antagonists are being evaluated, which will be administered once weekly.

Incretin-based therapies are most useful in obese patients and can be used in combination with other oral anti-diabetic agents.

Insulin therapy**Manufacture and formulation**

Insulin was discovered in 1921 and transformed the management of type 1 diabetes, until then a fatal disorder. Until the 1980s insulin was obtained by extraction and purification from pancreata of cows and pigs

**21.33 Duration of action (in hours) of insulin preparations**

Insulin	Onset	Peak	Duration
Rapid-acting (insulin analogues: lispro, aspart, glulisine)	< 0.5	0.5–2.5	3–4.5
Short-acting (soluble (regular))	0.5–1	1–4	4–8
Intermediate-acting (isophane (NPH), lente)	1–3	3–8	7–14
Long-acting (bovine ultralente)	2–4	6–12	12–30
Long-acting (insulin analogues: glargine, detemir)	1–2	None	18–24

(bovine and porcine insulins), and some patients still prefer to use animal insulins. Recombinant DNA technology enabled large-scale production of human insulin. More recently, the amino acid sequence of insulin has been altered to produce analogues of insulin, which differ in their rate of absorption from the site of injection.

The duration of action of short-acting, unmodified insulin ('soluble' or 'regular' insulin), which is a clear solution, can be extended by the addition of protamine and zinc at neutral pH (isophane or NPH insulin) or excess zinc ions (lente insulins). These modified 'depot' insulins are cloudy preparations. Pre-mixed formulations containing short-acting and isophane insulins in various proportions are available. The pharmacokinetics of these various insulins are shown in Box 21.33.

In most countries, the insulin concentration in available formulations has been standardised at 100 U/mL.

Subcutaneous multiple dose insulin therapy

In most patients, insulin is injected subcutaneously several times a day into the anterior abdominal wall, upper arms, outer thighs and buttocks (Box 21.34). Accidental intramuscular injection often occurs in children and thin adults. The rate of absorption of insulin may be influenced by many factors other than the insulin formulation, including the site, depth and volume of injection, skin temperature (warming), local massage and exercise. Absorption is delayed from areas of lipohypertrophy at injection sites (p. 797), which results from the local trophic action of insulin, so repeated injection at the same site should be avoided. Other routes of administration (intravenous and intraperitoneal) are reserved for specific circumstances.

Insulin can be administered using a disposable plastic syringe with a fine needle (which can be reused several times) in preference to the traditional glass syringe

**21.34 How to inject insulin subcutaneously**

- Needle sited at right angle to the skin
- Subcutaneous (not intramuscular) injection
- Delivery devices: glass syringe (requires re-sterilisation), plastic syringe (disposable), pen device, infusion pump

and metal needle which require repeated sterilisation. Pen injectors with insulin in cartridge form are popular and convenient and are also available as pre-loaded disposable pens.

Short-acting insulin has to be injected at least 30 minutes before a meal to allow adequate time for absorption. Many patients find this inconvenient and ignore this requirement. However, the rapidly absorbed fast-acting insulin analogues can be administered immediately before, during or even after meals, and their peak action coincides more closely with the post-prandial rise in blood glucose (see Box 21.33).

Once absorbed into the blood, insulin has a half-life of a few minutes. It is removed mainly by the liver and also the kidneys; plasma insulin concentrations are elevated in patients with liver disease or renal failure. The rate of clearance is also affected by binding to insulin antibodies (associated with the use of animal insulins).

The complications of insulin therapy are listed in Box 21.35; the most important of these is hypoglycaemia (p. 812). A common problem is fasting hyperglycaemia ('the dawn phenomenon') associated with the normal circadian rhythm and causing release of counter-regulatory hormones during the later part of the night, which antagonise insulin action before waking.

21.35 Side-effects of insulin therapy

- Hypoglycaemia
- Weight gain
- Peripheral oedema (insulin treatment causes salt and water retention in the short term)
- Insulin antibodies (animal insulins)
- Local allergy (rare)
- Lipodystrophy at injection sites

Insulin dosing regimens

The choice of regimen depends on the desired degree of glycaemic control, the severity of underlying insulin deficiency, the patient's lifestyle, and his or her ability to adjust the insulin dose. The time-action profile of different insulin regimens, compared to the secretory pattern of insulin in the non-diabetic state, is shown in Figure 21.13. Most people require two or more injections of insulin daily. Once-daily injections rarely achieve satisfactory glycaemic control and are reserved either for some elderly patients or for those who retain substantial endogenous insulin secretion and have a low insulin requirement.

Twice-daily administration of a short-acting and intermediate-acting insulin (usually soluble and isophane insulins), given in combination before breakfast and the evening meal, is the simplest regimen and is still used commonly. Individual doses vary considerably but usually two-thirds of the total daily requirement of insulin is given in the morning in a ratio of 1:2, short-intermediate-acting insulins. The remaining third is given in the evening, and doses are adjusted according to blood glucose measurements. Several pre-mixed formulations are available containing different proportions of soluble and isophane insulins (e.g. 30:70 and 50:50). These are useful for patients who have difficulty mix-

Fig. 21.13 Profiles of plasma insulin associated with different insulin regimens. The schematic profiles are compared with the insulin responses (mean \pm standard deviation) observed in non-diabetic adults, shown in the top panel (shaded area). These are theoretical patterns of plasma insulin and may differ considerably in magnitude and duration of action between individuals.

ing insulins, but are inflexible as the individual components cannot be adjusted independently, and require to be resuspended by shaking the vial several times before administration.

Multiple injection regimens are popular, with short-acting insulin being taken before each meal (usually by en injector), and intermediate- or long-acting insulin being injected once or twice daily (basal-bolus regimen). This type of regimen allows greater freedom of timing of meals and more variable day-to-day physical activity, but snacks may have to be taken between meals to prevent hypoglycaemia.

Alternative insulin therapies

'Open-loop' systems are battery-powered portable pumps providing continuous subcutaneous or intravenous infusion of insulin without reference to the blood glucose concentration. The rate of insulin infusion is variable and can be pre-programmed to match diurnal variation in requirements and manually boosted at mealtimes. In practice, the 'loop' is closed by the patient performing blood glucose estimations, and the use of these devices requires a high degree of patient motivation. These increasingly sophisticated systems can achieve excellent glycaemic control but widespread therapeutic use is limited by cost. Advanced models linked to a miniaturised glucose sensor to provide a closed loop system are not widely available.

Alternative routes of insulin delivery have been investigated. Intrapulmonary insulin by inhalation for the treatment of type 2 diabetes is effective, but has not been commercially viable and may be associated with an increased risk of lung cancer. Transdermal and even oral insulin therapies are being explored.

Combined oral anti-diabetic therapy and insulin

In patients with type 2 diabetes who are requiring increasing doses of oral anti-diabetic drugs, the introduction of a single dose of an intermediate- (e.g. isophane) or long-acting insulin analogue, administered at bedtime, may improve glycaemic control and delay the development of overt pancreatic β -cell failure. The exogenous insulin suppresses hepatic glucose output during the night and lowers fasting blood glucose. This treatment is ineffective in diabetic patients who have no residual endogenous insulin secretion. The combination of bedtime isophane insulin with metformin is the regimen least likely to promote weight gain.

Transplantation

Whole pancreas transplantation is carried out in a small number of patients with diabetes each year, but it presents problems relating to the exocrine pancreatic secretions and long-term immunosuppression is necessary. While results are steadily improving, they remain less favourable than for renal transplantation. At present the procedure is usually undertaken only in patients with end-stage renal failure who require a combined pancreas/kidney transplantation in whom diabetes control is particularly difficult, e.g. because of recurrent hypoglycaemia.

Transplantation of isolated pancreatic islets (usually into the liver via the portal vein) has been achieved safely in an increasing number of centres around the world. Progress is being made towards meeting the needs of supply, purification and storage of islets, but the problems of transplant rejection, and of destruction by the patient's autoantibodies against β cells, remain. Nevertheless, the development of methods of inducing tolerance to transplanted islets and the potential use of stem cells means that this may still prove the most promising approach in the long term.

LONG-TERM COMPLICATIONS OF DIABETES

The long-term results of treatment of diabetes are disappointing in many patients. Although a few diabetic patients die from acute metabolic complications (ketoacidosis and hypoglycaemia), the major problem is the excess mortality and serious morbidity suffered as a result of the long-term complications of diabetes (see Box 21.29, p. 818). The factors associated with these are listed in Box 21.36.

As shown in Box 21.37, excess mortality in diabetes is caused mainly by large blood vessel disease, particularly myocardial infarction and stroke. Macrovascular disease also causes substantial morbidity from myocardial infarction, stroke, angina, cardiac failure and intermittent claudication. The pathological changes associated with atherosclerosis in diabetic patients are similar to those seen in the non-diabetic population but they occur earlier in life and are more extensive and severe. Diabetes amplifies the effects of the other major cardiovascular risk factors: smoking, hypertension and dyslipidaemia (Fig. 21.14). Moreover, patients with type 2 diabetes are more likely to have additional cardiovascular risk factors, which co-segregate in the metabolic (insulin resistance) syndrome (see Box 21.4, p. 802).

Disease of small blood vessels is a specific complication of diabetes and is termed diabetic microangiopathy. It contributes to mortality through renal failure caused by diabetic nephropathy, and is responsible for substantial morbidity and disability: for example, blindness

21.36 Factors associated with increased mortality and morbidity in people with diabetes

- Duration of diabetes
- Early age at onset of disease
- High glycated haemoglobin (HbA_{1c})
- Raised blood pressure
- Proteinuria; microalbuminuria
- Dyslipidaemia
- Obesity

21.37 Mortality in diabetes

Risk versus non-diabetic controls (mortality ratio)

• Overall	2.6
• Coronary heart disease	} 2.8
• Cerebrovascular disease	
• Peripheral vascular disease	
• All other causes, including renal failure	2.7

Causes of death in diabetes (approximate proportion)

• Cardiovascular disease	70%
• Renal failure	10%
• Cancer	10%
• Infections	6%
• Diabetic ketoacidosis	1%
• Other	3%

6-year mortality
per 1000

Fig. 21.14 Diabetes mellitus as a risk factor for coronary heart disease (CHD). Three major factors—smoking, hypertension and dyslipidaemia—are associated with risk of CHD in the general population. The presence of diabetes mellitus produces an increment in risk in addition to these conventional factors (p. 580).

from diabetic retinopathy, difficulty in walking, chronic ulceration of the feet from peripheral neuropathy, and bowel and bladder dysfunction from autonomic neuropathy. Positive correlations exist between the duration and degree of sustained hyperglycaemia, however caused and at whatever age it develops, and the risk of microvascular disease.

Pathophysiology

The histopathological hallmark of diabetic microangiopathy is thickening of the capillary basement membrane, with associated increased vascular permeability throughout the body. The development of the characteristic clinical syndromes of diabetic retinopathy, nephropathy, neuropathy and accelerated atherosclerosis is thought to result from the local response to the generalised vascular injury. For example, in the wall of large vessels, increased permeability of arterial endothelium, particularly when combined with hyperinsulinaemia and hypertension, may increase the deposition of atherogenic lipoproteins.

The mechanisms linking hyperglycaemia to these pathological changes are, however, poorly characterised. Functional abnormalities found in long-standing, poorly controlled diabetes include endothelial dysfunction, haemodynamic disturbances, haemorrhological and coagulation abnormalities, microvascular hypertension and increased capillary permeability. Some of the numerous biochemical abnormalities are shown in Figure 21.15. It is thought that increased metabolism of glucose to sorbitol via the polyol pathway is of central importance in pathogenesis, since haemodynamic, vascular permeability and structural changes in capillaries are preventable in diabetic animals by treatment with a variety of structurally different aldose-reductase inhibitors which inhibit this process.

Preventing diabetes complications

Glycaemic control

The possibility of reversing early microvascular disease by improving metabolic control has been examined in several prospective randomised controlled clinical trials involving patients with early background retinopathy and minimal proteinuria. None of these

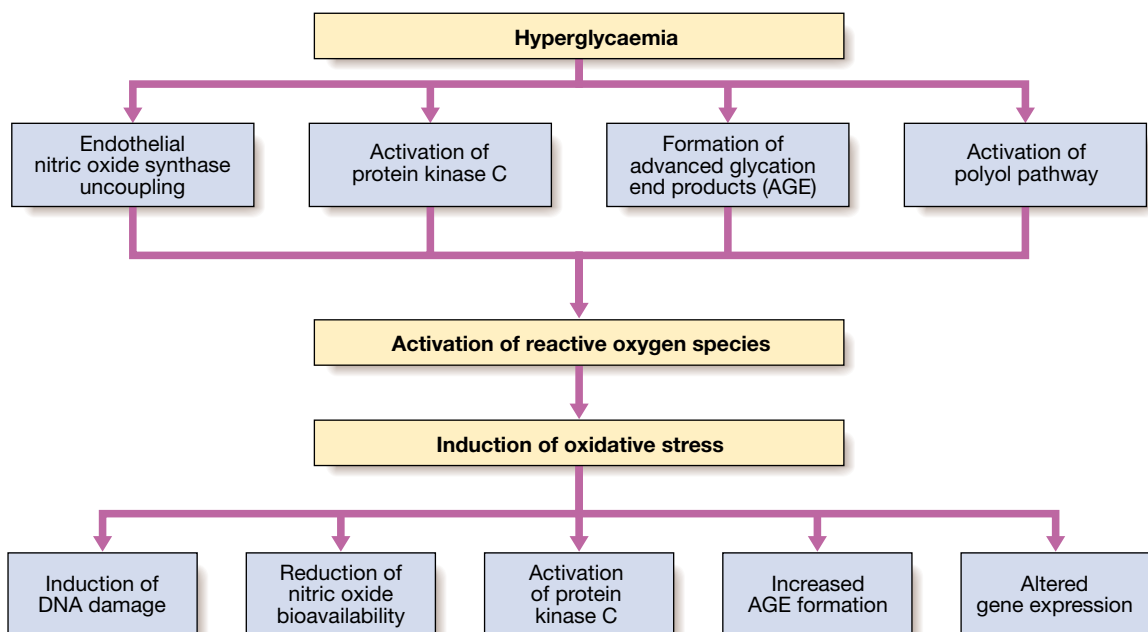

Fig. 21.15 The roles of hyperglycaemia-induced accumulation of reactive oxygen species and oxidative stress in causation of diabetic vascular complications. The induction of oxidative stress causes haemodynamic changes and endothelial and vascular dysfunction, leading to vascular damage.

studies produced any evidence of reversal of either retinopathy or nephropathy, and in some cases retinopathy worsened abruptly soon after control was improved. Despite this, in the long term the rate of progression of both retinopathy and nephropathy was reduced by maintaining good glycaemic control. These studies stimulated a search for markers of early reversible retinal, renal and neural dysfunction, and shifted the emphasis in the management of diabetes to primary prevention of complications.

The Diabetes Control and Complications Trial (DCCT) was a large study that lasted 9 years in type 1 diabetic patients. There was a 60% overall reduction in the risk of developing diabetic complications in those on intensive therapy with strict glycaemic control (mean HbA_{1c} around 7%), compared with those on conventional therapy (mean HbA_{1c} around 9%, Box 21.38). No single factor other than glycaemic control had a significant effect on outcome. A large study of patients with type 2 diabetes, the UK Prospective Diabetes Study (UKPDS), also showed that the frequency of diabetic complications is lower and progression is slower with good glycaemic control and effective treatment of hypertension, irrespective of the type of therapy used (Box 21.39). These landmark trials demonstrated that diabetic complications are preventable and that the aim of treatment should be 'near-normal' glycaemia.

However, in the patients with strict glycaemic control in the DCCT, weight gain was common and severe hypoglycaemic episodes occurred three times more often. Although there was no detectable increase in deaths, major macrovascular events or neurological/cognitive defects, this increased risk of hypoglycaemia may alter

EBM 21.38 Glycaemic control in type 1 diabetes

'In patients with type 1 diabetes, strict glycaemic control (mean HbA_{1c} 7%) reduced the development of retinopathy and other microvascular complications by 76% compared with conventional therapy (mean HbA_{1c} 9%). On longer-term follow-up strict glycaemic control also reduced cardiovascular events, including myocardial infarction, stroke and death from cardiovascular disease.'

21.40 Diabetes management in old age

- **Glycaemic control:** the optimal target for glycaemic control in older people has yet to be determined. Strict glycaemic control should be avoided in very frail patients.
- **Cognitive and affective function:** may benefit from improving glycaemic control.
- **Hypoglycaemia:** older people have reduced symptomatic awareness of hypoglycaemia and limited knowledge of symptoms, and are at greater risk of, and from, hypoglycaemia.
- **Mortality:** the mortality rate of older people with diabetes is more than double that of age-matched non-diabetic people, largely because of increased deaths from cardiovascular disease.

the risk:benefit ratio of good control in certain patients. Thus less intensive treatment may be indicated in:

- those with impaired awareness of hypoglycaemia
- those with severe macrovascular disease (particularly if they have a past history of myocardial infarction or cerebrovascular accident)
- those at the extremes of life (very young children and the frail elderly, Box 21.40).

Control of other risk factors

Randomised controlled trials have shown that aggressive management of blood pressure minimises the microvascular and macrovascular complications of diabetes. ACE inhibitors are valuable in improving outcome in heart disease and in preventing diabetic nephropathy (p. 829). The management of dyslipidaemia with a statin limits macrovascular disease in people with diabetes. This often results in the necessary use of multiple medications, which augments the problem of adherence to therapy by patients.

Other approaches

There are new approaches to preventing diabetic complications which have been effective in animal models. Aldose-reductase inhibitors have been disappointing in clinical trials. Aminoguanidine, an inhibitor of the formation of advanced glycation end-products, prevents damage to the retina, kidney, nerve and artery in diabetic animals. It has low toxicity and may be applicable for human use. Protein kinase C inhibitors have been shown to limit diabetic retinopathy and nephropathy in humans and are undergoing clinical trials.

Diabetic retinopathy

Diabetic retinopathy is one of the commonest causes of blindness in adults between 30 and 65 years of age in developed countries. Retinal photocoagulation is an effective treatment, particularly if it is given at a relatively early stage when the patient is usually symptomless. Expert annual examination of the fundi is therefore mandatory in all diabetic patients.

Pathogenesis

Hyperglycaemia increases retinal blood flow and metabolism and has direct effects on retinal endothelial cells and pericyte loss, which impairs vascular autoregulation. The resulting uncontrolled blood flow initially dilates capillaries but also increases production of vasoactive substances and endothelial cell proliferation,

resulting in capillary closure. This causes chronic retinal hypoxia and stimulates production of growth factors, including vascular endothelial growth factor (VEGF), which plays a major role in stimulating the deleterious changes of endothelial cell growth (causing new vessel formation) and increased vascular permeability (causing retinal leakage and exudation).

Clinical features

These are listed in Box 21.41. They occur in varying combinations in different patients and are used to classify the severity of retinopathy and assess the need for specialist referral, as shown in Box 21.42.

21.41 Clinical features of diabetic retinopathy

- Microaneurysms
- Retinal haemorrhages (dot and blot)
- Exudates
- Cotton wool spots
- Venous changes
- Neovascularisation (retina and iris)
- Pre-retinal/subhyaloid haemorrhage
- Vitreous haemorrhage
- Fibrosis/gliosis

Microaneurysms

In most cases these are the earliest clinical abnormality detected. They appear as tiny, discrete, circular, dark red dots near to, but apparently separate from, the retinal vessels (Fig. 21.16A). They look like tiny haemorrhages but they are in fact minute aneurysms arising mainly

from the venous end of capillaries. They may give rise to retinal leakage of plasma constituents.

Haemorrhages

These most characteristically occur in the deeper layers of the retina and hence are round and regular in shape and described as 'blot' haemorrhages (see Fig. 21.16A). The smaller ones may be difficult to differentiate from microaneurysms and the two are often grouped together as 'dots and blots'. Superficial flame-shaped haemorrhages in the nerve fibre layer may also occur, particularly if the patient is hypertensive.

Exudates

These are characteristic of diabetic retinopathy. They vary in size from tiny specks to large confluent patches and tend to occur particularly in the perimacular area (Fig. 21.16B). They result from leakage of plasma from abnormal retinal capillaries and overlie areas of neuronal degeneration. The terms 'hard' exudates and 'soft' exudates (i.e. cotton wool spots) are no longer recommended.

Cotton wool spots

These are similar to retinal changes that occur in hypertension, and also occur particularly within five disc diameters of the optic disc (Fig. 21.16E). They represent arteriolar occlusions causing retinal ischaemia and, if numerous, may represent pre-proliferative diabetic retinopathy; they are most often seen in rapidly advancing retinopathy or in association with uncontrolled hypertension.

Fig. 21.16 Diagrammatic representation of diabetic eye disease. **A** Background diabetic retinopathy showing microaneurysms and blot haemorrhages. **B** Background retinopathy showing exudates. **C** Maculopathy showing oedema. **D** Maculopathy with exudates. **E** Pre-proliferative retinopathy showing venous changes and cotton wool spots. **F** Proliferative retinopathy showing neovascularisation.

21.42 Classification of diabetic retinopathy based on prognosis for vision

Type of retinopathy	Prognosis	Action required
Non-proliferative 'background' retinopathy without maculopathy		
Venous dilatation	No immediate threat to vision	Maximise control of blood glucose, lipids and blood pressure
Peripheral		Give advice to stop smoking and reduce intake of alcohol
Microaneurysms		On first appearance inform diabetes team and carers
Blot haemorrhages		Observe carefully, i.e. fundoscopy with dilated pupils every 6–12 mths
Exudates		Refer for specialist opinion if rate of progression increases significantly
Maculopathy		
Macula	Sight-threatening	Refer for specialist opinion
Exudation		Medical review of risk factors, glycaemic control, blood pressure and lipid levels
Haemorrhage		
Ischaemia		
Oedema		
Pre-proliferative retinopathy		
Venous loops and beading	Sight-threatening	Refer for specialist opinion
Clusters/sheets of microaneurysms and small blot haemorrhages and/or large retinal haemorrhages		At this stage rapid lowering of the blood glucose may result in abrupt worsening of retinopathy with the appearance of cotton wool spots and an increased number of haemorrhages; it may be safer to lower the blood glucose gradually over a period of months
Intra-retinal microvascular abnormalities		
Multiple cotton wool spots		
Macular oedema with reduced visual acuity		
Perimacular exudates ± retinal haemorrhages of any size		
Proliferative retinopathy		
Pre-retinal haemorrhage	Sight-threatening	Urgent review and treatment by specialist is mandatory
Neovascularisation		
Fibrosis		
Exudative maculopathy		

Intra-retinal microvascular abnormalities

Intra-retinal microvascular abnormalities (IRMA) are dilated, tortuous capillaries which develop in severe pre-proliferative retinopathy. They represent the remaining patent capillaries in an area of ischaemic retina where most have been occluded.

Venous changes

These include venous dilatation (an early feature probably representing increased blood flow), 'beading' (sausage-like changes in calibre) and increased tortuosity, sometimes in the form of 'oxbow lakes' or loops. These latter changes indicate widespread non-perfusion of capillaries and are a feature of severe pre-proliferative retinopathy.

Neovascularisation

New vessel formation may arise from the venous circulation either on the optic disc (NVD) or elsewhere in the retina (NVE), in response to widespread retinal ischaemia. The earliest appearance is that of fine tufts of delicate vessels forming arcades on the surface of the retina (Fig. 21.16F). As they grow, they may extend forwards on to the posterior surface of the vitreous. They are fragile and leaky, and are liable to rupture during vitreous movement, causing a pre-retinal ('subhyaloid') or a vitreous haemorrhage. New vessels may be symptomless until haemorrhage occurs, when there may be sudden visual loss. Serous products leaking from these new vessels stimulate a connective tissue reaction, called gliosis

and fibrosis. This first appears as a white, cloudy haze among the network of new vessels. As it extends, the new vessels may be obliterated and the surrounding retina is covered by a dense white sheet. By this stage, haemorrhage is less common but retinal detachment can occur through traction on adhesions formed between the vitreous and the retina, causing serious visual impairment.

Rubeosis iridis

Proliferative retinopathy and severe ocular ischaemia may be accompanied by the development of new vessels on the anterior surface of the iris: 'rubeosis iridis'. These vessels may obstruct the drainage angle of the eye and the outflow of aqueous fluid, causing secondary glaucoma.

Loss of visual acuity

Microaneurysms, abnormalities of the veins, and small blot haemorrhages and exudates situated in the periphery will not interfere with vision unless they are associated with oedema and thickening in the macular area.

Macular oedema should be suspected if there is impairment of visual acuity, even if this is associated with only mild peripheral non-proliferative retinopathy and no other obvious pathology. Macular oedema can only be confirmed or excluded on slit lamp retinal biomicroscopy. If macular changes are observed by direct ophthalmoscopy or retinal photography, referable maculopathy should be suspected.

Sudden visual loss occurs with vitreous haemorrhage or retinal detachment. In pre-proliferative and proliferative retinopathy, whether or not visual acuity is impaired, prompt laser treatment is important to reduce the risk of haemorrhage, fibrosis/gliosis and severe irreversible visual impairment.

Prevention

Glycaemic, blood pressure and lipid profile control

Risk factors for retinopathy include early onset and long duration of diabetes, hypertension, poor glycaemic control, pregnancy, use of the oral contraceptive pill, smoking, excessive alcohol consumption and evidence of microangiopathy elsewhere, particularly neuropathy and nephropathy. Good glycaemic control, particularly in the early years following the development of diabetes, reduces the risk of developing retinopathy.

Hyperglycaemia promotes retinal hyperperfusion, so a rapid reduction in blood glucose may cause an initial deterioration of retinopathy by causing relative ischaemia. Improvement in glycaemic control should therefore be effected gradually. The rate of progression of retinopathy is significantly slower in intensively treated patients than in matched control subjects after a 12–18-month period.

Blood pressure lowering is of proven benefit in hypertensive patients, and there may be specific benefit from angiotensin II receptor antagonists. While the effect of statins in retinopathy is limited, clinical trials have suggested that fibrates treatment may reduce the requirement for laser therapy in type 2 diabetes.

Screening

Annual screening for retinopathy is essential in all diabetic patients as the disease is asymptomatic in the early stages, when treatment is most effective. Screening is particularly important in those with risk factors. It should be undertaken by trained personnel in an organised and audited programme. The preferred method is a digital photographic system for retinal imaging, with prompt referral of patients with sight-threatening retinopathy to an ophthalmologist for examination with slit lamp biomicroscopy. If direct ophthalmoscopy is used, the pupils should be dilated for adequate examination. Unfortunately, many people with diabetes receive no regular supervision and do not attend for eye screening.

Management

Severe retinopathy is treated with retinal photocoagulation (laser treatment), which has been shown to reduce severe visual loss by 85% (50% in patients with maculopathy). Photocoagulation is used:

- to treat leaking microaneurysms and areas of retinal thickening in the macular area, and to reduce macular oedema (focal laser)
- to destroy areas of retinal ischaemia and hence lower intra-ocular levels of VEGF which play a major role in the development of neovascularisation
- to reduce the risk of recurrent haemorrhage by inducing gliosis and fibrosis of new vessels (pan-retinal photocoagulation (PRP)).

Argon laser photocoagulation is the usual method used for PRP and focal treatment. This simple procedure can be carried out under topical anaesthesia. Patients should be reviewed regularly to look for further development of new vessels and/or maculopathy. Extensive

bilateral photocoagulation can cause significant visual field loss, which may interfere with driving ability and reduce night vision.

Vitrectomy may be used in selected cases with advanced diabetic eye disease where visual loss has been caused by recurrent vitreous haemorrhage that has failed to clear or by retinal detachment resulting from retinitis proliferans (extensive glial/fibrous tissue on the retina). Rubeosis iridis is a severe complication requiring early and extensive PRP.

Other causes of visual loss in people with diabetes

Around 50% of visual loss in people with type 2 diabetes results from causes other than diabetic retinopathy. These include cataract, age-related macular degeneration, retinal vein occlusion, retinal arterial occlusion, non-arteritic ischaemic optic neuropathy and glaucoma. Some of these conditions are to be expected in this group as they relate to cardiovascular risk factors (e.g. hypertension, hyperlipidaemia and smoking), all of which are prevalent in people with type 2 diabetes.

Cataract

Cataract is a permanent lens opacity and is a common cause of visual deterioration in the elderly. The lens thickens and opacifies with age; with diabetes, the increased metabolic insult to the lens causes these changes to accelerate and occur prematurely. A rare type of 'snow-flake' cataract occurs in young patients with poorly controlled diabetes. This does not usually affect vision but tends to make fundal examination difficult.

The indications for cataract extraction are similar to those for the non-diabetic population and depend on the degree of visual impairment. An additional indication in diabetes is when adequate assessment of the fundus, or laser treatment to the retina, is prevented. The usual method of extraction is by phakoemulsification, with implantation of an intra-ocular lens.

Diabetic nephropathy

Diabetic nephropathy is an important cause of morbidity and mortality, and is now among the most common causes of end-stage renal failure (ESRF) in developed countries. As it is found with other microvascular and macrovascular complications, management is frequently difficult. The benefits of prevention are substantial.

About 30% of patients with type 1 diabetes have developed diabetic nephropathy 20 years after diagnosis, but the risk after this time falls to less than 1% per year, and from the outset the risk is not equal in all patients (Box 21.43). Epidemiological data have indicated that the overall

21.43 Risk factors for developing diabetic nephropathy

- Poor control of blood glucose
- Long duration of diabetes
- Presence of other microvascular complications
- Ethnicity (e.g. Asian races, Pima Indians)
- Pre-existing hypertension
- Family history of diabetic nephropathy
- Family history of hypertension

Fig. 21.17 Natural history of diabetic nephropathy. In the first few years of type 1 diabetes mellitus there is hyperfiltration which declines fairly steadily to return to a normal value at approximately 10 years (blue line). In susceptible patients (about 30%), after about 10 years there is sustained proteinuria and by approximately 14 years it has reached the nephrotic range (red line). Renal function continues to decline, with the end stage being reached at approximately 16 years.

Fig. 21.18 Nodular diabetic glomerulosclerosis. There is thickening of basement membranes and mesangial expansion, and a Kimmelstiel–Wilson nodule (arrow).

incidence is declining as standards of glycaemic and blood pressure control have improved.

The pattern of progression of renal abnormalities in diabetes is shown schematically in Figure 21.17. Pathologically, the first changes coincide with the onset of microalbuminuria and include thickening of the glomerular basement membrane and accumulation of matrix material in the mesangium. Subsequently, nodular deposits (Fig. 21.18) are characteristic, and glomerulosclerosis worsens as heavy proteinuria develops, until glomeruli are progressively lost and renal function deteriorates.

Diagnosis and screening

Microalbuminuria (Box 21.44) is an important indicator of the risk of developing overt diabetic nephropathy, although it is also found in other conditions (p. 481). Microalbuminuria is therefore most reliable as an indicator of incipient diabetic nephropathy within the first 10 years of type 1 diabetes, when the majority of patients with microalbuminuria will progress to overt nephropathy within a further 10 years. It is a less reliable predictor of nephropathy in older patients with type 2 diabetes, in whom it may be accounted for by other

21.44 Screening for microalbuminuria (MA)

- Identifies incipient nephropathy in type 1 and type 2 diabetes; independent predictor of macrovascular disease in type 2 diabetes
- Risk factors include increased blood pressure, poor glycaemic control, smoking
- Random urine sample can estimate urinary albumin:creatinine ratio (MA values 3–30 mg/mmol (27–270 µg/mg)); normal range (mg/mmol) differs in males (< 2.5) and females (< 3.5)
- If possible, confirm MA with a timed collection of urine (overnight or 24 hrs) to quantify the albumin excretion rate (AER) (MA values 20–200 µg/min or 30–300 mg/24 hrs)

Who to screen

- Patients with type 1 diabetes annually from 5 yrs after diagnosis
- Patients with type 2 diabetes annually from time of diagnosis

Abnormal results

- Exclude recent (24 hrs) vigorous exercise, fever, heart failure, urine infection, prostatitis, menstruation
- Confirm observation twice within 3–6 mths
- Look for blood pressure above target levels

diseases, although it is a potentially useful marker of an increased risk of macrovascular disease. Nevertheless, progressively increasing albuminuria, or albuminuria accompanied by hypertension, is most likely to be due to early diabetic nephropathy.

Management

If there is evidence of incipient nephropathy, vigorous efforts should be made to reduce the risk of progression and of cardiovascular disease by:

- improved control of blood glucose
- aggressive reduction of blood pressure
- aggressive cardiovascular risk factor reduction (Box 21.45).

In type 1 diabetes ACE inhibitors have been shown to provide greater benefit than equal blood pressure reduction achieved with other drugs (p. 609), and subsequent studies have shown similar benefits from angiotensin II receptor blockers in patients with type 2 diabetes. There may be particular problems with the use of either in diabetic nephropathy because of hyperkalaemia (p. 440) and renal artery stenosis (p. 496). Non-dihydropyridine calcium antagonists (diltiazem, verapamil) may be suitable alternatives.

Diabetic control becomes difficult as renal impairment progresses. Treatment with metformin should be withdrawn when creatinine is higher than 150 µmol/L

EBM 21.45 Multi-risk factor intervention in type 2 diabetes

'In type 2 patients with microalbuminuria, intensive treatment (including control of glycaemia and hypertension, with use of ACE inhibitors, statins and aspirin) reduced the risk of cardiovascular disease by 53%, of nephropathy by 61%, and of retinopathy by 58% compared with conventional treatment. On longer-term follow-up there was a reduction in total mortality and death from cardiovascular causes.'

- Gaede P, et al. *N Engl J Med* 2003; 348:383–393.
- Gaede P, et al. *N Engl J Med* 2008; 358:580–591.

(1.7 mg/dL), as the risk of lactic acidosis is increased. Long-acting sulphonylureas should be replaced by short-acting agents that are metabolised rather than excreted.

Renal replacement therapy (p. 492) may benefit diabetic patients at an earlier stage than other patients with ESRF, although it may carry additional difficulties. Renal transplantation can dramatically improve the life of many, and any recurrence of diabetic nephropathy in the allograft is usually too slow to be a serious problem, but associated macrovascular and microvascular disease elsewhere may still progress. Pancreatic transplantation (generally carried out at the same time as renal transplantation) can produce insulin independence and slow or reverse microvascular disease, but the supply of organs is very limited and this is available to few. For further information on management, see Chapter 17.

Diabetic neuropathy

This is a relatively early and common complication affecting approximately 30% of diabetic patients. Although in a few patients it can cause severe disability, it is symptomless in the majority. Like retinopathy, it occurs secondary to metabolic disturbance, and prevalence is related to the duration of diabetes and the degree of metabolic control. Although there is some evidence that the central nervous system is affected in long-term diabetes, the clinical impact of diabetes is mainly manifested in the peripheral nervous system.

The main pathological features are listed in Box 21.46. They can occur in motor, sensory and autonomic nerves.

Various classifications of diabetic neuropathy have been proposed. One is shown in Box 21.47, but motor, sensory and autonomic nerves may be involved in varying combinations so that clinically mixed syndromes usually occur.

21.46 Diabetic neuropathy: histopathology

- Axonal degeneration of both myelinated and unmyelinated fibres
Early: axon shrinkage
Later: axonal fragmentation; regeneration
- Thickening of Schwann cell basal lamina
- Patchy, segmental demyelination
- Thickening of basement membrane and microthrombi in intraneural capillaries

21.47 Classification of diabetic neuropathy

Somatic

- Polyneuropathy
Symmetrical, mainly sensory and distal
Asymmetrical, mainly motor and proximal (including amyotrophy)
- Mononeuropathy (including mononeuritis multiplex)

Visceral (autonomic)

- Cardiovascular
- Gastrointestinal
- Genitourinary
- Sudomotor
- Vasomotor
- Pupillary

Clinical features

Symmetrical sensory polyneuropathy

This is frequently asymptomatic. The most common clinical signs are diminished perception of vibration sensation distally, 'glove-and-stocking' impairment of all other modalities of sensation, and loss of tendon reflexes in the lower limbs. In symptomatic patients, sensory abnormalities are predominant. Symptoms include paraesthesiae in the feet (and, rarely, in the hands), pain in the lower limbs (dull, aching and/or lancinating, worse at night, and mainly felt on the anterior aspect of the legs), burning sensations in the soles of the feet, cutaneous hyperaesthesia and an abnormal gait (commonly wide-based), often associated with a sense of numbness in the feet. Muscle weakness and wasting develop only in advanced cases, but subclinical motor nerve dysfunction is common. The toes may be clawed with wasting of the interosseous muscles, which results in increased pressure on the plantar aspects of the metatarsal heads with the development of callus skin at these and other pressure points. Electrophysiological tests (p. 1141) demonstrate slowing of both motor and sensory conduction, and tests of vibration sensitivity and thermal thresholds are abnormal.

A diffuse small-fibre neuropathy causes altered perception of pain and temperature, and is associated with symptomatic autonomic neuropathy; characteristic features include foot ulcers and Charcot neuroarthropathy.

Asymmetrical motor diabetic neuropathy

Sometimes called diabetic amyotrophy, this presents as severe and progressive weakness and wasting of the proximal muscles of the lower (and occasionally the upper) limbs. It is commonly accompanied by severe pain, mainly felt on the anterior aspect of the leg, and hyperaesthesia and paraesthesiae. Sometimes there may also be marked loss of weight ('neuropathic cachexia'). The patient may look extremely ill and be unable to get out of bed. Tendon reflexes may be absent on the affected side(s). Sometimes there are extensor plantar responses and the cerebrospinal fluid protein is often raised. This condition is thought to involve acute infarction of the lower motor neurons of the lumbosacral plexus. Other lesions involving this plexus, such as neoplasms and lumbar disc disease, must be excluded. Although recovery usually occurs within 12 months, some deficits become permanent. Management is mainly supportive.

Mononeuropathy

Either motor or sensory function can be affected within a single peripheral or cranial nerve. Unlike the gradual progression of distal symmetrical and autonomic neuropathies, mononeuropathies are severe and of rapid onset but they eventually recover. The nerves most commonly affected are the 3rd and 6th cranial nerves (resulting in diplopia), and the femoral and sciatic nerves. Rarely, involvement of other single nerves results in paresis and paraesthesiae in the thorax and trunk (truncal radiculopathies).

Nerve compression palsies commonly affect the median nerve, giving the clinical picture of carpal tunnel syndrome, and less commonly the ulnar nerve. Lateral popliteal nerve compression occasionally causes foot drop.

Autonomic neuropathy

This is not necessarily associated with peripheral somatic neuropathy. Either parasympathetic or sympathetic

21.48 Clinical features of autonomic neuropathy	
Cardiovascular	
<ul style="list-style-type: none"> • Postural hypotension • Resting tachycardia • Fixed heart rate 	
Gastrointestinal	
<ul style="list-style-type: none"> • Dysphagia, due to oesophageal atony • Abdominal fullness, nausea and vomiting, unstable glycaemia, due to delayed gastric emptying ('gastroparesis') • Nocturnal diarrhoea ± faecal incontinence • Constipation, due to colonic atony 	
Genitourinary	
<ul style="list-style-type: none"> • Difficulty in micturition, urinary incontinence, recurrent infection, due to atonic bladder • Erectile dysfunction and retrograde ejaculation 	
Sudomotor	
<ul style="list-style-type: none"> • Gustatory sweating • Nocturnal sweats without hypoglycaemia • Anhidrosis; fissures in the feet 	
Vasomotor	
<ul style="list-style-type: none"> • Feet feel cold, due to loss of skin vasomotor responses • Dependent oedema, due to loss of vasomotor tone and increased vascular permeability • Bullous formation 	
Pupillary	
<ul style="list-style-type: none"> • Decreased pupil size • Resistance to mydriatics • Delayed or absent reflexes to light 	

21.49 How to test cardiovascular autonomic function			
	Normal	Borderline	Abnormal
Simple reflex tests			
Heart rate responses			
• to Valsalva manoeuvre (15 secs) ¹ : ratio of longest to shortest R–R interval	≥1.21		≤1.20
• to deep breathing (6 breaths over 1 min): maximum–minimum heart rate	≥15	11–14	≤10
• to standing after lying: ratio of R–R interval of 30th to 15th beats	≥1.04	1.01–1.03	≤1.00
Blood pressure response ²			
• to standing: systolic BP fall (mmHg)	≤10	11–29	≥30
Specialised tests			
<ul style="list-style-type: none"> • Heart rate and blood pressure responses to sustained handgrip • Heart rate variability using power spectral analysis of ECG monitoring • Heart rate and blood pressure variability using time-domain analysis of ambulatory monitoring • MIBG (met-iodobenzylguanidine) scan of the heart 			
¹ Omit in patients with previous laser therapy for proliferative retinopathy.			
² Avoid arm with A–V fistula in dialysed patients.			

nerves may be predominantly affected in one or more visceral systems. The resulting symptoms and signs are listed in Box 21.48. Tests of autonomic function are listed in Box 21.49. The development of autonomic neuropathy is less clearly related to poor metabolic control than somatic neuropathy, and improved control rarely results in amelioration of symptoms. Within 10 years of developing overt symptoms of autonomic neuropathy, 30–50% of patients are dead—many from sudden cardiorespiratory arrest, the cause of which is unknown. Patients with postural hypotension (a drop in systolic pressure of ≥30 mmHg on standing from the supine position) have the highest subsequent mortality.

21.50 Management options for peripheral sensorimotor and autonomic neuropathies	
Pain and paraesthesiae from peripheral somatic neuropathies	
<ul style="list-style-type: none"> • Intensive insulin therapy (strict glycaemic control) • Anticonvulsants (gabapentin, pregabalin, carbamazepine, phenytoin) • Tricyclic antidepressants (amitriptyline, imipramine) • Other antidepressants (duloxetine) • Substance P depletor (capsaicin—topical) • Opiates (tramadol, oxycodone) • Membrane stabilisers (mexiletine, intravenous lidocaine) • Antioxidant (α-lipoic acid) 	
Postural hypotension	
<ul style="list-style-type: none"> • Support stockings • Fludrocortisone • α-adrenoceptor agonist (midodrine) • Non-steroidal anti-inflammatory drugs (NSAIDs) 	
Gastroparesis	
<ul style="list-style-type: none"> • Dopamine antagonists (metoclopramide, domperidone) • Erythromycin • Gastric pacemaker; percutaneous enteral (jejunal) feeding (Fig. 5.16, p. 124) 	
Diarrhoea (p. 856)	
<ul style="list-style-type: none"> • Loperamide • Broad-spectrum antibiotics • Clonidine • Octreotide 	
Constipation	
<ul style="list-style-type: none"> • Stimulant laxatives (senna) 	
Atonic bladder	
<ul style="list-style-type: none"> • Intermittent self-catheterisation (p. 1168) 	
Excessive sweating	
<ul style="list-style-type: none"> • Anticholinergic drugs (propantheline, poldine) • Clonidine • Topical antimuscarinic agent (glycopyrrolate cream) 	
Erectile dysfunction (impotence) (p. 477)	
<ul style="list-style-type: none"> • Phosphodiesterase type 5 inhibitors (sildenafil, vardenafil, tadalafil)—oral • Dopamine agonist (apomorphine)—sublingual • Prostaglandin E1 (alprostadil)—injected into corpus cavernosum, or intra-urethral administration of pellets • Vacuum tumescence devices • Implanted penile prosthesis • Psychological counselling; psychosexual therapy 	

Erectile dysfunction

Erectile failure (impotence) affects 30% of diabetic males and is often multifactorial. Although neuropathy and vascular causes are common, psychological factors, including depression, anxiety and reduced libido, may be partly responsible. Alcohol and antihypertensive drugs such as thiazide diuretics and β -adrenoceptor antagonists (β -blockers) may cause sexual dysfunction and, rarely, patients have an endocrine cause such as testosterone deficiency or hyperprolactinaemia. For further information, see page 477.

Management

Management of neuropathies is outlined in Box 21.50.

The diabetic foot

The foot is a frequent site for complications in patients with diabetes and for this reason foot care is particularly important. Tissue necrosis in the feet is a common reason for hospital admission in diabetic patients. Such admissions tend to be prolonged and may end with amputation.

Aetiology

Foot ulceration occurs as a result of trauma (often trivial) in the presence of neuropathy and/or peripheral vascular disease (p. 599), with infection occurring as a secondary phenomenon following disruption of the protective epidermis. The interplay between these factors is shown in Figure 21.19. Most ulcers develop at the site of a plaque of callus skin beneath which tissue necrosis occurs and eventually breaks through to the surface. In most cases multiple components are involved, but sometimes neuropathy or ischaemia predominate, as illustrated in Box 21.51. Ischaemia alone accounts for a minority of foot ulcers in diabetic patients, with most being either neuropathic or neuro-ischaemic in type.

21.51 Clinical features of the diabetic foot

	Neuropathy	Ischaemia
Symptoms	None Paraesthesiae Pain Numbness	None Claudication Rest pain
Structural damage	Ulcer Sepsis Abscess Osteomyelitis Digital gangrene Charcot joint	Ulcer Sepsis Gangrene

Management

The main components of medical management are listed in Box 21.52. Removal of callus skin with a scalpel is usually best done by a podiatrist who has specialist training and experience in diabetic foot problems. Effective treatment of local infection with appropriate antibiotics is essential, and may have to be continued for protracted periods; osteomyelitis may be extremely difficult to eradicate. Charcot neuroarthropathy with disorganisation of joints may cause serious deformity. Angiography may be necessary if the foot is ischaemic or ulcers are very slow to heal. Measures to improve glycaemic control may also promote healing. Amputation may be unavoidable if there is extensive tissue and/or bony destruction or intractable ischaemic pain at rest in a limb in which vascular reconstruction has failed or is impossible due to extensive large blood vessel disease. Further information is given on the management of peripheral arterial disease on page 601. Preventative measures are shown in Box 21.52.

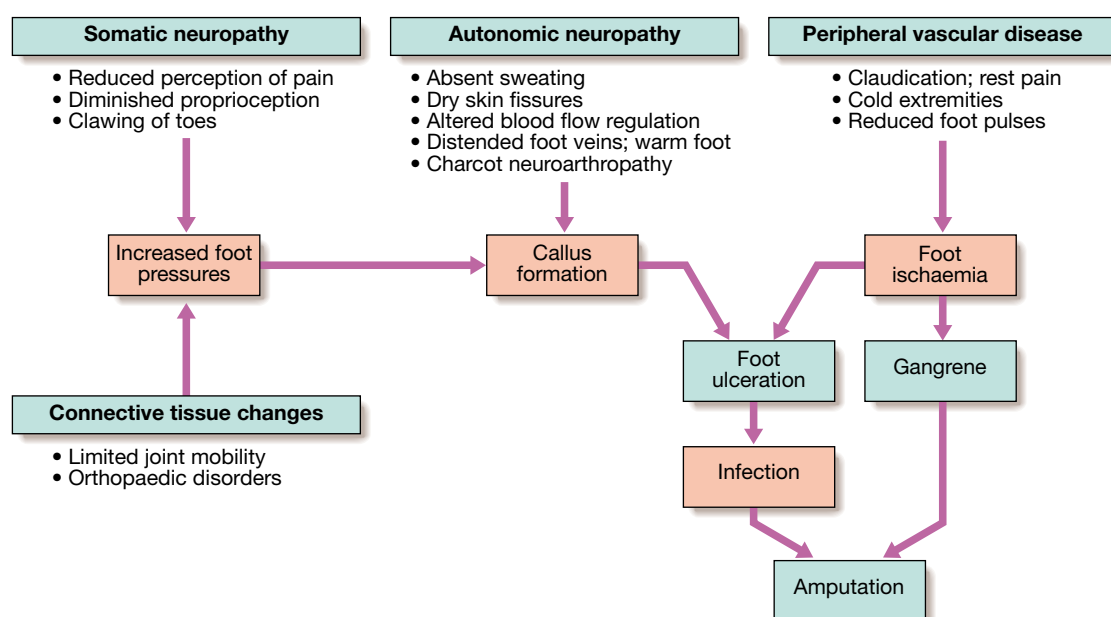

Fig. 21.19 Pathways leading to foot ulceration and amputation in diabetic foot disease.

Box 21.52 Management of diabetic foot ulcers

Prevention

- Prevention is the most effective way of dealing with the problem of tissue necrosis in the diabetic foot. Advice to all diabetic patients includes:
 - Inspect feet every day
 - Wash feet every day
 - Moisturise skin if dry
 - Cut or file toenails regularly
 - Change socks or stockings every day
 - Avoid walking barefoot
 - Check footwear for foreign bodies
 - Wear suitable good-fitting shoes
 - Cover minor cuts with sterile dressings
 - Do not burst blisters
 - Avoid over-the-counter corn/callus remedies
- Advice to high-risk patients is as above plus:
 - Do not attempt corn removal
 - Avoid high and low temperatures
- A podiatrist is an integral part of the diabetes team to ensure regular and effective podiatry and to educate patients in care of the feet
- Specially manufactured and fitted orthotic footwear is required to prevent recurrence of ulceration and protect the feet of patients with Charcot neuroarthropathy

Treatment

- Remove callus
- Treat infection
- Avoid weight-bearing
- Ensure good glycaemic control
- Control oedema
- Undertake angiogram to assess feasibility of vascular reconstruction where indicated

4 Abdominal examination: possible findings

6 Rectal examination: common findings

Diseases of the gastrointestinal tract are a major cause of morbidity and mortality. Approximately 10% of all general practitioner consultations in the United Kingdom are for indigestion, and 1 in 14 is for diarrhoea. Infective diarrhoea and malabsorption are responsible for much ill health and many deaths in the developing world. The gastrointestinal tract is the most common site for cancer development.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Functional anatomy

Oesophagus

This muscular tube extends 25 cm from the cricoid cartilage to the cardiac orifice of the stomach. It has an upper and a lower sphincter. A peristaltic swallowing wave propels the food bolus into the stomach (Fig. 22.1).

Stomach and duodenum (Fig. 22.2)

The stomach acts as a 'hopper', retaining and grinding food, then actively propelling it into the upper small bowel.

Gastric secretion

Hydrogen and chloride ions are secreted from the apical membrane of gastric parietal cells into the lumen of the stomach by a hydrogen-potassium ATPase ('proton pump') (Fig. 22.3). The hydrochloric acid sterilises the upper gastrointestinal tract and converts pepsinogen—which is secreted by chief cells—to pepsin. The glycoprotein intrinsic factor, secreted in parallel with acid, is necessary for vitamin B₁₂ absorption.

Gastrin and somatostatin

The hormone gastrin is produced by G cells in the antrum whereas somatostatin is secreted from D cells through-

out the stomach. Gastrin stimulates whilst somatostatin suppresses acid secretion.

Protective factors

Bicarbonate ions and mucus together protect the gastroduodenal mucosa from the ulcerative properties of acid and pepsin.

Small intestine

The small bowel extends from the ligament of Treitz to the ileocaecal valve (Fig. 22.4). During fasting, a wave of peristaltic activity passes down the small bowel every 1–2 hours. Entry of food into the gastrointestinal tract stimulates small bowel peristaltic activity. Functions of the small intestine are:

- digestion
- absorption—the products of digestion, water, electrolytes and vitamins
- protection against ingested toxins—immunological, mechanical, enzymatic and peristaltic.

Digestion and absorption

Fat

Dietary lipids comprise long chain triglycerides, cholesterol esters and lecithin. Lipids are insoluble in water and undergo lipolysis and incorporation into mixed micelles before they can be absorbed into enterocytes along with the fat-soluble vitamins A, D, K and E. The lipids are processed within enterocytes and pass via lymphatics into the systemic circulation. Fat absorption and digestion can be considered as a stepwise process:

- *Luminal phase* (Fig. 22.5, step 1). Fatty acids stimulate cholecystokinin (CCK) release from the duodenum and upper jejunum. The CCK stimulates release of amylase, lipase, colipase and proteases from the pancreas, causes gallbladder contraction and relaxes the sphincter of Oddi, causing bile to flow into the intestine. Pancreatic lipase, in the presence of its co-factor colipase, cleaves long chain triglycerides,

Fig. 22.1 The oesophagus: anatomy and function. The swallowing wave.

Fig. 22.2 Normal gastric and duodenal anatomy.

Enterochromaffin-like (ECL) cell

Fig. 22.3 Control of acid secretion. Gastrin released from antral G cells in response to food binds to cholecystokinin receptors (CCK-2R) on the surface of enterochromaffin-like (ECL) cells, which in turn release histamine. The histamine binds to H_2 receptors on parietal cells and this leads to secretion of hydrogen ions, in exchange for potassium ions at the apical membrane. Parietal cells also express CCK-2R and it is thought that activation of these receptors by gastrin is involved in regulatory proliferation of parietal cells. Cholinergic (vagal) activity and gastric distension also stimulate acid secretion; somatostatin, vasoactive intestinal polypeptide (VIP) and gastric inhibitory polypeptide (GIP) inhibit it.

yielding fatty acids and monoglycerides (Fig. 22.5, step 2). These are solubilised by interacting with bile salts and phospholipids to form mixed micelles. Mixed micelles also contain cholesterol and fat-soluble vitamins.

- **Absorption.** Mixed micelles diffuse to the brush border of the enterocytes (Fig. 22.5, step 3). Long chain fatty acids there bind to fatty acid-binding proteins and are transported into the cell. Cholesterol, short chain fatty acids, phospholipids and fat-soluble vitamins enter the enterocytes by obscure mechanisms. Bile salts remain in the small intestinal lumen and are actively transported from the terminal ileum into the portal circulation and returned to the liver (the enterohepatic circulation, step 4).
- **Re-esterification** (Fig. 22.5, step 5). Within the enterocyte, fatty acids are re-esterified to form triglycerides. Triglycerides combine with cholesterol ester, fat-soluble vitamins, phospholipids and apoproteins to form chylomicrons.
- **Transport** (Fig. 22.5, step 6). Chylomicrons leave the enterocytes by exocytosis, enter mesenteric lymphatics, pass into the thoracic duct, and eventually reach the systemic circulation.

Carbohydrates

Starch is hydrolysed by salivary and pancreatic amylases to alpha-limit dextrins containing 4–8 glucose molecules; to the disaccharide maltose; and to the trisaccharide maltotriose.

Disaccharides are digested by enzymes fixed to the microvillous membrane to form the monosaccharides glucose, galactose and fructose. Glucose and galactose enter the cell by an energy-requiring process involving a carrier protein, and fructose enters by simple diffusion.

Fig. 22.4 Small intestine: anatomy. Epithelial cells are formed in crypts and differentiate as they migrate to the tip of the villi to form enterocytes (absorptive cells) and goblet cells.

Fig. 22.5 Fat digestion.

Protein

The steps in protein digestion are shown in Figure 22.6. Intra-gastric digestion by pepsin is quantitatively modest but important because the resulting polypeptides and amino acids stimulate CCK release from the mucosa of the proximal jejunum, which in turn stimulates release of pancreatic proteases including trypsinogen, chymotrypsinogen, pro-elastases and procarboxypeptidases from the pancreas. On exposure to brush border enterokinase, inert trypsinogen is converted to the active proteolytic enzyme trypsin which activates the other pancreatic proenzymes. Trypsin digests proteins to produce oligopeptides, peptides and amino acids. Oligopeptides are further hydrolysed by brush border enzymes to yield dipeptides, tripeptides and amino acids. These small peptides and the amino acids are actively transported into the enterocytes where intracellular peptidases further digest peptides to amino acids. Amino acids are then actively transported across the basal cell membrane of the enterocyte into the portal circulation and the liver.

Water and electrolytes

Absorption and secretion of electrolytes and water occur throughout the intestine. Electrolytes and water are transported by two pathways:

- the *paracellular route*, in which passive flow through tight junctions between cells is a consequence of osmotic, electrical or hydrostatic gradients
- the *transcellular route* across apical and basolateral membranes by energy-requiring specific active transport carriers (pumps).

In healthy individuals, fluid balance is tightly controlled such that only 100 mL of the 8 litres of fluid entering the gastrointestinal tract daily is excreted in stools (Fig. 22.7).

Vitamins and trace elements

Water-soluble vitamins are absorbed throughout the intestine. The absorption of folic acid, vitamin B₁₂, calcium and iron is described on pages 1020–1022.

Protective function of the small intestine

Physical defence mechanisms

There are several levels of defence in the small bowel (Fig. 22.8). Firstly, the gut lumen contains host bacteria, mucins and secreted antibacterial products including defensins and immunoglobulins which help combat pathogenic infections. Secondly, epithelial cells have relatively impermeable brush border membranes and passage between cells is prevented by tight and adherens junctions. These cells can react to foreign peptides ('innate immunity') using pattern recognition receptors

Fig. 22.6 Protein digestion.

Fig. 22.7 Fluid homeostasis in the gastrointestinal tract.

found on cell surfaces (Toll receptors) or intracellularly. Lastly, in the subepithelial layer immune responses occur under control of the adaptive immune system in response to pathogenic compounds.

Immunological defence mechanisms

Gastrointestinal mucosa-associated lymphoid tissue (MALT) constitutes 25% of the total lymphatic tissue of the body and is at the heart of adaptive immunity. B lymphocytes within Peyer's patches differentiate to plasma cells following exposure to antigens, and these cells migrate to mesenteric lymph nodes, and thence to the blood stream via the thoracic duct, then returning

Fig. 22.8 Intestinal defence mechanisms. See text for details.

to the lamina propria of the gut, bronchial tree and other lymph nodes. They release IgA which is transported into the lumen of the intestine. Intestinal T lymphocytes probably help localise plasma cells to the site of antigen exposure, as well as producing inflammatory mediators. Macrophages phagocytose foreign materials and secrete a range of cytokines which mediate inflammation. Similarly, activation of mast cell surface IgE receptors leads to degranulation and release of other molecules involved in inflammation.

Pancreas

The exocrine pancreas (Box 22.1) is necessary for the digestion of fat, protein and carbohydrate. Inactive pro-enzymes are secreted from acinar cells in response to circulating gastrointestinal hormones (Fig. 22.9) and are then activated by trypsin. Bicarbonate-rich fluid is secreted from ductular cells to produce an optimum alkaline pH for enzyme activity.

22.1 Pancreatic enzymes		
Enzyme	Substrate	Product
Amylase	Starch and glycogen	Limit dextrans Maltose Maltotriose
Lipase Colipase	Triglycerides	Monoglycerides and free fatty acids
Proteolytic enzymes	Proteins and polypeptides	Short polypeptides
Trypsinogen		
Chymotrypsinogen		
Proelastase		
Procarboxypeptidases		

Colon

The colon (Fig. 22.10) absorbs water and electrolytes. It also acts as a storage organ and has contractile activity. Two types of contraction occur. The first of these is segmentation (ring contraction), which leads to mixing but not propulsion; this promotes absorption of water and electrolytes. Propulsive (peristaltic contraction) waves occur several times a day and propel faeces to the rectum. All activity is stimulated after meals, probably in response to release of motilin and CCK. Faecal continence depends upon maintenance of the anorectal angle and tonic contraction of the external anal sphincters. On defecation there is relaxation of the anorectal muscles, increased intra-abdominal pressure from the Valsalva manoeuvre and contraction of abdominal muscles, and relaxation of the anal sphincters.

Control of gastrointestinal function

Secretion, absorption, motor activity, growth and differentiation of the gut are all modulated by a combination of neuronal and hormonal factors.

22

Fig. 22.9 Pancreatic structure and function. Ductular cells secrete alkaline fluid in response to secretin. Acinar cells secrete digestive enzymes from zymogen granules in response to a range of secretagogues. The photograph shows a normal pancreatic duct (PD) and side branches as defined at magnetic resonance cholangiopancreatography (MRCP). Note the incidental calculi in the gallbladder and common bile duct (arrow).

Fig. 22.10 The normal colon, rectum and anal canal.

The nervous system and gastrointestinal function

The central nervous system (CNS), the autonomic system (ANS) and the enteric nervous system (ENS) interact to regulate gut function. The ANS comprises:

- *parasympathetic pathways* (vagal and sacral efferent), which are cholinergic and generally increase smooth muscle tone and promote sphincter relaxation
- *sympathetic pathways*, which release noradrenaline (norepinephrine), reduce smooth muscle tone and stimulate sphincter contraction.

The enteric nervous system

This comprises two major networks intrinsic to the gut wall. The myenteric (Auerbach's) plexus in the smooth muscle layer regulates motor control; and the submucosal (Meissner's) plexus exerts secretory control over the epithelium, enteroendocrine cells and submucosal vessels. Together these plexuses form a two-layered neuronal mesh along the length of the gut. Although connected centrally via the ANS, the ENS can function autonomously, using a variety of transmitters including acetylcholine, noradrenaline (norepinephrine), 5-hydroxytryptamine (5-HT, serotonin), nitric oxide, substance P and calcitonin gene-related peptide (CGRP). There are local reflex loops within the ENS but also loops involving the coeliac and mesenteric ganglia and the paravertebral ganglia too.

The parasympathetic system generally stimulates motility and secretion while the sympathetic system generally acts in an inhibitory manner.

Peristalsis

Peristalsis is a reflex triggered by gut wall distension, which consists of a wave of circular muscle contraction to propel contents from the oesophagus to the rectum. It can be influenced by innervation but functions independently. It results from a basic electrical rhythm originating from the interstitial cells of Cajal in the circular layer of intestinal smooth muscle. These are stellate cells of mesenchymal origin with smooth muscle features, which act as the 'pacemaker' of the gut.

Migrating motor complexes

Migrating motor complexes (MMC) are powerful waves of contraction spreading from the stomach to the ileum and occurring at a frequency of about 5 per minute every 90 minutes or so, between meals and during fasting. They may serve to sweep intestinal contents distally in preparation for the next meal and are inhibited by eating.

Gut hormones

The origin, action and control of the major gut hormones, peptides and non-peptide signalling transmitters are summarised in Box 22.2.

<div> <div>i</div> <div>22.2 Gut hormones and peptides</div> </div>			
Hormone	Origin	Stimulus	Action
Gastrin	Stomach (G cell)	Products of protein digestion Suppressed by acid and somatostatin	Stimulates gastric acid secretion Stimulates growth of gastrointestinal mucosa
Somatostatin	Throughout GI tract (D cell)	Fat ingestion	Inhibits gastrin and insulin secretion Decreases acid secretion Decreases absorption Inhibits pancreatic secretion
Cholecystokinin (CCK)	Duodenum and jejunum (I cells); also ileal and colonic nerve endings	Products of protein digestion Fat and fatty acids Suppressed by trypsin	Stimulates pancreatic enzyme secretion Gallbladder contraction Sphincter of Oddi relaxation Satiety Decreases gastric acid secretion Reduces gastric emptying Regulates pancreatic growth
Secretin	Duodenum and jejunum (S cells)	Duodenal acid Fatty acids	Stimulates pancreatic fluid and bicarbonate secretion Decreases acid secretion Reduces gastric emptying
Motilin	Duodenum, small intestine and colon (Mo cells)	Fasting Dietary fat	Regulates peristaltic activity including migrating motor complexes (MMC)
Gastric inhibitory polypeptide (GIP)	Duodenum (K cells) and jejunum	Glucose and fat	Stimulates insulin release (also known as glucose-dependent insulinotropic polypeptide) Inhibits acid secretion
Vasoactive intestinal peptide (VIP)	Nerve fibres throughout GI tract	Unknown	Vasodilator Smooth muscle relaxation Water and electrolyte secretion
Ghrelin	Stomach	Fasting Inhibited by eating	May regulate food intake
Guanylin	Small intestine	Unknown	Chloride secretion

INVESTIGATION OF GASTROINTESTINAL DISEASE

A wide range of tests are available for the investigation of patients with gastrointestinal symptoms. These can be classified broadly into tests of structure, tests for infection and tests of function.

Imaging

Plain X-rays

Plain X-rays of the abdomen are useful in the diagnosis of intestinal obstruction or paralytic ileus where dilated loops of bowel and (in the erect position) fluid levels may be seen. Calcified lymph nodes, gallstones and renal stones can also be detected. Chest X-ray is useful in the diagnosis of suspected perforation as it shows sub-diaphragmatic free air.

Contrast studies

X-rays with contrast medium are usually performed under fluoroscopic control to assess motility and to ensure that the patient is positioned correctly. Barium sulphate provides good mucosal coating and excellent opacification but can precipitate impaction proximal to

an obstructive lesion. Water-soluble contrast is used to opacify bowel prior to abdominal computed tomography and in cases of suspected perforation. The double contrast technique improves mucosal visualisation by using gas to distend the barium-coated intestinal surface. Contrast studies are useful for detecting filling defects such as tumours, strictures, ulcers and motility disorders but they are being replaced by endoscopic procedures and by more sophisticated cross-sectional imaging techniques such as computed tomography and magnetic resonance imaging. The major uses and limitations of various contrast studies are shown in Box 22.3 and Figure 22.11.

Ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI)

These are increasingly used in the evaluation of intra-abdominal disease. They are non-invasive and offer detailed images of the abdominal contents. Their main applications are summarised in Box 22.4 and Figure 22.12.

Endoscopy

Videoscopes have controls to allow steering of the tip and also possess channels for suction and insufflation of air and water. Accessories can be passed down the endoscope to allow both diagnostic and therapeutic

22.3 Contrast radiology in the investigation of gastrointestinal disease

	Barium swallow/meal	Barium follow-through	Barium enema
Indications and major uses	Possible motility disorder, e.g. achalasia or gastroparesis Suspected perforation or fistula (non-ionic contrast)	Diarrhoea and abdominal pain of small bowel origin Possible obstruction by strictures Suspected malabsorption Crohn's disease assessment	Altered bowel habit Evaluation of strictures or diverticular disease Megacolon Chronic constipation Suspected colon cancer (but superseded by colonoscopy in practice)
Limitations	Risk of aspiration Poor mucosal detail Low sensitivity for early cancer Inability to biopsy	Time-consuming Radiation exposure Relative insensitivity	Difficulty in frail elderly or incontinent patients Sigmoidoscopy necessary to evaluate rectum Low sensitivity for lesions < 1 cm

Fig. 22.11 Examples of contrast radiology. **A** Non-ionic contrast swallow shows leakage of contrast (arrow) into the mediastinum following stricture dilatation. **B** Barium follow-through. There are multiple diverticula (arrows) in this patient with jejunal diverticulosis. **C** Barium enema showing severe diverticular disease. There is tortuosity and narrowing of the sigmoid colon with multiple diverticula (arrows).

22.4 Ultrasound, computed tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography (PET) in gastroenterology

	Ultrasound	CT	MRI	(CT)-PET
Indications and major uses	Abdominal masses, e.g. cysts, tumours, abscesses Organomegaly Ascites Biliary tract dilatation Gallstones Guided biopsy of lesions	Assessment of pancreatic disease Hepatic tumour deposits CT colonography ('virtual colonoscopy') Tumour staging Assessment of vascularity of lesions Abscesses and collections	Hepatic tumour staging Magnetic resonance cholangiopancreatography (MRCP) Pelvic/perianal disease Crohn's fistulas Small bowel visualisation	Detection of metastases not seen on ultrasound or CT Images can be fused with CT to form composite image (Fig. 22.12D)
Limitations	Low sensitivity for small lesions Little functional information Operator-dependent Gas and obesity may obscure view	Cost Radiation dose Availability	Availability Time-consuming 'Claustrophobic' for some Contraindicated in presence of metallic prostheses, cardiac pacemaker, cochlear implants	Relatively poor localisation of lesions unless combined with CT Signal detection depends on metabolic activity within tumour—not all are metabolically active

Fig. 22.12 Examples of ultrasound, CT and MRI. **A** Ultrasound showing large gallstone (arrow) with acoustic shadowing. **B** Multidetector coronal CT showing large solid and cystic malignant tumour in the pancreatic tail (P). (PV = portal vein; L = liver) **C** Pelvic MRI showing large pelvic abscess (arrow) posterior to the rectum in a patient with Crohn's disease. **D** Fused CT-PET image showing two liver metastases (arrows).

procedures, some of which are illustrated in Figure 22.13. New high-definition endoscopes with magnifying lenses allow almost microscopic detail to be observed, and newer imaging modalities such as autofluorescence and 'narrow band imaging' are increasingly used to detect subtle abnormalities not visible by standard 'white light' endoscopy.

Upper gastrointestinal endoscopy

This is performed under light intravenous benzodiazepine sedation, or using only local anaesthetic throat spray after the patient has fasted for at least 4 hours. With the patient in the left lateral position the entire

oesophagus (excluding pharynx), stomach and first two parts of duodenum can be seen. Indications, contraindications and complications are given in Box 22.5.

Capsule endoscopy

Capsule endoscopy (Fig. 22.14) employs a 26 mm capsule containing an imaging device, battery, transmitter and antenna, which transmits images as it traverses the small intestine to a battery-powered recorder worn on a belt round the patient's waist. After approximately 8 hours the capsule is excreted. Images from the capsule are analysed as a video sequence and it is usually possible to loca-

Fig. 22.13 Examples of therapeutic techniques in endoscopy.

22.5 Upper gastrointestinal endoscopy	
Indications	
<ul style="list-style-type: none"> • Dyspepsia over 55 years of age or with alarm symptoms • Atypical chest pain • Dysphagia • Vomiting • Weight loss • Acute or chronic gastrointestinal bleeding • Suspicious barium meal • Duodenal biopsies in the investigation of malabsorption 	
Contraindications	
<ul style="list-style-type: none"> • Severe shock • Recent myocardial infarction, unstable angina, cardiac arrhythmia* • Severe respiratory disease* • Atlantoaxial subluxation* • Possible visceral perforation 	
Complications	
<ul style="list-style-type: none"> • Cardiorespiratory depression due to sedation • Aspiration pneumonia • Perforation 	
*These are 'relative' contraindications; in experienced hands, endoscopy can be safely performed.	

lise the segment of small bowel in which lesions are seen. Abnormalities detected usually require enteroscopy for confirmation and therapy. Indications, contraindications and complications are listed in Box 22.6.

Fig. 22.14 Wireless capsule endoscopy. [A] Wireless capsule. [B] Capsule endoscopy image of bleeding jejunal vascular malformation (arrow).

22.6 Capsule endoscopy
Indications
<ul style="list-style-type: none"> • Obscure gastrointestinal bleeding • Small bowel Crohn's disease • Assessment of coeliac disease and its complications • Screening and surveillance in familial polyposis syndromes
Contraindications
<ul style="list-style-type: none"> • Known or suspected small bowel stricture (risk of capsule retention) • Caution in people with pacemakers or implantable defibrillators
Complications
<ul style="list-style-type: none"> • Capsule retention (< 1%)

Double balloon enteroscopy

While standard endoscopy can reach the proximal small intestine in most patients, a newer technique called double balloon enteroscopy (DBE, Fig. 22.15) is also available, which uses a long endoscope with a flexible overtube. Sequential and repeated inflation and deflation of balloons on the tip of the overtube and enteroscope allow the operator to push and pull along the entire length of the small intestine to the terminal ileum to diagnose or treat small bowel lesions detected by capsule endoscopy or other imaging modalities. Indications, contraindications and complications are listed in Box 22.7.

Fig. 22.15 Double balloon enteroscopy. The enteroscope and an overtube both have balloons at their tips. Sequential inflation and deflation of the balloons, combined with push and pull movements, allows deep intubation of the small intestine.

22.7 Double balloon enteroscopy
Indications
Diagnostic
<ul style="list-style-type: none"> • Obscure gastrointestinal bleeding • Malabsorption or unexplained diarrhoea • Suspicious radiological findings • Suspected small bowel tumour • Surveillance of polyposis syndromes
Therapeutic
<ul style="list-style-type: none"> • Coagulation/diathermy of bleeding lesions • Jejunostomy placement
Contraindications
<ul style="list-style-type: none"> • As for upper gastrointestinal endoscopy
Complications
<ul style="list-style-type: none"> • As for upper gastrointestinal endoscopy • Post-procedure abdominal pain (up to 20%) • Pancreatitis (1–3%) • Perforation (especially after resection of large polyps)

Sigmoidoscopy and colonoscopy

Sigmoidoscopy can be carried out either in the out-patient clinic using a 20 cm rigid plastic sigmoidoscope or in the endoscopy suite using a 60 cm flexible colonoscope following bowel preparation. When sigmoidoscopy is combined with proctoscopy, accurate detection of haemorrhoids, ulcerative colitis and distal colorectal neoplasia is possible. After full bowel cleansing it is possible to examine the entire colon and often the terminal ileum using a longer colonoscope. Indications, contraindications and complications of colonoscopy are listed in Box 22.8.

Endoscopic retrograde cholangiopancreatography (ERCP)

Using a side-viewing duodenoscope, it is possible to cannulate the main pancreatic duct and common bile duct. ERCP visualises the ampulla of Vater and produces

22.8 Colonoscopy
Indications*
<ul style="list-style-type: none"> • Suspected inflammatory bowel disease • Chronic diarrhoea • Altered bowel habit • Rectal bleeding or anaemia • Assessment of abnormal barium enema • Colorectal cancer screening • Colorectal adenoma follow-up • Therapeutic procedures
Contraindications
<ul style="list-style-type: none"> • Severe, active ulcerative colitis • As for upper gastrointestinal endoscopy
Complications
<ul style="list-style-type: none"> • Cardiorespiratory depression due to sedation • Perforation • Bleeding following polypectomy
*Colonoscopy is not useful in the investigation of constipation.

22.9 Endoscopic retrograde cholangiopancreatography (ERCP)

Indications

Diagnostic ERCP

- Rarely indicated—MRCP/EUS/CT provide excellent images of biliary tree and pancreas
- Occasionally performed when images are equivocal or MRCP is contraindicated

Therapeutic ERCP

- Biliary disease
 - Removal of CBD calculi (N.B. In fit individuals who also require cholecystectomy laparoscopic surgery may be preferred)
 - Palliation of biliary obstruction due to advanced malignant disease
 - Management of biliary leaks/damage complicating biliary surgery
 - Dilatation of benign strictures (e.g. primary sclerosing cholangitis)
- Pancreatic disease
 - Drainage of pancreatic disruption (e.g. pseudocysts, pancreatic fistulas)
 - Removal of pancreatic calculi (selected cases)

Contraindications

- Severe cardiopulmonary comorbidity
- Coagulopathy

Complications

- Occur in 5–10% with a 30-day mortality of 0.5–1%

General

- As for upper endoscopy

Specific

- Biliary disease
 - Bleeding following sphincterotomy
 - Cholangitis (only when biliary obstruction is not achieved at ERCP)
 - Gallstone impaction
- Pancreatic disease
 - Acute pancreatitis
 - Infection of pseudocyst

radiological images of the biliary tree and pancreas. Diagnostic ERCP has largely been replaced by magnetic resonance cholangiopancreatography (MRCP), which provides comparable images of the biliary tree and pancreas. MRCP complements CT and endoscopic ultrasound (EUS) in the evaluation of obstructive jaundice, biliary pain and suspected pancreatic disease, and therapeutic ERCP is then used to treat a range of biliary and pancreatic diseases identified by these non-invasive imaging techniques. Indications for and risks of ERCP are listed in Box 22.9.

Histology

Biopsy material obtained during endoscopy or percutaneously can provide useful information (Box 22.11).

Tests of infection

Bacterial cultures

Stool cultures are essential in the investigation of diarrhoea, especially when it is acute or bloody, to identify pathogenic organisms (Ch. 13).

22.10 Endoscopy in old age

- **Tolerance:** endoscopic procedures are generally well tolerated, even in very old people.
- **Side-effects from sedation:** older people are more sensitive, and respiratory depression, hypotension and prolonged recovery times are more common.
- **Bowel preparation for colonoscopy:** can be difficult in frail, immobile people. Sodium phosphate-based preparations can cause dehydration or hypotension and should be avoided in those with underlying cardiac or renal failure.
- **Antiperistaltic agents:** hyoscine should be avoided in those with glaucoma and can also cause tachyarrhythmias. Glucagon is preferred if an antiperistaltic agent is needed.

22.11 Reasons for biopsy or cytological examination

- Suspected malignant lesions
- Assessment of mucosal abnormalities
- Diagnosis of infection (e.g. *Candida*, *Helicobacter pylori*, *Giardia lamblia*)
- Measurement of enzyme contents (e.g. disaccharidases)
- Analysis of genetic mutations (e.g. oncogenes, tumour suppressor genes)

Serology

Detection of antibodies plays a limited role in the diagnosis of gastrointestinal infection caused by organisms such as *Helicobacter pylori*, *Salmonella* species and *Entamoeba histolytica*.

Breath tests

Non-invasive breath tests for *H. pylori* infection are discussed on page 850. Breath tests for suspected small intestinal bacterial overgrowth are discussed on page 881.

Tests of function

A number of dynamic tests can be used to investigate aspects of gut function, including digestion, absorption, inflammation and epithelial permeability. Some of the more commonly used ones are listed in Box 22.12. In the assessment of suspected malabsorption, blood tests (full blood count, erythrocyte sedimentation rate (ESR), folate, B₁₂, iron status, albumin, calcium and phosphate) are essential, and endoscopy is undertaken to obtain mucosal biopsies.

Oesophageal motility

A barium swallow can give useful information about oesophageal motility. Videofluoroscopy, with joint assessment by a speech and language therapist and a radiologist, may be necessary in difficult cases. Oesophageal manometry (see Fig. 22.1, p. 838), often in conjunction with 24-hour pH measurements, is of value in diagnosing cases of refractory gastro-oesophageal reflux, achalasia and non-cardiac chest pain. Oesophageal impedance testing is useful for detecting non-acid or gas reflux events, especially in patients with atypical symptoms or those who respond poorly to acid suppression.

22.12 Dynamic tests of gastrointestinal function

Process	Test	Principle	Comments
Absorption			
Fat	¹⁴ C-triolein breath test	Measurement of ¹⁴ CO ₂ in breath after oral ingestion of radio-labelled fat	Non-invasive but not quantitative
Lactose	Lactose H ₂ breath test	Measurement of breath H ₂ content after 50 g oral lactose. Undigested sugar is metabolised by colonic bacteria in hypolactasia, and expired hydrogen is measured	Non-invasive and accurate. May provoke pain and diarrhoea in sufferers
Bile acids	⁷⁵ SeHCAT test	Isotopic quantification of 7-day whole-body retention of oral dose ⁷⁵ Se-labelled homocholyltaurine (> 15% = normal, < 5% = abnormal)	Accurate and specific but requires two visits and involves radiation. Can be equivocal. Serum 7α-hydroxycholestenone is as sensitive and specific
Pancreatic exocrine function	Pancreolauryl test	Pancreatic esterases cleave fluorescein dilaurate after oral ingestion. Fluorescein is absorbed and quantified in urine	Accurate and avoids duodenal intubation Takes 2 days. Accurate urine collection essential. Rarely performed
	Faecal elastase	Immunoassay of pancreatic enzymes on stool sample	Simple, quick and avoids urine collection Does not detect mild disease
Mucosal inflammation/permeability	Calprotectin	A protein secreted non-specifically by neutrophils into the colon in response to inflammation or neoplasia	Useful screening test for colonic disease

Gastric emptying

This involves administering a test meal containing solids and liquids labelled with different radioisotopes and measuring the amount retained in the stomach afterwards (Box 22.13). It is useful in the investigation of suspected delayed gastric emptying (gastroparesis) when other studies are normal.

Colonic and anorectal motility

A plain abdominal X-ray taken on day 5 after ingestion of different-shaped inert plastic pellets on days 1–3 gives an estimate of whole gut transit time. The test is useful in the evaluation of chronic constipation when the position of

any retained pellets can be observed, and helps to differentiate cases of slow transit from those due to obstructed defecation. The mechanism of defecation and anorectal function can be assessed by anorectal manometry, electrophysiological tests and defecating proctography.

Radioisotope tests

Many different radioisotope tests are used (see Box 22.13). In some, structural information is obtained, e.g. localisation of a Meckel's diverticulum. Others use radioisotopes for functional information, e.g. rates of gastric emptying or ability to reabsorb bile acids. Yet others are tests of infection and rely on the presence of bacteria to hydrolyse a radio-labelled test substance followed by detection of the radioisotope in expired air (e.g. urea breath test for *H. pylori*).

22.13 Commonly used radioisotope tests in gastroenterology

Test	Isotope	Major uses and principle of test
Gastric emptying study	$^{99\text{m}}\text{Tc}$ -sulphur	Used in assessment of gastric emptying, particularly for possible gastroparesis
	^{111}In -DTPA	
Urea breath test	^{13}C -urea	Used in non-invasive diagnosis of <i>H. pylori</i> . Bacterial urease enzyme splits urea to ammonia and CO_2 , which is detected in expired air
Meckel's scan	$^{99\text{m}}\text{Tc}$ -pertechnetate	Diagnosis of Meckel's diverticulum in cases of obscure gastrointestinal bleeding. Isotope is injected i.v. and localises in ectopic parietal mucosa within diverticulum
Somatostatin receptor scan (SRS)	^{111}In -DTPA-DPhe-octreotide	Labelled somatostatin analogue binds to cell surface somatostatin receptors on pancreatic neuroendocrine tumours

PRESENTING PROBLEMS IN GASTROINTESTINAL DISEASE**Dysphagia**

Dysphagia is defined as difficulty in swallowing. It may coexist with heartburn or vomiting but should be distinguished from both globus sensation (in which anxious people feel a lump in the throat without organic cause) and odynophagia (pain during swallowing, usually from gastro-oesophageal reflux or candidiasis).

Dysphagia can occur due to problems in the oropharynx or oesophagus (Fig. 22.16). Oropharyngeal disorders affect the initiation of swallowing at the pharynx and upper oesophageal sphincter. The patient has difficulty initiating swallowing and complains of choking, nasal regurgitation or tracheal aspiration. Drooling, dysarthria, hoarseness and cranial nerve or other neurological signs may be present. Oesophageal disorders cause dysphagia by obstructing the lumen or by

Fig. 22.16 Investigation of dysphagia.

affecting motility. Patients with oesophageal disease complain of food 'sticking' after swallowing, although the level at which this is felt correlates poorly with the true site of obstruction. Swallowing of liquids is normal until strictures become extreme.

Investigations

Dysphagia should always be investigated. Endoscopy is the investigation of choice because it allows biopsy and dilatation of suspicious strictures. If no abnormality is found, then barium swallow with videofluoroscopic swallowing assessment is indicated to detect motility disorders. In a few cases oesophageal manometry is required. Figure 22.16 summarises a diagnostic approach to dysphagia and lists the major causes.

Dyspepsia

Dyspepsia is the term used to describe symptoms such as bloating and nausea which are thought to originate from the upper gastrointestinal tract. There are many causes (Box 22.14), including some arising outside the digestive system. Heartburn and other 'reflux' symptoms are separate entities and are considered elsewhere. Although symptoms often correlate poorly with the underlying diagnosis, a careful history is important to detect 'alarm' features requiring urgent investigation (Box 22.15) and to detect atypical symptoms which might be due to problems outside the gastrointestinal tract.

Dyspepsia affects up to 80% of the population at some time in life and many patients have no serious underlying disease. Patients who present with new dyspepsia at an age of more than 55 years and younger

22.14 Causes of dyspepsia

Upper gastrointestinal disorders

- Peptic ulcer disease
- Acute gastritis
- Gallstones
- Motility disorders, e.g. oesophageal spasm
- 'Functional' (non-ulcer dyspepsia and irritable bowel syndrome)

Other gastrointestinal disorders

- Pancreatic disease (cancer, chronic pancreatitis)
- Hepatic disease (hepatitis, metastases)
- Colonic carcinoma

Systemic disease

- Renal failure
- Hypercalcaemia

Drugs

- Non-steroidal anti-inflammatory drugs (NSAIDs)
- Iron and potassium supplements
- Corticosteroids
- Digoxin

Others

- Alcohol
- Psychological, e.g. anxiety, depression

22.15 'Alarm' features in dyspepsia

- Weight loss
- Anaemia
- Vomiting
- Haematemesis and/or melaena
- Dysphagia
- Palpable abdominal mass

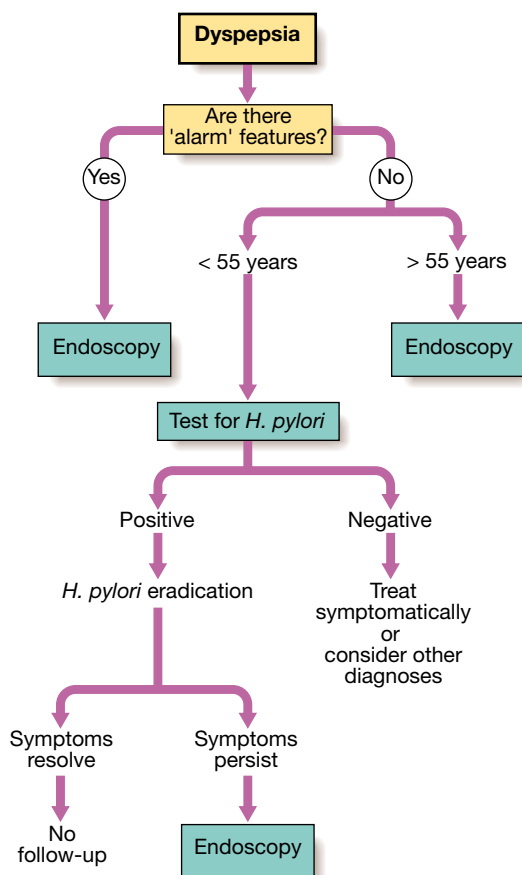

Fig. 22.17 Investigation of dyspepsia.

patients unresponsive to empirical treatment require investigation to exclude serious disease. An algorithm for the investigation of dyspepsia is outlined in Figure 22.17.

Vomiting

Vomiting is a complex reflex involving both autonomic and somatic neural pathways. Synchronous contraction of the diaphragm, intercostal muscles and abdominal muscles raises intra-abdominal pressure and, combined with relaxation of the lower oesophageal sphincter, results in forcible ejection of gastric contents. It is important to distinguish true vomiting from regurgitation and to elicit whether the vomiting is acute or chronic (recurrent), as the underlying causes may differ. The major causes are shown in Figure 22.18.

Gastrointestinal bleeding

Acute upper gastrointestinal haemorrhage

This is the most common gastrointestinal emergency, accounting for 50–170 admissions to hospital per 100 000 of the population each year in the UK. The mortality of patients admitted to hospital is about 10% but there is some evidence that outcome is better when patients are treated in specialised units. Risk factors for death are shown in Box 22.16 and the common causes of upper gastrointestinal bleeding are shown in Figure 22.19.

Fig. 22.18 Causes of vomiting.

<div> <div></div> <div>22.16 Rockall score for risk stratification in acute upper gastrointestinal haemorrhage</div> </div>					
Variable	Score 0	Score 1	Score 2	Score 3	Score
Calculate on admission					
Age	< 60	60–79	> 80		
Shock	No shock	Pulse > 100	SBP < 100		
Comorbidity	Nil major	CCF, IHD, major comorbidity	Renal/liver failure	Metastatic cancer	
Calculate after endoscopy					
Diagnosis	Mallory-Weiss tear or normal	All other diagnoses	GI malignancy ¹		
Evidence of bleeding	None	Blood in stomach	Adherent clot Visible or spurting vessel ²		
					Final score (range 0–11)
¹ Malignancy and varices have the worst prognosis.					
² These features are associated with a high risk of rebleeding. Rebleeding (fresh haematemesis or melaena associated with shock or a fall of haemoglobin > 20 g/L over 24 hours) is associated with a 10-fold increased risk of death.					

Fig. 22.19 Causes of acute upper gastrointestinal haemorrhage. (Frequency in parentheses.)

Clinical assessment

Haematemesis is red with clots when bleeding is profuse, or black ('coffee grounds') when less severe. Syncope may occur and is due to hypotension from intravascular volume depletion. Symptoms of anaemia suggest chronic bleeding. Melaena is the passage of black, tarry stools containing altered blood; it is usually caused by bleeding from the upper gastrointestinal tract, although haemorrhage from the right side of the colon is occasionally responsible. The characteristic colour and smell are the result of the action of digestive enzymes and of bacteria upon haemoglobin. Severe acute upper gastrointestinal bleeding can sometimes cause maroon or bright red stool.

Management

The principles of emergency management of non-variceal bleeding are summarised in Box 22.17 and are discussed in detail below. Management of variceal bleeding is discussed on page 939.

1. Intravenous access

The first step is to gain intravenous access using at least one large-bore cannula.

2. Initial clinical assessment

- **Define circulatory status.** Severe bleeding causes tachycardia, hypotension and oliguria. The patient is cold and sweating, and may be agitated.

22.17 Emergency management of acute non-variceal upper gastrointestinal haemorrhage

- Gain intravenous access with large-bore cannula
- Check full blood count and routine biochemistry; cross-match blood
- Perform hourly measurements of blood pressure, pulse and urine output; consider central venous pressure (CVP) monitoring in severe bleeding
- Give intravenous colloids or crystalloids in patients with hypotension and tachycardia
- Transfuse with blood if blood pressure remains low and patient is actively bleeding
- Organise endoscopy for diagnosis and treatment
- Give i.v. PPI therapy for bleeding peptic ulcer
- Consider surgery or arterial embolisation if bleeding recurs

- *Seek evidence of liver disease.* Jaundice, cutaneous stigmata, hepatosplenomegaly and ascites may be present in decompensated cirrhosis.
- *Identify comorbidity.* The presence of cardiorespiratory, cerebrovascular or renal disease is important, both because these may be worsened by acute bleeding and because they increase the hazards of endoscopy and surgical operations.

These factors can be combined using the Rockall scoring system to predict severity (see Box 22.16). An initial score can be calculated, endoscopic findings can be added later and a final score may be obtained, ranging from 0 to 11. A score < 3 is associated with a good prognosis while a total score > 8 carries a high risk of mortality.

3. Basic investigations

- *Full blood count.* Chronic or subacute bleeding leads to anaemia, but the haemoglobin concentration may be normal after sudden, major bleeding until haemodilution occurs.
- *Urea and electrolytes.* This test may show evidence of renal failure. The blood urea rises as the absorbed products of luminal blood are metabolised by the liver; an elevated blood urea with normal creatinine concentration implies severe bleeding.
- *Liver function tests.* These may show evidence of chronic liver disease.
- *Prothrombin time,* if there is clinical suggestion of liver disease or in anticoagulated patients.
- *Cross-matching* of at least 2 units of blood.

4. Resuscitation

Intravenous crystalloid fluids or colloid should be given to raise the blood pressure, and blood should be transfused when the patient is actively bleeding with low blood pressure and tachycardia. Comorbidities should be managed as appropriate. Patients with suspected chronic liver disease should receive broad-spectrum antibiotics. Central venous pressure (CVP) monitoring is useful in severe bleeding, particularly in patients who have cardiac disease, to assist in defining the volume of fluid replacement and in identification of rebleeding.

5. Oxygen

This should be given by facemask to all patients in shock.

6. Endoscopy

This should be carried out after adequate resuscitation, ideally within 24 hours, and will yield a diagnosis in 80% of cases. Patients who are found to have major endoscopic stigmata of recent haemorrhage (Fig. 22.20) can be treated endoscopically using a thermal modality such as a 'heater probe', by injection of dilute adrenaline (epinephrine) into the bleeding point, or by application of metallic clips. Endoscopic therapy may stop active bleeding and, combined with intravenous PPI (PPI) therapy, prevent rebleeding, thus avoiding the need for surgery (Boxes 22.18 and 22.19). Patients found to have bled from varices are treated by band ligation as described in Chapter 23.

7. Monitoring

Patients should be closely observed, with hourly pulse, blood pressure and urine output measurements.

8. Surgery

Surgery is indicated when endoscopic haemostasis fails to stop active bleeding and if rebleeding occurs on one occasion in an elderly or frail patient, or twice in a younger, fitter patients.

The choice of operation depends on the site and diagnosis of the bleeding lesion. Duodenal ulcers are treated by under-running with or without pyloroplasty. Under-running for gastric ulcers can also be carried out (a biopsy must be taken to exclude carcinoma). Local excision may also be performed, but when neither is possible, partial gastrectomy will be required. Following successful surgery for ulcer bleeding, all patients should be treated with

Fig. 22.20 Major stigmata of recent haemorrhage and endoscopic treatment. [A] Active arterial spurting from a gastric ulcer. An endoscopic clip is about to be placed on the bleeding vessel. When associated with shock, 80% of cases will continue to bleed or rebleed. [B] 'Visible vessel' (arrow). In reality, this is a pseudoaneurysm of the feeding artery seen here in a pre-pyloric peptic ulcer. It carries a 50% chance of rebleeding. [C] Haemostasis is achieved after endoscopic clipping of the bleeding vessel in the duodenum.

EBM 22.18 Endoscopic therapy in acute upper gastrointestinal haemorrhage

'Peptic ulcers that are actively bleeding or have a protruberant vessel or adherent blood clot are treated endoscopically using a combination of injection (adrenaline (epinephrine)), application of thermal energy or clips.'

- Scottish Intercollegiate Guideline Network. Guideline 105. Management of acute upper and lower gastrointestinal bleeding, 2008.

For further information:  www.sign.ac.uk

EBM 22.19 Adjunctive drug therapy for bleeding ulcers

'Intravenous proton pump inhibitor infusions reduce rebleeding ($NNT_B = 12$) and need for surgery ($NNT_B = 20$) but not mortality in patients who have been subjected to endoscopic therapy for major peptic ulcer haemorrhage. When given prior to endoscopy they reduce the need for endoscopic therapy and hospital stay but not need for surgery or mortality.'

- Lau JY, et al. *New Engl J Med* 2007; 356:1631–1640.

For further information:  www.sign.ac.uk

H. pylori eradication therapy if positive and should avoid NSAIDs. Ulcer patients need confirmation of successful eradication by urea breath testing.

Lower gastrointestinal bleeding

This may be due to haemorrhage from the colon, anal canal or small bowel. It is useful to distinguish those patients who present with profuse, acute bleeding from those who present with chronic or subacute bleeding of lesser severity (Box 22.20).

Severe acute lower gastrointestinal bleeding

Patients present with profuse red or maroon diarrhoea and with shock. Diverticular disease is the most common cause and is often due to erosion of an artery within the mouth of a diverticulum. Bleeding almost always stops spontaneously, but if it does not, the diseased segment of colon should be resected after confirmation of the site by angiography or colonoscopy. Angiodysplasia is a disease of the elderly in which vascular malformations develop in the proximal colon. Bleeding can be acute and profuse; it usually stops spontaneously but commonly recurs. Diagnosis is often difficult. Colonoscopy may reveal characteristic vascular spots, and in the acute

phase visceral angiography can show bleeding into the intestinal lumen and an abnormal large, draining vein. In some patients, diagnosis is only achieved by laparotomy with on-table colonoscopy. The treatment of choice is endoscopic thermal ablation, but resection of the affected bowel may be required if bleeding continues. Bowel ischaemia due to occlusion of the inferior mesenteric artery can present with abdominal colic and rectal bleeding. It should be considered in patients (particularly the elderly) who have evidence of generalised atherosclerosis. The diagnosis is made at colonoscopy. Resection is required only in the presence of peritonitis. Meckel's diverticulum with ectopic gastric epithelium may ulcerate and erode into a major artery. The diagnosis should be considered in children or adolescents who present with profuse or recurrent lower gastrointestinal bleeding. A Meckel's ^{99m}Tc -pertechnetate scan is sometimes positive but the diagnosis is commonly made only by laparotomy, at which time the diverticulum is excised.

Subacute or chronic lower gastrointestinal bleeding

This is common at all ages and is usually due to haemorrhoids or anal fissure. Haemorrhoidal bleeding is bright red and occurs during or after defecation. Proctoscopy is used to make the diagnosis but in subjects who also have altered bowel habit and in all patients presenting at over 40 years of age, colonoscopy is necessary to exclude coexisting colorectal cancer. Anal fissure should be suspected when fresh rectal bleeding and anal pain occur during defecation.

Obscure major gastrointestinal bleeding

In some patients who present with major gastrointestinal bleeding, upper endoscopy and colonoscopy fail to reveal a diagnosis. When severe life-threatening bleeding continues, urgent mesenteric angiography is indicated. This will usually identify the site if the bleeding rate exceeds 1 mL/min and embolisation can often stop the bleeding. If angiography is negative or bleeding is less severe, push or double balloon enteroscopy can visualise the small intestine (Fig. 22.21,

Fig. 22.21 Jejunal angiodysplastic lesion seen at enteroscopy in a patient with recurrent obscure bleeding.

22.20 Causes of lower gastrointestinal bleeding**Severe acute**

- Diverticular disease
- Angiodysplasia
- Ischaemia
- Meckel's diverticulum
- Inflammatory bowel disease (rarely)

Moderate, chronic/subacute

- Anal disease, e.g. fissure, haemorrhoids
- Inflammatory bowel disease
- Carcinoma
- Large polyps
- Angiodysplasia
- Radiation enteritis
- Solitary rectal ulcer

and see Figs 22.14 and 22.15) and treat the bleeding source. Wireless capsule endoscopy is often used to define a source of bleeding prior to enteroscopy. When all else fails, laparotomy with on-table endoscopy is indicated.

Occult gastrointestinal bleeding

In this context occult means that blood or its breakdown products are present in the stool but cannot be seen by the naked eye. Occult bleeding may reach 200 mL per day, cause iron deficiency anaemia and signify serious gastrointestinal disease. Any cause of gastrointestinal bleeding may be responsible but the most important is colorectal cancer, particularly carcinoma of the caecum which may have no gastrointestinal symptoms. In clinical practice, investigation of the gastrointestinal tract should be considered whenever a patient presents with unexplained iron deficiency anaemia. Testing the stool for the presence of blood is unnecessary and should not influence whether or not the gastrointestinal tract is imaged because bleeding from tumours is often intermittent and a negative faecal occult blood (FOB) test does not exclude important gastrointestinal disease. Many colorectal cancer patients are FOB-negative at presentation, and the only value of FOB testing is as a means of screening for colonic disease in asymptomatic populations (p. 912).

Diarrhoea

Gastroenterologists define diarrhoea as the passage of more than 200 g of stool daily, and measurement of stool volume is helpful in confirming this. The most severe symptom in many patients is urgency of defecation, and faecal incontinence is a common event in acute and chronic diarrhoeal illnesses.

Acute diarrhoea

This is extremely common and usually due to faecal-oral transmission of bacteria, their toxins, viruses or

parasites (Ch. 13). Infective diarrhoea is usually short-lived and patients who present with a history of diarrhoea lasting more than 10 days rarely have an infective cause. A variety of drugs, including antibiotics, cytotoxic drugs, PPIs and NSAIDs, may be responsible for acute diarrhoea.

Chronic or relapsing diarrhoea

The most common cause is irritable bowel syndrome (p. 904), which can present with increased frequency of defecation and loose, watery or pelleted stools. Diarrhoea rarely occurs at night and is most severe before and after breakfast. At other times the patient is constipated and there are other characteristic symptoms of irritable bowel syndrome. The stool often contains mucus but never blood, and 24-hour stool volume is less than 200 g. Chronic diarrhoea can be categorised as disease of the colon or small bowel, or malabsorption (Box 22.21). Clinical presentation, examination of the stool, routine blood tests and imaging reveal a diagnosis in many cases. A series of negative investigations usually implies irritable bowel syndrome but some patients clearly have organic disease and need more extensive investigations.

Malabsorption

Diarrhoea and weight loss in patients with a normal diet should always lead to the suspicion of malabsorption. The symptoms are diverse in nature and variable in severity. A few patients have apparently normal bowel habit but diarrhoea is usual and may be watery and voluminous. Bulky, pale and offensive stools which float in the toilet (steatorrhoea) signify fat malabsorption. Abdominal distension, borborygmi, cramps, weight loss and undigested food in the stool may be present. Some patients complain only of malaise and lethargy. In others, symptoms related to deficiencies of specific vitamins, trace elements and minerals (e.g. calcium, iron, folic acid) may occur (Fig. 22.22).

22.21 Chronic or relapsing diarrhoea

	Colonic	Malabsorption	Small bowel
Clinical features	Blood and mucus in stool Cramping lower abdominal pain	Steatorrhoea Undigested food in the stool Weight loss and nutritional disturbances	Large-volume, watery stool Abdominal bloating Cramping mid-abdominal pain
Some causes	Inflammatory bowel disease Neoplasia Ischaemia Irritable bowel syndrome	Pancreatic Chronic pancreatitis Cancer of pancreas Cystic fibrosis Enteropathy Coeliac disease Tropical sprue Lymphoma Lymphangiectasia	VIPoma Drug-induced NSAIDs Aminosalicylates Selective serotonin re-uptake inhibitors (SSRIs)
Investigations	Colonoscopy with biopsies	Ultrasound, CT and MRCP Small bowel biopsy Barium follow-through	Stool volume Gut hormone profile Barium follow-through

Fig. 22.22 Possible physical consequences of malabsorption.

Pathophysiology

Malabsorption results from abnormalities of the three processes which are essential to normal digestion:

1. *Intraluminal maldigestion* occurs when deficiency of bile or pancreatic enzymes results in inadequate solubilisation and hydrolysis of nutrients. Fat and protein malabsorption results. This may also occur in the presence of small bowel bacterial overgrowth.
2. *Mucosal malabsorption* results from small bowel resection or conditions which damage the small intestinal epithelium, thereby diminishing the surface area for absorption and depleting brush border enzyme activity.
3. *'Postmucosal' lymphatic obstruction* prevents the uptake and transport of absorbed lipids into lymphatic vessels. Increased pressure in these vessels results in leakage into the intestinal lumen, leading to protein-losing enteropathy.

Investigations

Investigations are performed to confirm that malabsorption is present and then to determine the cause. Routine blood tests may show one or more of the abnormalities listed in Box 22.22. Tests to confirm fat and protein malabsorption are performed as described on page 850. An approach to the investigation of malabsorption is shown in Figure 22.23.

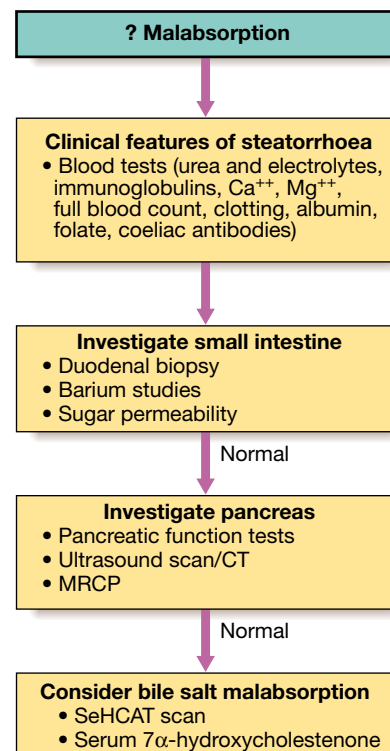

Fig. 22.23 Investigation for suspected malabsorption.

22.22 Routine blood test abnormalities in malabsorption

Haematology

- Microcytic anaemia (iron deficiency)
- Macrocytic anaemia (folate or B₁₂ deficiency)
- Increased prothrombin time (vitamin K deficiency)

Biochemistry

- Hypoalbuminaemia
- Hypocalcaemia (p. 765)
- Hypomagnesaemia
- Deficiencies of phosphate, zinc

Weight loss

Weight loss may be 'physiological' due to dieting, exercise, starvation, or the decreased nutritional intake which accompanies old age. Alternatively, weight loss may signify disease and in this case a loss of more than 3 kg over 6 months is significant. Hospital and general practice weight records may be valuable in confirming that weight loss has occurred, as may reweighing patients at intervals; sometimes weight is regained or stabilises in those with no obvious cause. Pathological weight loss can be due to psychiatric illness, systemic disease, gastrointestinal causes or advanced disease of many organ systems (Fig. 22.24).

Physiological

Weight loss can occur in the absence of serious disease in healthy individuals who have changes in physical activity or social circumstances. It may be difficult to be sure of this diagnosis in older patients when the dietary history may be unreliable and professional help from a dietitian is often valuable under these circumstances.

Psychiatric illness

Features of anorexia nervosa (p. 249), bulimia (p. 250) and affective disorders (p. 250) may only be apparent after formal psychiatric input. Alcoholic patients lose weight as a consequence of self-neglect and poor dietary intake. Depression may cause weight loss.

Systemic diseases

Chronic infections, including tuberculosis (p. 688), recurrent urinary or chest infections, and a range of parasitic and protozoan infections (Ch. 13), should be considered. A history of foreign travel, high-risk activities and specific features such as fever, night sweats, rigors, productive cough and dysuria must be sought. Promiscuous sexual activity and drug misuse suggest HIV-related illness (Ch. 14). Weight loss is a late feature of disseminated malignancy but by the time the patient presents other features of cancer are often present.

Gastrointestinal disease

Almost any disease of the gastrointestinal tract can cause weight loss. Dysphagia and gastric outflow

Fig. 22.24 Some important causes of weight loss.

22.23 Some easily overlooked causes of unexplained weight loss

- Depression/anxiety
- Chronic pain or sleep deprivation
- Psychosocial deprivation/malnutrition in the elderly
- Existing conditions (severe chronic obstructive pulmonary disease, cardiac failure)
- Diabetes mellitus/hyperthyroidism
- Occult malignancy (e.g. proximal colon, renal, lymphoma)
- Anorexia nervosa in atypical groups, e.g. young men
- Rare endocrine disorders, e.g. Addison's disease, panhypopituitarism

obstruction (pp. 851 and 874) cause defective dietary intake. Malignancy at any site may cause weight loss by mechanical obstruction, anorexia or cytokine-mediated systemic effects. Malabsorption from pancreatic diseases (p. 888) or small bowel causes may lead to profound weight loss with specific nutritional deficiencies (Ch. 5). Inflammatory diseases such as Crohn's disease or ulcerative colitis (p. 895) cause anorexia, fear of eating and loss of protein, blood and nutrients from the gut.

Metabolic disorders and miscellaneous causes

Weight loss may occur in association with metabolic disorders as well as end-stage respiratory and cardiac disease. Some easily overlooked causes of weight loss are listed in Box 22.23.

Investigations

In cases where the cause of weight loss is not obvious after thorough history-taking and physical examination, or where it is considered that an existing condition is unlikely, the following investigations are indicated: urinalysis for sugar, protein and blood; blood tests including liver function tests, random blood glucose, and thyroid function tests; and ESR (may be raised in unsuspected infections such as tuberculosis, connective tissue disorders and malignancy). Sometimes invasive tests such as bone marrow aspiration or liver biopsy may be necessary to identify conditions like cryptic miliary tuberculosis (p. 689). Rarely, abdominal and pelvic imaging by CT may be necessary, but before embarking on invasive or very costly investigations it is always worth revisiting the patient's history and reweighing at intervals.

Constipation

Constipation is defined as infrequent passage of hard stools. Patients may also complain of straining, a sensation of incomplete evacuation and either perianal or abdominal discomfort. Constipation may be the end result of many gastrointestinal and other medical disorders (Box 22.24).

Clinical assessment and management

The onset, duration and characteristics are important; for example, a neonatal onset suggests Hirschsprung's disease, while a recent change in bowel activity in middle age should raise the suspicion of organic disorders such as colonic carcinoma. The presence of symptoms such

22.24 Causes of constipation

Gastrointestinal disorders

Dietary

- Lack of fibre and/or fluid intake

Motility

- Slow-transit constipation (p. 913)
- Irritable bowel syndrome
- Drugs (see below)
- Chronic intestinal pseudo-obstruction

Structural

- Colonic carcinoma
- Diverticular disease
- Hirschsprung's disease

Defecation

- Obstructed defecation (p. 913)
- Anorectal disease (Crohn's, fissures, haemorrhoids)

Non-gastrointestinal disorders

Drugs

- Opiates
- Anticholinergics
- Calcium antagonists
- Iron supplements
- Aluminium-containing antacids

Neurological

- Multiple sclerosis
- Spinal cord lesions
- Cerebrovascular accidents
- Parkinsonism

Metabolic/endocrine

- Diabetes mellitus
- Hypercalcaemia
- Hypothyroidism
- Pregnancy

Others

- Any serious illness with immobility, especially in the elderly
- Depression

as rectal bleeding, pain and weight loss is important, as are excessive straining, symptoms suggestive of irritable bowel syndrome, a history of childhood constipation and emotional distress.

Careful examination contributes more to the diagnosis than extensive investigation. A search should be made for general medical disorders as well as signs of intestinal obstruction. Neurological disorders, especially spinal cord lesions, should be sought. Perineal inspection and rectal examination are essential and may reveal abnormalities of the pelvic floor (e.g. abnormal descent, impaired sensation), anal canal or rectum (masses, faecal impaction, prolapse).

It is neither possible nor appropriate to investigate every person with this very common complaint. Most will respond to dietary fibre supplementation and the judicious use of laxatives. Middle-aged or elderly patients with a short history or worrying symptoms (rectal bleeding, pain or weight loss) must be investigated promptly, by either barium enema or colonoscopy. For those with simple constipation, investigation will usually proceed along the following lines.

Initial visit

Digital rectal examination, proctoscopy and sigmoidoscopy (to detect anorectal disease), routine biochemistry, including serum calcium and thyroid function tests, and

a full blood count should be carried out. If these are normal, a 1-month trial of dietary fibre and/or laxatives is justified.

Next visit

If symptoms persist, then examination of the colon by barium enema or colonoscopy is indicated to look for structural disease.

Further investigation

If no cause is found and disabling symptoms are present, then specialist referral for investigation of possible dysmotility may be necessary. The problem may be one of infrequent desire to defecate ('slow transit') or else may result from excessive straining ('obstructed defecation', p. 913). Intestinal marker studies, anorectal manometry, electrophysiological studies and defecating proctography can all be used to define the problem.

Abdominal pain

There are four types of abdominal pain:

- **Visceral.** Gut organs are insensitive to stimuli such as burning and cutting but are sensitive to distension, contraction, twisting and stretching. Pain from unpaired structures is usually but not always felt in the midline.
- **Parietal.** The parietal peritoneum is innervated by somatic nerves, and its involvement by inflammation, infection or neoplasia causes sharp, well-localised and lateralised pain.
- **Referred pain.** (For example, gallbladder pain is referred to the back or shoulder tip.)
- **Psychogenic.** Cultural, emotional and psychosocial factors influence everyone's experience of pain. In some patients, no organic cause can be found despite investigation, and psychogenic causes (depression or somatisation disorder) may be responsible (pp. 242 and 250).

The acute abdomen

This accounts for approximately 50% of all urgent admissions to general surgical units. The acute abdomen is a consequence of one or more pathological processes (Box 22.25):

22.25 Causes of acute abdominal pain

Inflammation	
• Appendicitis	• Pancreatitis
• Diverticulitis	• Pyelonephritis
• Cholecystitis	• Intra-abdominal abscess
• Pelvic inflammatory disease	
Perforation/rupture	
• Peptic ulcer	• Ovarian cyst
• Diverticular disease	• Aortic aneurysm
Obstruction	
• Intestinal obstruction	• Ureteric colic
• Biliary colic	
Other (rare)	
• See 'extraintestinal' causes (see Box 22.28)	

- **Inflammation.** Pain develops gradually, usually over several hours. It is initially rather diffuse until the parietal peritoneum is involved, when it becomes localised. Movement exacerbates the pain; abdominal rigidity and guarding occur.
- **Perforation.** When a viscus perforates, pain starts abruptly; it is severe and leads to generalised peritonitis.
- **Obstruction.** Pain is colicky, with spasms which cause the patient to writhe around and double up. Colicky pain which does not disappear between spasms suggests complicating inflammation.

Initial clinical assessment

If there are signs of peritonitis (guarding and rebound tenderness with rigidity), adequate resuscitation should be arranged. In other circumstances further investigations are required (Fig. 22.25).

Investigations

Patients should have a full blood count, urea and electrolytes, and amylase taken to look for evidence of dehydration, leucocytosis and pancreatitis. An erect chest X-ray may show air under the diaphragm suggestive of perforation and a plain abdominal film may show evidence of obstruction. An abdominal ultrasound may help if gallstones or renal stones are suspected. Ultrasonography is also useful in the detection of free fluid and any possible intra-abdominal abscess. Contrast studies, by either mouth or anus, are useful in the further evaluation of intestinal obstruction, and essential in the differentiation of pseudo-obstruction from mechanical large bowel obstruction. Other investigations commonly used include CT (seeking evidence of pancreatitis, retroperitoneal collections or masses, including an aortic aneurysm) and angiography (mesenteric ischaemia).

Diagnostic laparotomy should be considered when the diagnosis has not been revealed by other investigations. All patients must be carefully and regularly reassessed (every 2–4 hours) so that any change in condition which might alter both the suspected diagnosis and clinical decision can be observed and acted upon early.

Management

In general, and depending on the organ affected, perforations are closed, inflammatory conditions are treated with antibiotics or resection, and obstructions are relieved. The speed of intervention and the necessity for surgery depend on a number of factors, of which the presence or absence of peritonitis is the most important. A treatment summary of some of the more common surgical conditions follows.

Acute appendicitis

Although non-operative treatment can be successful in some patients, the risk of perforation and subsequent recurrent attacks dictates that early surgery is undertaken. The appendix can be removed through a conventional right iliac fossa skin crease incision or by laparoscopic techniques.

Acute cholecystitis

This can be successfully treated non-operatively but the high risk of recurrent attacks and the low morbidity of surgery have made early laparoscopic cholecystectomy the treatment of choice.

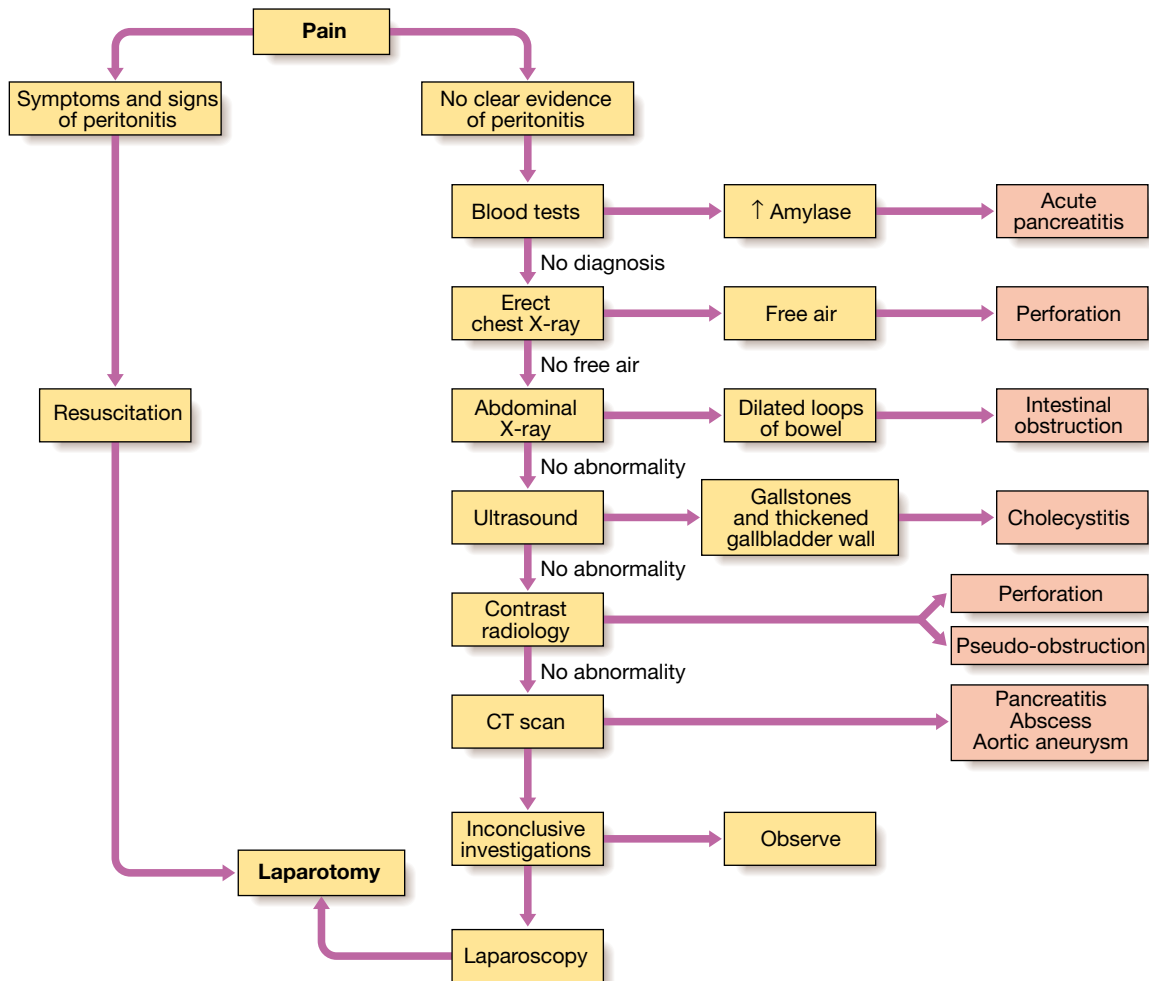

Fig. 22.25 Management of abdominal pain: an algorithm.

Acute diverticulitis

Conservative therapy is usually recommended, but if perforation has occurred, resection is advisable. Depending on peritoneal contamination and the state of the patient, primary anastomosis is preferable to a Hartmann's procedure (oversew of rectal stump and end colostomy).

22.26 Acute abdominal pain in old age

- **Presentation:** severity and localisation may blunt with age. Presentation may be atypical, even with perforation of a viscus.
- **Cancer:** a more common cause of acute pain in those over 70 years than in those under 50 years. Older people with vague abdominal symptoms should therefore be carefully assessed.
- **Non-specific symptoms:** intra-abdominal inflammatory conditions such as diverticulitis may present with non-specific symptoms such as acute confusion or anorexia and relatively little abdominal tenderness. The reasons for this are not clear but may result from altered sensory perception.
- **Outcome of abdominal surgery:** determined by the degree of comorbid disease and whether surgery is elective or emergency, rather than by chronological age.

Small bowel obstruction

If the cause is obvious and surgery inevitable (e.g. for an external hernia) an early operation is appropriate. If the suspected cause is adhesions from previous surgery, only those patients who do not resolve within the first 48 hours or who develop signs of strangulation (colicky pain becomes constant, peritonitis, tachycardia, fever, leucocytosis) will require surgery.

Large bowel obstruction

Pseudo-obstruction is treated non-operatively. Some patients benefit from colonoscopic decompression, but mechanical obstruction merits surgical resection, usually with primary anastomosis. Differentiation between the two is made by a water-soluble contrast enema.

Perforated peptic ulcer

Although surgical closure of the perforation is standard practice, some patients without generalised peritonitis in whom a water-soluble contrast meal has confirmed spontaneous sealing of the perforation can be treated non-operatively. Adequate and aggressive resuscitation is mandatory before surgery.

For a more detailed discussion of acute abdominal pain the reader is referred to the sister volume of this text, *Principles and Practice of Surgery*.

Chronic or recurrent abdominal pain

A detailed history, with particular attention to the features of the pain and any associated symptoms (Boxes 22.27 and 22.28), is essential.

Note should be made of the patient's general demeanour, mood and emotional state, signs of weight loss, fever, jaundice or anaemia. If a thorough abdominal and rectal examination is normal, a careful search should be made for evidence of disease affecting other structures, particularly the vertebral column, spinal cord, lungs and cardiovascular system.

Investigations will depend to a large extent on the clinical features elicited during the history and examination:

- Endoscopy and ultrasound are indicated for epigastric pain, and for dyspepsia and symptoms suggestive of gallbladder disease

22.27 'Extraintestinal' causes of chronic or recurrent abdominal pain

Retroperitoneal	
• Aortic aneurysm	• Lymphadenopathy
• Malignancy	• Abscess
Psychogenic	
• Depression	• Hypochondriasis
• Anxiety	• Somatisation
Locomotor	
• Vertebral compression	• Abdominal muscle strain
Metabolic/endocrine	
• Diabetes mellitus	• Acute intermittent porphyria
• Addison's disease	• Hypercalcaemia
Drugs/toxins	
• Corticosteroids	• Lead
• Azathioprine	• Alcohol
Haematological	
• Sickle-cell disease	• Haemolytic disorders
Neurological	
• Spinal cord lesions	• Radiculopathy
• Tabes dorsalis	

22.28 How to assess abdominal pain

- Duration
- Site and radiation
- Severity
- Precipitating and relieving factors (food, drugs, alcohol, posture, movement, defecation)
- Nature (colicky, constant, sharp or dull, wakes patient at night)
- Pattern (intermittent or continuous)
- Associated features (vomiting, dyspepsia, altered bowel habit)

- Colonoscopy is indicated for patients with altered bowel habit, rectal bleeding or features of obstruction suggesting colonic disease.
- Angiography should be considered when pain is provoked by food in a patient with widespread atherosclerosis since this may indicate mesenteric ischaemia.
- Persistent symptoms require exclusion of colonic or small bowel disease. However, young patients with pain relieved by defecation, bloating and alternating bowel habit are likely to have irritable bowel syndrome (p. 904). Simple investigations (blood tests, faecal calprotectin and sigmoidoscopy) are sufficient in the absence of rectal bleeding, weight loss and abnormal physical findings.
- Ultrasound, CT and faecal elastase are required for patients with upper abdominal pain radiating to the back. A history of alcohol misuse, weight loss and diarrhoea suggest chronic pancreatitis or pancreatic cancer.
- Recurrent attacks of pain in the loins radiating to the flanks with urinary symptoms should prompt investigation for renal or ureteric stones by abdominal X-ray, ultrasound and intravenous urography.
- A past history of psychiatric disturbance, repeated negative investigations or vague symptoms which do not fit any particular disease or organ pattern suggest a psychological origin for the patient's pain (p. 238). Careful review of case notes and previous investigations, along with open and honest discussion with the patient, reduces the need for further cycles of unnecessary and invasive tests. Care must always be taken, however, not to miss rare pathology or atypical presentations of common diseases.

Constant abdominal pain

Patients with chronic pain which is constant or nearly always present will usually have features to suggest the underlying diagnosis. In a minority no cause will be found despite thorough investigation, leading to the diagnosis of 'chronic functional abdominal pain'. In these patients a psychological cause is highly likely (p. 238) and the most important tasks are to provide symptom control, if not relief, and to minimise the effects of the pain on social, personal and occupational life. Patients are best managed in specialised pain clinics where, in addition to psychological support, appropriate use of drugs including amitriptyline, gabapentin, ketamine and opioids may be necessary.

DISEASES OF THE MOUTH AND SALIVARY GLANDS

Aphthous ulceration

Aphthous ulcers are superficial and painful; they occur in any part of the mouth. Recurrent ulcers afflict up to 30% of the population and are particularly common in women prior to menstruation. The cause is unknown, but in severe cases other causes of oral ulceration must be considered (Box 22.29). Occasionally, biopsy is necessary for diagnosis.

22.29 Causes of oral ulceration

Aphthous

- Idiopathic
- Premenstrual

Infection

- Fungal, e.g. candidiasis
- Bacterial, including syphilis
- Viral, e.g. herpes simplex

Gastrointestinal diseases

- Crohn's disease
- Coeliac disease

Dermatological conditions

- Lichen planus
- Pemphigus
- Pemphigoid

Drugs

- Hypersensitivity, e.g. Stevens–Johnson syndrome (p. 1285)
- Cytotoxic drugs

Systemic diseases

- Systemic lupus erythematosus (SLE, p. 1107)
- Behçet's syndrome (p. 1114)

Neoplasia

- Carcinoma
- Kaposi's sarcoma
- Leukaemia

Management is with topical corticosteroids (such as 0.1% triamcinolone in Orabase) or choline salicylate (8.7%) gel. Symptomatic relief is achieved using local anaesthetic mouthwashes. Rarely, patients with very severe, recurrent aphthous ulcers may need oral corticosteroids.

Oral cancer

Squamous carcinoma of the oral cavity is common world-wide and the incidence has increased by 19% since the mid-1990s in the UK. The mortality rate is around 50%, largely as a result of late diagnosis. Poor diet, alcohol excess and smoking or tobacco chewing are the main risk factors. In parts of Asia the disease is common among people who chew areca nuts wrapped in leaves of the betel plant ('betel nuts'). Oral cancer may present in many ways (Box 22.30) and a high index of suspicion is required. Patients with suspicious lesions should have all possible sources of local trauma or infection treated and be reviewed after 2 weeks. If the lesion persists, biopsy is advisable. Small cancers can be resected but extensive surgery with neck dissection to remove involved lymph nodes may be necessary. Some patients can be treated with radical radiotherapy alone, and radiotherapy is sometimes also given after surgery to treat microscopic residual disease. Some tumours may be amenable to photodynamic therapy (PDT), avoiding the need for surgery.

22.30 Symptoms and signs of oral cancer

- Solitary ulcer without precipitant, e.g. local trauma
- Solitary white patch ('leukoplakia') which fails to wipe off
- Solitary red patch
- Fixed lump
- Lip numbness in absence of trauma or infection
- Trismus (painful/difficult mouth opening)
- Cervical lymphadenopathy

Candidiasis

The yeast *Candida albicans* is a normal mouth commensal but it may proliferate to cause thrush. This occurs in babies, debilitated patients, patients receiving corticosteroid or antibiotic therapy, patients with diabetes and immunosuppressed patients, especially those receiving cytotoxic therapy and those with AIDS. White patches are seen on the tongue and buccal mucosa. Odynophagia or dysphagia suggests pharyngeal and oesophageal candidiasis. A clinical diagnosis is sufficient to instigate therapy, although brushings or biopsies can be obtained for mycological examination. Oral thrush is treated using nystatin or amphotericin suspensions or lozenges. Resistant cases or immunosuppressed patients may require oral fluconazole.

Parotitis

Parotitis is due to viral or bacterial infection. Mumps causes a self-limiting acute parotitis (p. 315). Bacterial parotitis usually occurs as a complication of major surgery. It is a consequence of dehydration and poor oral hygiene, and can be avoided by good post-operative care. Patients present with painful parotid swelling and this can be complicated by abscess formation. Broad-spectrum antibiotics are required, whilst surgical drainage is necessary for abscesses. Other causes of salivary gland enlargement are listed in Box 22.31.

22.31 Causes of salivary gland swelling

- Infection
 - Mumps
 - Bacterial (post-operative)
- Tumours
 - Benign: pleomorphic adenoma (95% of cases)
 - Intermediate: mucoepidermoid tumour
 - Malignant: carcinoma
- Calculi
- Sjögren's syndrome (p. 1111)
- Sarcoidosis

22.32 Oral health in old age

- **Dry mouth:** affects around 40% of healthy older people.
- **Gustatory and olfactory sensation:** declines and chewing power is diminished.
- **Salivation:** baseline salivary flow falls but stimulated salivation is unchanged.
- **Root caries and periodontal disease:** common partly because oral hygiene deteriorates with increasing frailty.
- **Bacteraemia and septicaemia:** may complicate Gram-negative anaerobic infection in the periodontal pockets of the very frail.

DISEASES OF THE OESOPHAGUS

Gastro-oesophageal reflux disease

Gastro-oesophageal reflux resulting in heartburn affects approximately 30% of the general population.

Pathophysiology

Occasional episodes of gastro-oesophageal reflux are common in health. Reflux is normally followed by oesophageal peristaltic waves which efficiently clear

Fig. 22.26 Factors associated with the development of gastro-oesophageal reflux disease.

the gullet, alkaline saliva neutralises residual acid, and symptoms do not occur. Gastro-oesophageal reflux disease develops when the oesophageal mucosa is exposed to gastroduodenal contents for prolonged periods of time, resulting in symptoms and, in a proportion of cases, oesophagitis. Several factors are known to be involved (Fig. 22.26).

Abnormalities of the lower oesophageal sphincter

In health, the lower oesophageal sphincter is tonically contracted, relaxing only during swallowing (p. 838).

Some patients with gastro-oesophageal reflux disease have reduced lower oesophageal sphincter tone, permitting reflux when intra-abdominal pressure rises. In others, basal sphincter tone is normal but reflux occurs in response to frequent episodes of inappropriate sphincter relaxation.

Hiatus hernia

Hiatus hernia (Box 22.33 and Fig. 22.27) causes reflux because the pressure gradient between the abdominal and thoracic cavities, which normally pinches the hiatus,

i

22.33 Important features of hiatus hernia

- Herniation of the stomach through the diaphragm into the chest
- Occurs in 30% of the population over the age of 50 years
- Often asymptomatic
- Heartburn and regurgitation can occur
- Gastric volvulus may complicate large para-oesophageal hernias

is lost. In addition, the oblique angle between the cardia and oesophagus disappears. Many patients who have large hiatus hernias develop reflux symptoms, but the relationship between the presence of a hernia and symptoms is poor. Hiatus hernia is very common in individuals who have no symptoms, and some symptomatic patients have only a very small or no hernia. Nevertheless, almost all patients who develop oesophagitis, Barrett's oesophagus or peptic strictures have a hiatus hernia.

Delayed oesophageal clearance

Defective oesophageal peristaltic activity is commonly found in patients who have oesophagitis. It is a primary abnormality, since it persists after oesophagitis has been healed by acid-suppressing drug therapy. Poor oesophageal clearance leads to increased acid exposure time.

Gastric contents

Gastric acid is the most important oesophageal irritant and there is a close relationship between acid exposure time and symptoms.

Defective gastric emptying

Gastric emptying is delayed in patients with gastro-oesophageal reflux disease. The reason for this is unknown.

Increased intra-abdominal pressure

Pregnancy and obesity are established predisposing causes. Weight loss may improve symptoms.

Dietary and environmental factors

Dietary fat, chocolate, alcohol and coffee relax the lower oesophageal sphincter and may provoke symptoms.

Patient factors

Visceral sensitivity and patient vigilance play a role in determining symptom severity and consulting behaviour in individual patients.

Fig. 22.27 Types of hiatus hernia.

Clinical features

The major symptoms are heartburn and regurgitation, often provoked by bending, straining or lying down. 'Waterbrash', which is salivation due to reflex salivary gland stimulation as acid enters the gullet, is often present. The patient is often overweight. Some patients are woken at night by choking as refluxed fluid irritates the larynx. Others develop odynophagia or dysphagia. A variety of 'extra-oesophageal' features have been described such as atypical chest pain which may be severe, can mimic angina and may be due to reflux-induced oesophageal spasm. Others include so-called 'acid laryngitis', recurrent chest infections, chronic cough and asthma (Box 22.34). The true relationship of these to gastro-oesophageal reflux disease remains unclear.

Complications

Oesophagitis

A range of endoscopic findings, from mild redness to severe, bleeding ulceration with stricture formation, are recognised, although appearances may be completely normal (Fig. 22.28). There is a poor correlation between symptoms and histological and endoscopic findings.

Barrett's oesophagus

Barrett's oesophagus is a pre-malignant condition in which the normal squamous lining of the lower oesophagus is replaced by columnar mucosa (columnar lined oesophagus; CLO) containing areas of intestinal metaplasia (Fig. 22.29). It occurs as an adaptive

Fig. 22.29 Barrett's oesophagus. Pink columnar mucosa is seen extending upwards above the oesophago-gastric junction.

response to chronic gastro-oesophageal reflux and is found in 10% of patients undergoing gastroscopy for reflux symptoms. Community-based epidemiological and autopsy studies suggest the true prevalence may be up to 20 times greater, as the condition is often asymptomatic until first discovered when the patient presents with oesophageal cancer. CLO is a major risk factor for oesophageal adenocarcinoma, with a lifetime cancer risk of around 10%. The absolute risk is low, however, and more than 95% of patients with CLO die from causes other than oesophageal cancer. The epidemiology and aetiology of CLO are poorly understood. The prevalence is increasing, and it is more common in men (especially white) and those over 50 years of age. It is weakly associated with smoking but not alcohol. Cancer risk is more closely related to the severity and duration of reflux rather than the presence of CLO per se. Recent attention has focused on the importance of duodenogastro-oesophageal reflux, containing bile, pancreatic enzymes and pepsin in addition to acid. The molecular events underlying the progression of CLO from metaplasia to dysplasia to cancer are not well understood but E-cadherin polymorphisms, p53 mutations, transforming growth factor- β (TGF- β), epidermal growth factor (EGF) receptors, COX-2 and tumour necrosis factor- α (TNF- α) may play roles in neoplastic progression.

Diagnosis This requires multiple systematic biopsies to maximise the chance of detecting intestinal metaplasia and/or dysplasia.

Management Neither potent acid suppression nor anti-reflux surgery will stop progression or induce regression of CLO, and treatment is only indicated for symptoms of reflux or complications such as stricture. Endoscopic therapies such as argon plasma coagulation, radiofrequency ablation or photodynamic therapy can induce regression but remain experimental. Regular endoscopic surveillance can detect dysplasia and malignancy at an early stage and may improve survival but, because most CLO is undetected until cancer develops, surveillance strategies are unlikely to influence the overall mortality rate of oesophageal cancer. Surveillance is expensive and cost-effectiveness studies have been conflicting, but currently it is recommended that patients with CLO without

EBM 22.34 The association between gastro-oesophageal reflux disease and asthma

'Reflux is significantly more common in asthma patients (odds ratio 5.5) and asthma is more common in GORD patients (odds ratio 2.3), compared to controls. Evidence for the direction of causality, however, is lacking.'

• Havemann BD, et al. Gut 2007; 56:1654–1664.

Fig. 22.28 Reflux oesophagitis. There are numerous linear streaks of superficial ulceration extending up the gullet.

dysplasia should undergo endoscopy every 2–3 years and those with low-grade dysplasia at 6–12-monthly intervals.

Oesophagectomy is widely recommended for those with high-grade dysplasia (HGD), as the resected specimen harbours cancer in up to 40%. This may be an over-estimate and recent data suggest that HGD often remains stable and may not progress to cancer, at least in the medium term. A combination of endoscopic mucosal resection (EMR) of any visibly abnormal areas and ablation of the remaining Barrett's mucosa shows promise as an 'organ-preserving' alternative to surgery.

Anaemia

Iron deficiency anaemia occurs as a consequence of chronic, insidious blood loss from long-standing oesophagitis. Most patients have a large hiatus hernia and bleeding can occur from subtle erosions in the neck of the sac ('Cameron lesions'). Nevertheless, hiatus hernia is very common and other causes of blood loss, particularly colorectal cancer, must be considered in anaemic patients, even when endoscopy reveals oesophagitis and a hiatus hernia.

Benign oesophageal stricture

Fibrous strictures develop as a consequence of long-standing oesophagitis. Most patients are elderly and have poor oesophageal peristaltic activity. They present with dysphagia which is worse for solids than for liquids. Bolus obstruction following ingestion of meat causes absolute dysphagia. A history of heartburn is common but not invariable; many elderly patients presenting with strictures have no preceding heartburn.

Diagnosis is by endoscopy, when biopsies of the stricture can be taken to exclude malignancy. Endoscopic balloon dilatation or bouginage is helpful. Subsequently, long-term therapy with a PPI drug at full dose should be started to reduce the risk of recurrent oesophagitis and stricture formation. The patient should be advised to chew food thoroughly, and it is important to ensure adequate dentition.

Gastric volvulus

Occasionally a massive intrathoracic hiatus hernia may twist upon itself, in either the organo-axial or the lateral axis, leading to a gastric volvulus. This leads to complete oesophageal or gastric obstruction and the patient presents with severe chest pain, vomiting and dysphagia. The diagnosis is made by chest X-ray (air bubble in the chest) and barium swallow. Most cases spontaneously resolve but tend to recur and surgery is usually advised after nasogastric decompression.

Investigations

Young patients who present with typical symptoms of gastro-oesophageal reflux, without worrying features such as dysphagia, weight loss or anaemia, can be treated empirically without investigation. Investigation is advisable if patients present in middle or late age, if symptoms are atypical or if a complication is suspected. Endoscopy is the investigation of choice. This is performed to exclude other upper gastrointestinal diseases which can mimic gastro-oesophageal reflux, and to identify complications. A normal endoscopy in a patient with compatible symptoms should not preclude treatment for gastro-oesophageal reflux disease.

Twenty-four-hour pH monitoring is indicated if the diagnosis is unclear or surgical intervention is under

consideration. This involves tethering a slim catheter with a terminal radiotelemetry pH-sensitive probe above the gastro-oesophageal junction. The intraluminal pH is recorded whilst the patient undergoes normal activities, and episodes of pain are noted and related to pH. A pH of less than 4 for more than 6–7% of the study time is diagnostic of reflux disease. In a few patients with difficult reflux, impedance testing can detect weakly acidic or alkaline reflux that is not revealed by standard pH testing.

Management

Lifestyle advice, including weight loss, avoidance of dietary items which the patient finds worsen symptoms, elevation of the bed head in those who experience nocturnal symptoms, avoidance of late meals and giving up smoking, are recommended but rarely heeded. PPIs are the treatment of choice. Symptoms usually resolve and oesophagitis heals in the majority of patients. Recurrence of symptoms is common when therapy is stopped and some patients require life-long treatment at the lowest acceptable dose. There is no evidence that *H. pylori* eradication has any therapeutic value. Proprietary antacids and alginates also provide symptomatic benefit. H_2 -receptor antagonist drugs also help symptoms without healing oesophagitis.

Patients who fail to respond to medical therapy, those who are unwilling to take long-term PPIs and those whose major symptom is severe regurgitation should be considered for laparoscopic anti-reflux surgery. Although heartburn and regurgitation are alleviated in most patients, a small minority develop complications such as inability to vomit and abdominal bloating ('gas-bloat' syndrome'). A treatment algorithm is outlined in Figure 22.30.

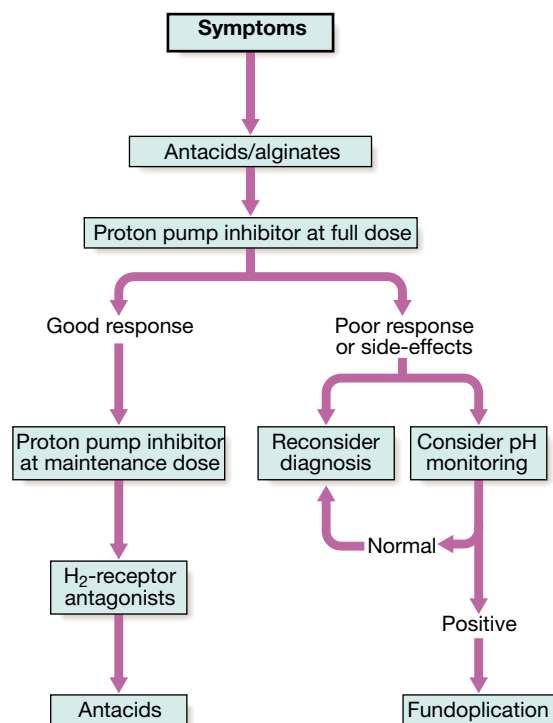

Fig. 22.30 Treatment of gastro-oesophageal reflux disease: a 'step-down' approach.

22.35 Gastro-oesophageal reflux disease in old age

- **Prevalence:** higher.
- **Severity of symptoms:** does not correlate with the degree of mucosal inflammation.
- **Complications:** late complications such as peptic strictures or bleeding from oesophagitis are more common.
- **Recurrent pneumonia:** consider aspiration from occult gastro-oesophageal reflux disease.

Other causes of oesophagitis

Infection

Oesophageal candidiasis occurs in debilitated patients and those taking broad-spectrum antibiotics or cytotoxic drugs. It is a particular problem in AIDS patients, who are also susceptible to a spectrum of other oesophageal infections (p. 393).

Corrosives

Suicide attempt by strong household bleach or battery acid is followed by painful burns of the mouth and pharynx and by extensive erosive oesophagitis. This is complicated by oesophageal perforation with mediastinitis and by stricture formation. At the time of presentation treatment is conservative, based upon analgesia and nutritional support; vomiting and endoscopy should be avoided because of the high risk of oesophageal perforation. Following the acute phase, a barium swallow should be performed to demonstrate the extent of stricture formation. Endoscopic dilatation is usually necessary, although it is difficult and hazardous because strictures are often long, tortuous and easily perforated.

Drugs

Potassium supplements and NSAIDs may cause oesophageal ulcers when the tablets are trapped above an oesophageal stricture. Liquid preparations of these drugs should be used in such patients. Bisphosphonates, especially alendronate, cause oesophageal ulceration and should be used with caution in patients with known oesophageal disorders.

Eosinophilic oesophagitis

This is more common in children but increasingly recognised in young adults. It occurs more often in atopic individuals and is characterised by eosinophilic infiltration of the oesophageal mucosa. Patients present with dysphagia more often than heartburn, and other symptoms such as chest pain and vomiting may be present. Endoscopy is usually normal although mucosal rings (that sometimes need endoscopic dilatation), strictures or a narrow-calibre oesophagus sometimes occur. Children may respond to elimination diets, but these are less successful in adults who should first be treated with PPIs. Good responses are reported with 8–12 weeks of therapy with topical corticosteroids (fluticasone or betamethasone); a metered dose inhaler is used but sprayed into the mouth and swallowed, rather than inhaled. Refractory symptoms sometimes respond to montelukast, a leukotriene inhibitor.

Motility disorders

Pharyngeal pouch

Incoordination of swallowing within the pharynx leads to herniation through the cricopharyngeus muscle and formation of a pouch. Most patients are elderly and have no symptoms, although regurgitation, halitosis and dysphagia can occur. Some notice gurgling in the throat after swallowing. A barium swallow demonstrates the pouch and reveals incoordination of swallowing, often with pulmonary aspiration. Endoscopy may be hazardous since the instrument may enter and perforate the pouch. Surgical myotomy and resection of the pouch are indicated in symptomatic patients.

Achalasia of the oesophagus

Achalasia is a rare disease affecting 1:100000 people. It usually develops in middle life but can occur at any age.

Pathophysiology

Achalasia is characterised by:

- a hypertonic lower oesophageal sphincter which fails to relax in response to the swallowing wave
- failure of propagated oesophageal contraction, leading to progressive dilatation of the gullet.

The cause is unknown. Defective release of nitric oxide by inhibitory neurons in the lower oesophageal sphincter has been reported, and there is degeneration of ganglion cells within the sphincter and the body of the oesophagus. Loss of the dorsal vagal nuclei within the brain stem can be demonstrated in later stages. Infection with *Trypanosoma cruzi* in Chagas disease (p. 354) causes a syndrome that is clinically indistinguishable from achalasia.

Clinical features

The presentation is with dysphagia. This develops slowly, is initially intermittent, and is worse for solids and eased by drinking liquids, and by standing and moving around after eating. Heartburn does not occur because the closed oesophageal sphincter prevents gastro-oesophageal reflux. Some patients experience episodes of chest pain due to oesophageal spasm. As the disease progresses, dysphagia worsens, the oesophagus empties poorly and nocturnal pulmonary aspiration develops. Achalasia predisposes to squamous carcinoma of the oesophagus.

Investigations

Endoscopy should always be carried out because carcinoma of the cardia can mimic the presentation and radiological and manometric features of achalasia ('pseudo-achalasia'). A barium swallow shows tapered narrowing of the lower oesophagus and in late disease the oesophageal body is dilated, aperistaltic and food-filled (Fig. 22.31A). Manometry confirms the high-pressure, non-relaxing lower oesophageal sphincter with poor contractility of the oesophageal body (Fig. 22.31C).

Management

Endoscopic

Forceful pneumatic dilatation using a 30–35 mm diameter fluoroscopically positioned balloon disrupts the

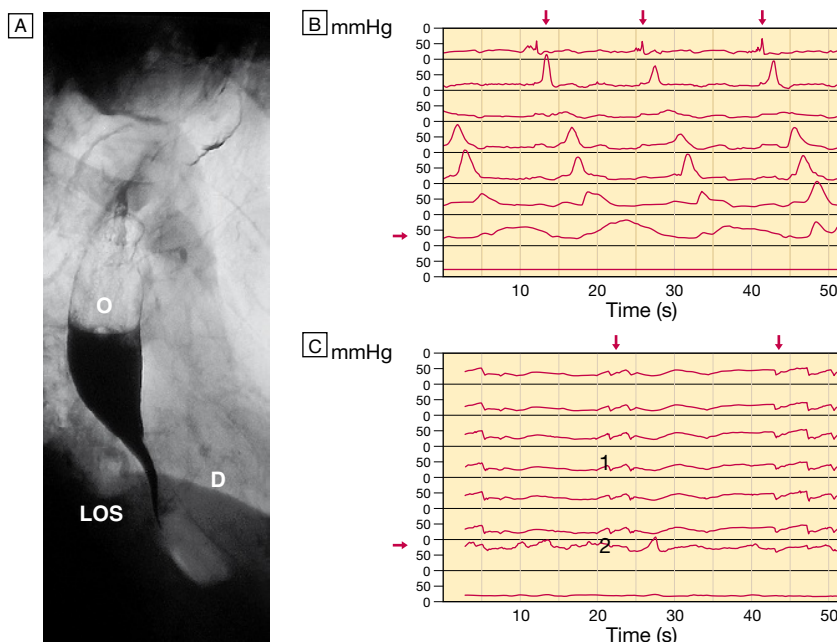

Fig. 22.31 Achalasia. [A] X-ray showing a dilated, barium-filled oesophagus (O) with fluid level and distal tapering, and a closed lower oesophageal sphincter (LOS). (D = diaphragm) [B] Normal oesophageal manometry showing propagated swallows and normal LOS pressure with relaxation on swallowing. [C] Manometry in achalasia showing non-propagated, ineffective contractions (1) and raised LOS pressure with failure of relaxation on swallowing (2). Compare with Figure 22.1, page 838.

oesophageal sphincter and improves symptoms in 80% of patients. Some patients require more than one dilatation but those requiring frequent dilatation are best treated surgically. Endoscopically directed injection of botulinum toxin into the lower oesophageal sphincter induces clinical remission, but relapse is common.

Surgical

Surgical myotomy ('Heller's operation'), performed either laparoscopically or as an open operation, is an extremely effective, although more invasive option. Both pneumatic dilatation and myotomy may be complicated by gastro-oesophageal reflux, and this can lead to severe oesophagitis because oesophageal clearance is so poor. For this reason Heller's myotomy is accompanied by a partial fundoplication anti-reflux procedure. PPI therapy is often necessary after surgery.

Other oesophageal motility disorders

Diffuse oesophageal spasm presents in late middle age with episodic chest pain which may mimic angina, but is sometimes accompanied by transient dysphagia. Some cases occur in response to gastro-oesophageal reflux. Treatment is based upon the use of PPI drugs when gastro-oesophageal reflux is present. Oral or sublingual nitrates or nifedipine may relieve attacks of pain. Drug therapy is often disappointing, as are the alternatives, pneumatic dilatation and surgical myotomy. 'Nutcracker' oesophagus is a condition in which extremely forceful peristaltic activity leads to episodic chest pain and dysphagia. Treatment is with nitrates or nifedipine. Some patients present with oesophageal motility disorders which do not fit into a specific disease entity. The patients are usually elderly and present

with dysphagia and chest pain. Manometric abnormalities ranging from poor peristalsis to spasm occur. Treatment is with dilatation and/or vasodilators for chest pain.

Secondary causes of oesophageal dysmotility

In systemic sclerosis the muscle of the oesophagus is replaced by fibrous tissue which causes failure of peristalsis leading to heartburn and dysphagia. Oesophagitis is often severe, and benign fibrous strictures occur. These patients require long-term therapy with PPIs. Dermatomyositis, rheumatoid arthritis and myasthenia gravis may also cause dysphagia.

Benign oesophageal stricture

Benign oesophageal stricture is usually a consequence of gastro-oesophageal reflux disease (Box 22.36) and occurs most often in elderly patients who have poor oesophageal clearance. Rings, due to submucosal fibrosis, occur at the

22.36 Causes of oesophageal stricture

- Gastro-oesophageal reflux disease
- Webs and rings
- Carcinoma of the oesophagus or cardia
- Eosinophilic oesophagitis
- Extrinsic compression from bronchial carcinoma
- Corrosive ingestion
- Post-operative scarring following oesophageal resection
- Post-radiotherapy
- Following long-term nasogastric intubation

oesophago-gastric junction ('Schatzki ring') and cause intermittent dysphagia, often starting in middle age. A post-cricoid web is a rare complication of iron deficiency anaemia (Paterson-Kelly or Plummer-Vinson syndrome), and may be complicated by the development of squamous carcinoma. Benign strictures are treated by endoscopic dilatation, in which wire-guided bougies or balloons are used to disrupt the fibrous tissue of the stricture.

Tumours of the oesophagus

Benign tumours

The most common is a gastrointestinal stromal tumour (GIST). This is usually asymptomatic but may cause bleeding or dysphagia.

Carcinoma of the oesophagus

Squamous oesophageal cancer (Box 22.37) is relatively rare in Caucasians (4/100 000), whilst in Iran, parts of Africa and China it is much more common (200 per 100 000). Squamous cancer can arise in any part of the oesophagus, and almost all tumours in the upper oesophagus are squamous cancers. Adenocarcinomas typically arise in the lower third of the oesophagus from Barrett's oesophagus or from the cardia of the stomach. The incidence is increasing and is now approximately 5:100 000 in the UK; this is possibly because of the high prevalence of gastro-oesophageal reflux and Barrett's oesophagus in Western populations. Despite modern treatment, the overall 5-year survival of patients presenting with oesophageal cancer is only 9–13%.

Clinical features

Most patients have a history of progressive, painless dysphagia for solid foods. Others present acutely because of food bolus obstruction. In late stages weight loss is often extreme; chest pain or hoarseness suggests mediastinal invasion. Fistulation between the oesophagus and the trachea or bronchial tree leads to coughing after swallowing, pneumonia and pleural effusion. Physical signs may be absent, but even at initial presentation cachexia, cervical lymphadenopathy or other evidence of metastatic spread is common.

Investigations

The investigation of choice is upper gastrointestinal endoscopy (Fig. 22.32) with cytology and biopsy. A barium swallow demonstrates the site and length of the stricture but adds little useful information. Once a diagnosis has been achieved, investigations are performed

Fig. 22.32 Adenocarcinoma of the lower oesophagus. Adenocarcinoma in association with Barrett's oesophagus (arrow).

to stage the tumour and define operability. Thoracic and abdominal CT are carried out to identify metastatic spread and local invasion. Invasion of the aorta and other local structures may preclude surgery. EUS is the most sensitive method for determining depth of penetration of the tumour into the oesophageal wall and for detecting involved locoregional lymph nodes (Fig. 22.33). These investigations will define the TNM stage of the disease (Ch. 11).

Management

The treatment of choice is surgery if the patient presents at a point at which resection is possible. Tumours which have extended beyond the wall of the oesophagus and have lymph node involvement (T3,N1) are associated with a 5-year survival of around 10%. However, this figure improves significantly if the tumour is confined to the oesophageal wall and there is no spread to lymph nodes. Overall survival following 'potentially curative'

Fig. 22.33 Endoscopic ultrasound staging of oesophageal carcinoma. The tumour (T) has extended through the oesophageal wall (stage T3, arrows). A small peritumoral lymph node (LN) is also seen. (Ao = aorta; LA = left atrium; E = echoendoscope)

22.37 Squamous carcinoma: aetiological factors

- Smoking
- Alcohol excess
- Chewing betel nuts or tobacco
- Coeliac disease
- Achalasia of the oesophagus
- Post-cricoid web
- Post-caustic stricture
- Tylosis (familial hyperkeratosis of palms and soles)

surgery (all macroscopic tumour removed) is about 30% at 5 years, but recent studies have suggested that this can be improved by neoadjuvant (pre-operative) chemotherapy with agents such as cisplatin and 5-fluorouracil. Although squamous carcinomas are radiosensitive, radiotherapy alone is associated with a 5-year survival of only 5%, but combined chemoradiotherapy for these tumours can achieve 5-year survival rates of 25–30%.

Approximately 70% of patients have extensive disease at presentation; in these, treatment is palliative and based upon relief of dysphagia and pain. Endoscopic laser therapy or self-expanding metallic stents are used to improve swallowing. Palliative radiotherapy may induce shrinkage of both squamous cancers and adenocarcinomas but symptomatic response may be slow. Quality of life can be improved by nutritional support and appropriate analgesia.

Perforation of the oesophagus

The most common cause is endoscopic perforation complicating dilatation or intubation. Malignant, corrosive or post-radiotherapy strictures are more likely to be perforated than peptic strictures. A perforated peptic stricture is usually managed conservatively using broad-spectrum antibiotics and parenteral nutrition; most heal within days. Malignant, caustic and radiotherapy stricture perforations require surgical resection or intubation.

Spontaneous oesophageal perforation ('Boerhaave's syndrome') results from forceful vomiting and retching. Severe chest pain and shock occur as oesophago-gastric contents enter the mediastinum and thoracic cavity. Subcutaneous emphysema, pleural effusions and pneumothorax develop. The diagnosis is made using a water-soluble contrast swallow, but in difficult cases both CT and careful endoscopy (usually in an intubated patient) may be required. Treatment is surgical. Delay in diagnosis is a key factor in the high mortality associated with this condition.

DISEASES OF THE STOMACH AND DUODENUM

Gastritis

Gastritis is a histological diagnosis, although it can sometimes be recognised at endoscopy.

Acute gastritis

Acute gastritis is often erosive and haemorrhagic. Neutrophils are the predominant inflammatory cell in the superficial epithelium. Many cases result from aspirin or NSAID ingestion (Box 22.38). Acute gastritis often produces no symptoms but may cause dyspepsia, anorexia, nausea or vomiting, and haematemesis or melaena. Many cases resolve quickly and do not merit investigation; in others, endoscopy and biopsy may be necessary to exclude peptic ulcer or cancer. Treatment should be directed to the underlying cause. Short-term symptomatic therapy with antacids, and acid suppression using PPIs or antiemetics (e.g. metoclopramide) may be necessary.

22.38 Common causes of gastritis

Acute gastritis (often erosive and haemorrhagic)

- Aspirin, NSAIDs
- *H. pylori* (initial infection)
- Alcohol
- Other drugs, e.g. iron preparations
- Severe physiological stress, e.g. burns, multi-organ failure, CNS trauma
- Bile reflux, e.g. following gastric surgery
- Viral infections, e.g. cytomegalovirus (CMV), herpes simplex virus in AIDS (pp. 393–394)

Chronic non-specific gastritis

- *H. pylori* infection
- Autoimmune (pernicious anaemia)
- Post-gastrectomy

Chronic 'specific' forms (rare)

- Infections, e.g. CMV, tuberculosis
- Gastrointestinal diseases, e.g. Crohn's disease
- Systemic diseases, e.g. sarcoidosis, graft-versus-host disease
- Idiopathic, e.g. granulomatous gastritis

Chronic gastritis due to *Helicobacter pylori* infection

This is the most common cause of chronic gastritis (see Box 22.38). The predominant inflammatory cells are lymphocytes and plasma cells. Correlation between symptoms and endoscopic or pathological findings is poor. Most patients are asymptomatic and do not require any treatment, but patients with dyspepsia may benefit from *H. pylori* eradication.

Autoimmune chronic gastritis

This involves the body of the stomach but spares the antrum; it results from autoimmune activity against parietal cells. The histological features are diffuse chronic inflammation, atrophy and loss of fundic glands, intestinal metaplasia and sometimes hyperplasia of enterochromaffin-like (ECL) cells. Circulating antibodies to parietal cell and intrinsic factor may be present. In some patients the degree of gastric atrophy is severe, and loss of intrinsic factor secretion leads to pernicious anaemia (p. 1021). The gastritis itself is usually asymptomatic. Some patients have evidence of other organ-specific autoimmunity, particularly thyroid disease. There is a fourfold increase in the risk of gastric cancer (see also p. 876).

Ménétrier's disease

In this rare condition the gastric pits are elongated and tortuous, with replacement of the parietal and chief cells by mucus-secreting cells. As a result, the mucosal folds of the body and fundus are greatly enlarged. Most patients are hypochlorhydric. Whilst some patients have upper gastrointestinal symptoms, the majority present in middle or old age with protein-losing enteropathy (p. 885) due to exudation from the gastric mucosa. Barium meal shows enlarged, nodular and coarse folds which are also seen at endoscopy, although biopsies may not be deep enough to show all the histological features. Treatment with antisecretory drugs may reduce protein loss but unresponsive patients require partial gastrectomy.

Peptic ulcer disease

The term 'peptic ulcer' refers to an ulcer in the lower oesophagus, stomach or duodenum, in the jejunum after surgical anastomosis to the stomach or, rarely, in the ileum adjacent to a Meckel's diverticulum. Ulcers in the stomach or duodenum may be acute or chronic; both penetrate the muscularis mucosae but the acute ulcer shows no evidence of fibrosis. Erosions do not penetrate the muscularis mucosae.

Gastric and duodenal ulcer

The prevalence of peptic ulcer is decreasing in many Western communities as a result of widespread use of *H. pylori* eradication therapy but it remains high in developing countries. The male to female ratio for duodenal ulcer varies from 5:1 to 2:1, whilst that for gastric ulcer is 2:1 or less. Chronic gastric ulcer is usually single; 90% are situated on the lesser curve within the antrum or at the junction between body and antral mucosa. Chronic duodenal ulcer usually occurs in the first part of the duodenum just distal to the junction of pyloric and duodenal mucosa; 50% are on the anterior wall. Gastric and duodenal ulcers coexist in 10% of patients and more than one peptic ulcer is found in 10–15% of patients.

Pathophysiology

H. pylori

Peptic ulceration is strongly associated with *H. pylori* infection. The prevalence of *H. pylori* infection in developed nations rises steadily with age, and in the UK approximately 50% of people over the age of 50 years are infected. In many parts of the developing world infection is more common, affecting up to 90% of the adult population. These infections are probably acquired in childhood. The vast majority of colonised people remain healthy and asymptomatic and only a minority develop clinical disease. Around 90% of duodenal ulcer patients and 70% of gastric ulcer patients are infected with *H. pylori*; the remaining 30% of gastric ulcers are due to NSAIDs. *H. pylori* is Gram-negative and spiral, and has multiple flagella at one end which make it motile, allowing it to burrow and live deep beneath the mucus layer closely adherent to the epithelial surface. It uses an adhesin molecule (BabA) to bind to the Lewis b antigen on epithelial cells. Here the surface pH is close to neutral and any acidity is buffered by the organism's production of the enzyme urease. This produces ammonia from urea and raises the pH around the bacterium and between its two cell membrane layers. The bacteria spread by person-to-person contact via gastric refluxate or vomit. *H. pylori* exclusively colonises gastric-type epithelium and is only found in the duodenum in association with patches of gastric metaplasia. The bacterium stimulates chronic gastritis by provoking a local inflammatory response in the underlying epithelium (Fig. 22.34). This depends on numerous factors, notably expression of bacterial *cagA* and *vacA* genes. The *cagA* gene product is injected into epithelial cells, ultimately interacting with numerous cell-signalling pathways involved in cell replication and apoptosis. *H. pylori* strains expressing *cagA* (*cagA*⁺) are more often associated with disease than *cagA*⁻ strains. Most strains also secrete a large pore-forming protein called *vacA* which causes large vacuoles to form

Other factors

- Vacuolating cytotoxin (*vacA*)
- Cytotoxin-associated gene (*cagA*)
- Adhesins (BabA)
- Outer inflammatory protein A (*oipA*)

Fig. 22.34 Factors which influence the virulence of *H. pylori*.

in cells in vitro. In vivo, *vacA* has many effects, including increased cell permeability, efflux of micronutrients from the epithelium, induction of apoptosis and suppression of local immune cell activity. Several forms of *vacA* exist and pathology is most strongly associated with the s1/ml form of the toxin. Host genetic polymorphisms are also important—for example, those that lead to greater levels of expression of the proinflammatory cytokine interleukin-1 β (IL-1 β) are associated with greater risk of gastric atrophy and subsequent carcinoma. In most people *H. pylori* causes antral gastritis associated with depletion of somatostatin (from D cells) and increased gastrin release from G cells. The subsequent hypergastrinaemia stimulates acid production by parietal cells, but in the majority of cases this has no clinical consequences. In a minority of patients (perhaps smokers) this effect is exaggerated, leading to duodenal ulceration (Fig. 22.35). The role of *H. pylori* in the pathogenesis of gastric ulcer is less clear

Fig. 22.35 Sequence of events in the pathophysiology of duodenal ulceration.

but it probably acts by reducing gastric mucosal resistance to attack from acid and pepsin. In approximately 1% of infected people, *H. pylori* causes a pangastritis leading to gastric atrophy and hypochlorhydria. This allows bacteria to proliferate within the stomach; these may produce mutagenic nitrites from dietary nitrates, predisposing to the development of gastric cancer (Fig. 22.36). Most duodenal ulcer patients have exaggerated acid secretion in response to stimulation by gastrin, and *H. pylori* exacerbates this by stimulating gastrin production. The effects of *H. pylori* are more complex in gastric ulcer patients; here the ulcer probably occurs because of impaired mucosal defence resulting from a combination of *H. pylori* infection, NSAIDs and smoking.

NSAIDs

NSAIDs are associated with peptic ulcers due to impairment of mucosal defences, as discussed on page 1076.

Smoking

Smoking confers an increased risk of gastric ulcer and, to a lesser extent, duodenal ulcer. Once the ulcer has formed, it is more likely to cause complications and less likely to heal if the patient continues to smoke.

Clinical features

Peptic ulcer disease is a chronic condition with a natural history of spontaneous relapse and remission lasting for decades, if not for life. Although they are different diseases, duodenal and gastric ulcers share common symptoms which will be considered together. The most common presentation is that of recurrent abdominal pain which has three notable characteristics: localisation to the epigastrium, relationship to food and episodic occurrence. Occasional vomiting occurs in about 40% of ulcer subjects; persistent daily vomiting suggests gastric outlet obstruction. In one-third of patients the history is less characteristic. This is especially true in elderly subjects under treatment with NSAIDs. In these patients pain may be absent or so slight that it is experienced only as a vague sense of epigastric unease. Occasionally, the only

symptoms are anorexia and nausea, or a sense of undue repletion after meals. In some patients the ulcer is completely 'silent', presenting for the first time with anaemia from chronic undetected blood loss, as an abrupt haematemesis or as acute perforation; in others there is recurrent acute bleeding without ulcer pain between the attacks. The diagnostic value of individual symptoms for peptic ulcer disease is poor; the history is therefore a poor predictor of the presence of an ulcer.

Investigations

Endoscopy is the preferred investigation. Gastric ulcers may occasionally be malignant and therefore must always be biopsied and followed up to ensure healing. Patients should also be screened for *H. pylori* infection. The current options available are listed in Box 22.39. Some are invasive and require endoscopy; others are non-invasive. They vary in sensitivity and specificity. Overall, breath tests are best because of their accuracy, simplicity and non-invasiveness.

Management

The aims of management are to relieve symptoms, induce healing and prevent recurrence. *H. pylori* eradication is the cornerstone of therapy for peptic ulcers, as this will successfully prevent relapse and eliminate the need for long-term therapy in the majority of patients.

H. pylori eradication

All patients with proven acute or chronic duodenal ulcer disease and those with gastric ulcers who are *H. pylori*-positive should be offered eradication as primary therapy. Treatment is based upon a PPI taken simultaneously with two antibiotics (from amoxicillin, clarithromycin and metronidazole) for 7 days (Box 22.40). Success is achieved in over 90% of patients, although compliance, side-effects (Box 22.41) and metronidazole resistance influence the success of therapy.

Fig. 22.36 Consequences of *H. pylori* infection.

22.39 Methods for the diagnosis of <i>Helicobacter pylori</i> infection		
Test	Advantages	Disadvantages
Non-invasive		
Serology	Rapid office kits available Good for population studies	Lacks sensitivity and specificity Cannot differentiate current from past infection
¹³ C-urea breath tests	High sensitivity and specificity	Requires expensive mass spectrometer
Faecal antigen test	Cheap, specific (> 95%)	Acceptability
Invasive (antral biopsy)		
Histology	Sensitivity and specificity	False negatives occur Takes several days to process
Rapid urease tests	Cheap, quick, specific (> 95%)	Sensitivity 85%
Microbiological culture	'Gold standard' Defines antibiotic sensitivity	Slow and laborious Lacks sensitivity

EBM 22.40 Antibiotic regimens for *H. pylori* eradication

'First-line therapy is a proton pump inhibitor (12-hourly), clarithromycin 500 mg 12-hourly, and amoxicillin 1 g 12-hourly or metronidazole 400 mg 12-hourly, for 7 days. This is superior to ulcer-healing drugs for duodenal ulcer healing (relative risk of ulcer persistence 0.66, 95% confidence interval 0.58–0.78).'

• Ford, AC, et al. (Cochrane Review). Cochrane Library, issue 2, 2006. Oxford: Update Software.

For further information:  www.cochrane.org/reviews

22.41 Common side-effects of *H. pylori* eradication therapy

- Diarrhoea
- 30–50% of patients; usually mild but *Clostridium difficile*-associated colitis can occur
- Flushing and vomiting when taken with alcohol (metronidazole)
- Nausea, vomiting
- Abdominal cramp
- Headache
- Rash

Second-line therapy should be offered to those patients who remain infected after initial therapy once the reasons for failure of first-line therapy have been established. For those who are still colonised after two treatments, the choice lies between a third attempt with quadruple therapy (bismuth, PPI and two antibiotics) or long-term maintenance therapy with acid suppression.

H. pylori and NSAIDs are independent risk factors for ulcer disease but it is not clear whether patients requiring long-term NSAID therapy should first undergo eradication therapy to reduce ulcer risk. Current evidence suggests that this is not necessary in young, fit patients with no history of ulcer disease or dyspepsia, but a 'test and treat' strategy for older patients with major comorbidity or a previous ulcer history is recommended. Subsequent co-prescription of a PPI along with the NSAID is advised but is not always necessary for patients being given low-dose aspirin in whom the risk of ulcer complications is lower.

Other indications for *H. pylori* eradication are shown in Box 22.42.

22.42 Indications for *H. pylori* eradication**Definite**

- Peptic ulcer
- MALToma
- *H. pylori*-positive dyspepsia

Not indicated

- Gastro-oesophageal reflux disease
- Asymptomatic

Uncertain

- Family history of gastric cancer
- Non-ulcer dyspepsia
- Long-term NSAID users

General measures

Cigarette smoking, aspirin and NSAIDs should be avoided. Alcohol in moderation is not harmful and no special dietary advice is required.

Maintenance treatment

Continuous maintenance treatment should not be necessary after successful *H. pylori* eradication. For the minority who do require it, the lowest effective dose of PPI should be used.

Surgical treatment

The cure of most peptic ulcers by *H. pylori* eradication therapy and the availability of safe, potent acid-suppressing drugs have made elective surgery for peptic ulcer disease a rare event. Indications for surgery are listed in Box 22.43.

The operation of choice for a chronic non-healing gastric ulcer is partial gastrectomy, preferably with a Billroth I anastomosis, in which the ulcer itself and the ulcer-bearing area of the stomach are resected. The reason for this is to exclude an underlying cancer. In an emergency situation 'under-running' the ulcer for bleeding or 'oversewing' (patch repair) for perforation is all that is required, in addition to taking a biopsy. In the presence of giant duodenal ulcers partial gastrectomy using a 'Polya' or Billroth II reconstruction may be required.

Complications of gastric resection or vagotomy

Although gastric surgery is now rarely undertaken for benign disease, many patients underwent ulcer operations in the pre-*H. pylori* era and some degree of disability is seen in up to 50% of these. In most, the effects are minor, but in 10% of cases they significantly impair quality of life.

- **Dumping.** Rapid gastric emptying leads to distension of the proximal small intestine as the hypertonic contents draw fluid into the lumen. This leads to abdominal discomfort and diarrhoea after eating. Autonomic reflexes release a range of gastrointestinal hormones which lead to vasomotor features such as flushing, palpitations, sweating, tachycardia and hypotension. Patients should therefore avoid large meals with high carbohydrate content.
- **Bile reflux gastritis.** Duodenogastric bile reflux leads to chronic gastritis. This is usually asymptomatic but dyspepsia can occur. Symptomatic treatment with aluminium-containing antacids or sucralfate may be effective. A few patients require revisional surgery with creation of a Roux en Y loop to prevent bile reflux into the stomach.

22.43 Indications for surgery in peptic ulcer**Emergency**

- Perforation
- Haemorrhage

Elective

- Complications, e.g. gastric outflow obstruction
- Recurrent ulcer following gastric surgery

- **Diarrhoea and maldigestion.** Diarrhoea may develop after any peptic ulcer operation and usually occurs 1–2 hours after eating. Poor mixing of food in the stomach, with rapid emptying, inadequate mixing with pancreatic biliary secretions, reduced small intestinal transit times and bacterial overgrowth, may lead to malabsorption. Diarrhoea often responds to dietary advice to eat small, dry meals with a reduced intake of refined carbohydrates. Antidiarrhoeal drugs such as codeine phosphate (15–30 mg 4–6 times a day) or loperamide (2 mg after each loose stool) are helpful.
- **Weight loss.** Most patients lose weight shortly after surgery and 30–40% are unable to regain all the weight which is lost. The usual cause is reduced intake because of a small gastric remnant, but diarrhoea and mild steatorrhoea also contribute.
- **Anaemia.** Anaemia is common many years after subtotal gastrectomy. Iron deficiency is the most common cause; folic acid and B₁₂ deficiency are much less frequent. Inadequate dietary intake of iron and folate, lack of acid and intrinsic factor secretion, mild chronic low-grade blood loss from the gastric remnant and recurrent ulceration are responsible.
- **Metabolic bone disease.** Both osteoporosis and osteomalacia can occur as a consequence of calcium and vitamin D malabsorption.
- **Gastric cancer.** An increased risk of gastric cancer has been reported from several epidemiological studies. The risk is highest in those with hypochlorhydria, duodenogastric reflux of bile, smoking and *H. pylori* infection. Although the relative risk is increased, the absolute risk of cancer remains low and endoscopic surveillance is not indicated following gastric surgery.

Complications of peptic ulcer disease

Perforation

When perforation occurs, the contents of the stomach escape into the peritoneal cavity, leading to peritonitis. This is more common in duodenal than in gastric ulcers, and is usually found with ulcers on the anterior wall. About one-quarter of all perforations occur in acute ulcers and NSAIDs are often incriminated. Perforation can be the first sign of ulcer, and a history of recurrent epigastric pain is uncommon. The most striking symptom is sudden, severe pain; its distribution follows the spread of the gastric contents over the peritoneum. The pain initially develops in the upper abdomen and rapidly becomes generalised; shoulder tip pain is due to irritation of the diaphragm. The pain is accompanied by shallow respiration due to limitation of diaphragmatic movements, and by shock. The abdomen is held immobile and there is generalised 'board-like' rigidity. Bowel sounds are absent and liver dullness to percussion decreases due to the presence of gas under the diaphragm. After some hours symptoms may improve, although abdominal rigidity remains. Later the patient's condition deteriorates as general peritonitis develops. In at least 50% of cases an erect chest X-ray shows free air beneath the diaphragm. If not, a water-soluble contrast swallow will confirm leakage of gastroduodenal contents. After resuscitation, the acute perforation is treated surgically, either by simple closure, or by converting the perforation into a pyloroplasty if it is large. On rare occa-

22.44 Peptic ulcer disease in old age

- **Gastroduodenal ulcers:** have a greater incidence, admission rate and mortality.
- **Causes:** high prevalence of *H. pylori*, NSAID use and impaired defence mechanisms.
- **Atypical presentations:** pain and dyspepsia are frequently absent or atypical. Older people often develop complications such as bleeding or perforation without a dyspeptic history.
- **Bleeding:** older patients require more intensive management (including CVP measurement) than younger patients because they tolerate hypovolaemic shock poorly.

sions a 'Polya' partial gastrectomy is required. Following surgery, *H. pylori* should be treated (if present) and NSAIDs avoided. Perforation carries a mortality of 25%. This high figure reflects the advanced age and significant comorbidity of this population.

Gastric outlet obstruction

The causes are shown in Box 22.45. The most common is an ulcer in the region of the pylorus. The presentation is with nausea, vomiting and abdominal distension. Large quantities of gastric content are often vomited, and food eaten 24 hours or more previously may be recognised. Physical examination may show evidence of wasting and dehydration. A succussion splash may be elicited 4 hours or more after the last meal or drink. Visible gastric peristalsis is diagnostic of gastric outlet obstruction. Loss of gastric contents leads to dehydration with low serum chloride and potassium, and raised serum bicarbonate and urea concentrations. This results in enhanced renal absorption of Na⁺ in exchange for H⁺ and paradoxical aciduria. Nasogastric aspiration of at least 200 mL of fluid from the stomach after an overnight fast suggests the diagnosis. Endoscopy should be performed after the stomach has been emptied by a wide-bore nasogastric tube. Nasogastric suction and intravenous correction of dehydration are undertaken. In severe cases at least 4 L of isotonic saline and 80 mmol of potassium may be necessary during the first 24 hours. In some patients PPI drugs heal ulcers, relieve pyloric oedema and overcome the need for surgery. Endoscopic balloon dilatation of benign stenoses may be possible in some patients, but in others partial gastrectomy is necessary, although this is best done after a 7-day period of nasogastric aspiration which enables the stomach to return to normal size. A gastroenterostomy is an alternative operation

22.45 Differential diagnosis and management of gastric outlet obstruction

Cause	Management
Fibrotic stricture from duodenal ulcer, i.e. 'pyloric stenosis'	Balloon dilatation or surgery
Oedema from pyloric channel or duodenal ulcer	PPI therapy
Carcinoma of antrum	Surgery
Adult hypertrophic pyloric stenosis	Surgery

but, unless this is accompanied by vagotomy, patients will require long-term PPI therapy to prevent stomal ulceration.

Bleeding

See pages 852–856.

Zollinger–Ellison syndrome

This is a rare disorder characterised by the triad of severe peptic ulceration, gastric acid hypersecretion and a non-beta cell islet tumour of the pancreas ('gastrinoma'). It probably accounts for about 0.1% of all cases of duodenal ulceration. The syndrome occurs in either sex at any age, although it is most common between 30 and 50 years of age.

Pathophysiology

The tumour secretes large amounts of gastrin, which stimulates the parietal cells of the stomach to secrete acid to their maximal capacity and increases the parietal cell mass three- to sixfold. The acid output may be so great that it reaches the upper small intestine, reducing the luminal pH to 2 or less. Pancreatic lipase is inactivated and bile acids are precipitated. Diarrhoea and steatorrhoea result. Around 90% of tumours occur in the pancreatic head or proximal duodenal wall. At least half are multiple, and tumour size can vary from 1 mm to 20 cm. Approximately one-half to two-thirds are malignant but are often slow-growing. Adenomas of the parathyroid and pituitary glands (multiple endocrine neoplasia, MEN type 1; p. 793) are present in 20–60% of patients.

Clinical features

The presentation is with severe and often multiple peptic ulcers in unusual sites such as the post-bulbar duodenum, jejunum or oesophagus. There is a poor response to standard ulcer therapy. The history is usually short; bleeding and perforations are common. The syndrome may present as severe recurrent ulceration following a standard operation for peptic ulcer. Diarrhoea is seen in one-third or more of patients and can be the presenting feature.

Investigations

Hypersecretion of acid under basal conditions with little increase following pentagastrin may be confirmed by gastric aspiration. Serum gastrin levels are grossly elevated (10- to 1000-fold). Injection of the hormone secretin normally causes no change or a slight decrease in circulating gastrin concentrations, but in Zollinger–Ellison syndrome produces a paradoxical and dramatic increase in gastrin. Tumour localisation is best achieved by EUS and radio-labelled somatostatin receptor scintigraphy.

Management

Approximately 30% of small and single tumours can be localised and resected but many tumours are multifocal. Some patients present with metastatic disease and surgery is inappropriate. PPIs have made total gastrectomy unnecessary, and in the majority of patients continuous therapy with omeprazole heals ulcers and alleviates diarrhoea. Larger doses (60–80 mg daily) than those used to treat duodenal ulcer are required. The synthetic somatostatin analogue, octreotide, given by subcutaneous injection, reduces gastrin secretion and is sometimes of value. Overall 5-year survival is 60–75% and all

patients should be monitored for the later development of other manifestations of MEN 1.

Functional disorders

Non-ulcer dyspepsia

This is defined as chronic dyspepsia in the absence of organic disease. Other commonly reported symptoms include early satiety, fullness, bloating and nausea. 'Ulcer-like' and 'dysmotility-type' subgroups are reported, but there is great overlap between these and also with irritable bowel syndrome.

Pathophysiology

The cause is poorly understood but probably covers a spectrum of mucosal, motility and psychiatric disorders.

Clinical features

Patients are usually young (< 40 years) and women are affected twice as commonly as men. Abdominal pain is associated with a variable combination of other 'dyspeptic' symptoms, the most common being nausea and bloating after meals. Morning symptoms are characteristic and pain or nausea may occur on waking. Direct enquiry may elicit symptoms suggestive of irritable bowel syndrome. Peptic ulcer disease must be considered, whilst in older subjects intra-abdominal malignancy is a prime concern. There are no diagnostic signs, apart perhaps from inappropriate tenderness on abdominal palpation. Symptoms may appear disproportionate to clinical well-being and there is no weight loss. Patients often appear anxious. A drug history should be taken and the possibility of a depressive illness should be considered. Pregnancy should be ruled out in young women before radiological studies are undertaken. Alcohol misuse should be suspected when early morning nausea and retching are prominent.

Investigations

The history will often suggest the diagnosis but in older subjects an endoscopy is necessary to exclude mucosal disease. While an ultrasound scan may detect gallstones, these are rarely responsible for dyspeptic symptoms.

Management

The most important elements are explanation and reassurance. Possible psychological factors should be explored and the concept of psychological influences on gut function should be explained. Idiosyncratic and restrictive diets are of little benefit, but fat restriction may help.

Drug treatment is not especially successful but merits trial. Antacids are sometimes helpful. Prokinetic drugs such as metoclopramide (10 mg 8-hourly) or domperidone (10–20 mg 8-hourly) may be given before meals if nausea, vomiting or bloating is prominent. Metoclopramide may induce extrapyramidal side-effects, including tardive dyskinesia in young subjects. H₂-receptor antagonist drugs may be tried if night pain or heartburn is troublesome. Low-dose amitriptyline is sometimes of value. The role of *H. pylori* eradication remains controversial, although up to 10% may benefit and a minority (5–15%) avoid ulcer development in the next 3 years. Eradication

also removes a major risk factor for gastric cancer but at the cost of a small risk of side-effects and worsening symptoms of underlying gastro-oesophageal reflux disease.

Symptoms which can be associated with an identifiable cause of stress resolve with appropriate counselling. Some patients have major chronic psychological disorders resulting in persistent or recurrent symptoms and need behavioural or other formal psychotherapy (p. 239).

Functional causes of vomiting

Psychogenic retching or vomiting may occur in anxiety. It typically occurs on waking or immediately after breakfast and only rarely later in the day. The disorder is probably a reaction to facing up to the worries of everyday life; in the young it can be due to school phobia. Early morning vomiting also occurs in pregnancy, alcohol misuse and depression. Although functional vomiting may occur regularly over long periods, there is little or no weight loss. Children, and less often adults, sometimes suffer from acute and recurrent disabling bouts of vomiting for days at a time. The cause of this 'cyclical vomiting syndrome' is unknown.

In all patients it is essential to exclude other common causes (p. 852). Tranquillisers and antiemetic drugs (e.g. metoclopramide 10 mg 8-hourly, domperidone 10 mg 8-hourly, prochlorperazine 5–10 mg 8-hourly) have only a secondary place in management. Antidepressants in full dose may be effective (p. 852).

Gastroparesis

Defective gastric emptying without mechanical obstruction of the stomach or duodenum can occur as a primary event, due to inherited or acquired disorders of the gastric pacemaker, or can be secondary to disorders of autonomic nerves (particularly diabetic neuropathy) or the gastroduodenal musculature (e.g. systemic sclerosis, myotonic dystrophies and amyloidosis). Drugs such as opiates, calcium channel antagonists and those with anticholinergic activity (tricyclics, phenothiazines) can also cause gastroparesis. Early satiety and recurrent vomiting are the major symptoms; abdominal fullness and a succussion splash may be present on examination. Treatment is based upon small, frequent, low-fat meals and the use of metoclopramide and domperidone. In severe cases nutritional failure can occur and long-term jejunostomy feeding or total parenteral nutrition is required. Surgical insertion of a gastric pacing device has been successful in some cases but remains experimental.

Tumours of the stomach

Gastric carcinoma

This remains the leading cause of cancer death worldwide, but there is marked geographical variation in incidence. It is extremely common in China, Japan and parts of South America (mortality rate 30–40 per 100 000), less common in the UK (12–13 deaths per 100 000) and uncommon in the USA. Studies of Japanese migrants to the USA have revealed a much lower incidence in second-generation migrants, confirming the importance of environmental factors. Gastric cancer is more common

in men and the incidence rises sharply after 50 years of age. The overall prognosis is poor, with less than 30% surviving 5 years, and the best hope for improved survival lies in greater detection of tumours at an earlier stage.

Pathophysiology

H. pylori is associated with chronic atrophic gastritis and gastric cancer (Fig. 22.37). *H. pylori* infection may be responsible for 60–70% of cases and acquisition of infection at an early age may be important. Although *H. pylori* infection is common in Africa, gastric cancer is uncommon and this 'enigma' may be explained by lower life expectancy in this part of the world. Although the majority of *H. pylori*-infected individuals have normal or increased acid secretion, a few become hypo- or achlorhydric and these people are thought to be at greatest risk. Chronic inflammation with generation of reactive oxygen species and depletion of the normally abundant antioxidant ascorbic acid are also important.

Diets rich in salted, smoked or pickled foods and the consumption of nitrites and nitrates may increase cancer risk. Carcinogenic N-nitroso-compounds are formed from nitrates by the action of nitrite-reducing bacteria which colonise the achlorhydric stomach. Diets lacking fresh fruit and vegetables as well as vitamins C and A may also contribute. Other risk factors are listed in Box 22.46. No predominant genetic abnormality has been identified, although cancer risk is increased two- to three-fold in first-degree relatives of patients, and links with blood group A have been reported. Rare 'gastric cancer families' have also been described, in which diffuse gastric cancers occur in association with mutations of the *E-cadherin* (CDH1) gene. This is inherited as an autosomal dominant trait. Virtually all tumours are adenocarcinomas arising from mucus-secreting cells in the base of the gastric crypts. Most develop upon a background of

Fig. 22.37 Gastric carcinogenesis: a possible mechanism.

22.46 Risk factors for gastric cancer

- *H. pylori*
- Smoking
- Alcohol
- Dietary associations (see text)
- Autoimmune gastritis (pernicious anaemia)
- Adenomatous gastric polyps
- Previous partial gastrectomy (> 20 years)
- Ménétrier's disease
- Hereditary diffuse gastric cancer families (HDC-1 mutations)
- Familial adenomatous polyposis (FAP, p. 908)

chronic atrophic gastritis with intestinal metaplasia and dysplasia. Cancers are either 'intestinal', arising from areas of intestinal metaplasia with histological features reminiscent of intestinal epithelium, or 'diffuse', arising from normal gastric mucosa. Intestinal carcinomas are more common, and arise against a background of chronic mucosal injury. Diffuse cancers tend to be poorly differentiated and occur in younger patients. In the developing world 50% of gastric cancers develop in the antrum, 20–30% occur in the gastric body, often on the greater curve, and 20% are found in the cardia. In Western populations, however, proximal gastric tumours are becoming more common than those arising in the body and distal stomach. This change in disease pattern may be a reflection of changes in lifestyle or the decreasing prevalence of *H. pylori* in the West. Diffuse submucosal infiltration by a scirrhous cancer (linitis plastica) is uncommon. Macroscopically, tumours may be classified as polypoid, ulcerating, fungating or diffuse. Early gastric cancer is defined as cancer confined to the mucosa or submucosa (Fig. 22.38A). It is more often recognised in Japan, where widespread screening is practised, but is increasingly seen in Western countries. Some cases can be cured by endoscopic mucosal resection (Fig. 22.38B) or endoscopic submucosal dissection (ESD). The majority of patients (> 80%) in the West, however, present with advanced gastric cancer.

Clinical features

Early gastric cancer is usually asymptomatic but may occasionally be discovered during endoscopy for investigation of dyspepsia. Two-thirds of patients with advanced cancers have weight loss and 50% have ulcer-like pain. Anorexia and nausea occur in one-third, while early satiety, haematemesis, melaena and dyspepsia alone are less common features. Dysphagia occurs in tumours of the gastric cardia which obstruct the gastro-oesophageal junction. Anaemia from occult bleeding is also common. Examination may reveal no abnormalities, but signs of weight loss, anaemia or a palpable epigastric mass are not infrequent. Jaundice or ascites may signify metastatic spread. Occasionally, tumour spread occurs to the supraclavicular lymph nodes (Troisier's sign), umbilicus ('Sister Joseph's nodule') or ovaries (Krukenberg tumour). Paraneoplastic phenomena, such as acanthosis nigricans, thrombophlebitis (Trousseau's sign) and dermatomyositis, occur rarely. Metastases occur most commonly in the liver, lungs, peritoneum and bone marrow.

Investigations

There are no laboratory markers of sufficient accuracy for the diagnosis of gastric cancer. Upper gastrointestinal endoscopy is the investigation of choice and should be performed promptly in any dyspeptic patient with 'alarm features' (see Box 22.15, p. 851). Multiple biopsies from the edge and base of a gastric ulcer are required. Barium meal is a poor alternative approach and any abnormalities must be followed by endoscopy to obtain biopsy. Once the diagnosis is made, further imaging is necessary for accurate staging and assessment of resectability. CT may not demonstrate small involved lymph nodes, but will show evidence of intra-abdominal spread or liver metastases. Even with these techniques, laparoscopy is required to determine whether the tumour is resectable, as it is the only modality that will reliably detect peritoneal spread.

Management

Surgery

Resection offers the only hope of cure, which can be achieved in 90% of patients with early gastric cancer. For the majority who have locally advanced disease

Fig. 22.38 Gastric carcinoma. [A] Endoscopic image of a small superficial prepyloric cancer (arrows). [B] Appearance after endoscopic mucosal resection (EMR). The tumour has been completely removed.

radical and total gastrectomy with lymphadenectomy is the operation of choice, preserving the spleen if possible. Proximal tumours involving the oesophago-gastric junction require an associated distal oesophagectomy. Small, distally sited tumours can be managed by a partial gastrectomy with lymphadenectomy and either a Billroth I or a Roux en Y reconstruction. More extensive lymph node resection may increase survival rates but carries greater morbidity. Even for those who cannot be cured, palliative resection may be necessary when patients present with bleeding or gastric outflow obstruction. Following surgery, recurrence is much more likely if serosal penetration has occurred, although complete removal of all macroscopic tumour combined with lymphadenectomy will achieve a 50–60% 5-year survival. Recent evidence suggests that perioperative chemotherapy with epirubicin, cisplatin and fluorouracil (ECF) improves survival rates.

Palliative treatment

In patients with inoperable tumours, palliation of symptoms can sometimes be achieved with chemotherapy using FAM (5-fluorouracil, doxorubicin and mitomycin C) or ECF. Endoscopic laser ablation for control of dysphagia or recurrent bleeding benefits some patients. Carcinomas at the cardia or pylorus may require endoscopic dilatation, laser therapy or insertion of expandable metallic stents for relief of dysphagia or vomiting. A nasogastric tube may offer temporary relief of vomiting from gastric outlet obstruction (Box 22.47).

Gastric lymphoma

Primary gastric lymphoma accounts for less than 5% of all gastric malignancies. The stomach is, however, the most common site for extranodal non-Hodgkin's lymphoma and 60% of all primary gastrointestinal lymphomas occur at this site. Lymphoid tissue is not found in the normal stomach but lymphoid aggregates develop in the presence of *H. pylori* infection. Indeed, *H. pylori* infection is closely associated with the development of a low-grade lymphoma ('MALToma'). EUS plays an important role in accurately staging these lesions.

The clinical presentation is similar to that of gastric cancer, and endoscopically the tumour appears as a polypoid or ulcerating mass. While initial treatment of low-grade MALTomas consists of *H. pylori* eradication and close observation, 25% contain t(11:18) chromosomal translocations and will rarely respond. In these cases, radiotherapy or chemotherapy is necessary. High-grade B-cell lymphomas are treated by a combination of chemotherapy, surgery and radiotherapy. The choice depends on the site and extent of tumour, the presence of comorbid illnesses, and other factors such as symptoms of bleeding and gastric outflow obstruction. The prognosis depends on the stage at diagnosis. Features predicting a favourable prognosis are stage I or II disease, small resectable tumours, tumours with low-grade histology, and age below 60 years.

Other tumours of the stomach

Gastrointestinal stromal cell tumours (GIST) arising from the interstitial cells of Cajal are occasionally found at upper gastrointestinal endoscopy. They are

22.47 How to insert a nasogastric (NG) tube

Equipment

- 8–9F 'fine-bore' tube for feeding or 16–18F 'wide-bore' tube for drainage
- Lubricant jelly
- Cup of water and straw for sipping
- Adhesive tape
- pH (not litmus) paper
- Sickness bowl and tissues
- Catheter drainage bag and clamp (for drainage)

Technique

- A clear explanation and a calm patient are essential
- Establish a 'stop signal' for the patient to use, if needed
- Ask the patient to sit semi-upright
- Examine the nose for deformity or blockage to determine which side to use
- Measure the distance from ear to xiphoid process via the nose and mark the position on the tube
- Advance the lubricated tube tip slowly along the floor of the nasal passage to the oropharynx
- Ask the patient to sip water and advance the tube 2–3 cm with each swallow
- Stop, withdraw and retry if the patient is distressed or coughing, as the tube may have entered the larynx
- Advance until the mark on the tube reaches the tip of the nose and secure with tape
- Aspirate the contents and check pH (gastric acid confirmed if pH < 5). If in doubt, perform a chest X-ray to confirm tube position (usually necessary with feeding tubes)
- Attach the catheter drainage bag, if necessary, and clamp

Aftercare

- Flush the tube daily after feeding or drug dosing
- Check position regularly and look for signs of displacement
- Check with the pharmacist what drugs, if any, can be safely given via the tube

differentiated from other mesenchymal tumours by expression of the *c-kit* proto-oncogene, which encodes a tyrosine kinase receptor. GISTs are usually benign and asymptomatic, but may occasionally be responsible for dyspepsia; they can also ulcerate and cause gastrointestinal bleeding.

A variety of polyps occur. Hyperplastic polyps and fundic cystic gland polyps are common and of no consequence. Adenomatous polyps are rare; they have malignant potential and should be removed endoscopically.

Occasionally, gastric carcinoid tumours are seen in the fundus and body in patients with long-standing pernicious anaemia. These benign tumours arise from ECL or other endocrine cells, and are often multiple but rarely invasive. Unlike carcinoid tumours arising elsewhere in the gastrointestinal tract, they usually run a benign and favourable course. However, large (> 2 cm) carcinoids may metastasise and should be removed. Rarely, small nodules of ectopic pancreatic exocrine tissue are found. These 'pancreatic rests' may be mistaken for gastric neoplasms and usually cause no symptoms. EUS is the most useful investigation.

DISEASES OF THE SMALL INTESTINE

Disorders causing malabsorption

Coeliac disease

Coeliac disease is an immunologically mediated inflammatory disorder of the small bowel occurring in genetically susceptible individuals and resulting from intolerance to wheat gluten and similar proteins found in rye, barley and, to a lesser extent, oats. It can result in malabsorption and responds to a gluten-free diet. The condition occurs world-wide but is more common in northern Europe. The prevalence in the UK is approximately 1%, although 50% of these people are asymptomatic. These include both undiagnosed 'silent' cases of the disease and cases of 'latent' coeliac disease—genetically susceptible people who may later develop clinical coeliac disease.

Pathophysiology

The precise mechanism of mucosal damage is unclear but immunological responses to gluten play a key role (Fig. 22.39). Tissue transglutaminase (tTG) is now recognised as the autoantigen for anti-endomysial antibodies, often used in serological diagnosis.

Clinical features

Coeliac disease can present at any age. In infancy it occurs after weaning on to cereals and typically presents with diarrhoea, malabsorption and failure to thrive. In older children it may present with non-specific features such as delayed growth. Features of malnutrition are often found on examination and mild abdominal distension may be present. Affected children have both growth and pubertal delay, leading to short stature in adulthood.

In adults peak onset is in the third or fourth decade and females are affected twice as often as males. The presentation is highly variable, depending on the severity and extent of small bowel involvement. Some patients have florid malabsorption while others develop non-specific symptoms such as tiredness, weight loss, folate deficiency or iron deficiency anaemia. Other recognised presentations include oral ulceration, dyspepsia and bloating. Unrecognised coeliac disease is associated with mild undernutrition and increased risk of osteoporosis.

Coeliac disease is associated with other human leucocyte antigen (HLA)-linked autoimmune disorders and with certain other diseases (Box 22.48).

Investigations

These are performed to confirm the diagnosis and to look for consequences of malabsorption.

i

22.48 Disease associations of coeliac disease

|---|--|
| <ul style="list-style-type: none"> • Insulin-dependent diabetes mellitus (2–8%) • Thyroid disease (5%) • Primary biliary cirrhosis (3%) • Sjögren's syndrome (3%) • IgA deficiency (2%) • Pernicious anaemia • Inflammatory bowel disease • Sarcoidosis • Myasthenia gravis • Neurological complications: encephalopathy, cerebellar atrophy, peripheral neuropathy, epilepsy | <ul style="list-style-type: none"> • Dermatitis herpetiformis • Down's syndrome • Enteropathy-associated T-cell lymphoma • Small bowel carcinoma • Squamous carcinoma of oesophagus • Ulcerative jejunitis • Pancreatic insufficiency • Microscopic colitis • Splenic atrophy |
|---|--|

Fig. 22.39 Pathophysiology of coeliac disease. After being taken up by epithelial cells, gluten peptides are deamidated by the enzyme tissue transglutaminase in the subepithelial layer. They are then able to fit the antigen-binding motif on HLA-DQ2-positive antigen-presenting cells. Recognition by CD4+ T cells triggers a Th₁ immune response with generation of pro-inflammatory cytokines (IL-1, IFN-γ and TNF-α). Lymphocytes infiltrate the lamina propria, and increased intraepithelial lymphocytes (IEL), crypt hyperplasia and villous atrophy ensue.

22.49 Important causes of subtotal villous atrophy

- Coeliac disease
- Tropical sprue
- Dermatitis herpetiformis
- Lymphoma
- AIDS enteropathy
- Giardiasis
- Hypogammaglobulinaemia
- Radiation
- Whipple's disease
- Zollinger–Ellison syndrome

Duodenal biopsy

Endoscopic small bowel biopsy is the gold standard. The histological features are usually characteristic but other causes of villous atrophy should also be considered (Box 22.49 and Fig. 22.40). Sometimes the villi appear normal but there are excess numbers of intra-epithelial lymphocytes present.

Antibodies

IgA anti-endomysial antibodies are detectable by immunofluorescence in most untreated cases. They are not quantitative, but are sensitive (85–95%) and specific (approximately 99%) for the diagnosis, except in very young infants. IgG antibodies, however, must be analysed in patients with coexisting IgA deficiency. The tTG assay has replaced other blood tests in many countries as it is easier to perform, semi-quantitative and more accurate in patients with IgA deficiency. These antibody tests constitute a valuable screening tool in patients with diarrhoea but are not a substitute for small bowel biopsy; they usually become negative with successful treatment.

Haematology and biochemistry

A full blood count may show microcytic or macrocytic anaemia from iron or folate deficiency and features of hyposplenism (target cells, spherocytes and Howell–Jolly bodies). Biochemical tests may reveal reduced concentrations of calcium, magnesium, total protein, albumin or vitamin D.

Other investigations

Measurement of bone density should be considered to look for evidence of osteoporosis, especially in older patients and post-menopausal women.

Management

The aims are to correct existing deficiencies of iron, folate, calcium and/or vitamin D, and to commence a life-long gluten-free diet. This requires the exclusion of wheat, rye, barley and initially oats, although oats may be reintroduced safely in most patients after 6–12 months. Initially, frequent dietary counselling is required to make sure the diet is being observed, as the most common reason for failure to improve with dietary treatment is accidental or unrecognised gluten ingestion. Mineral and vitamin supplements are also given when indicated but are seldom necessary when a strict gluten-free diet is adhered to. Booklets produced by coeliac societies in many countries, containing diet sheets and recipes for the use of gluten-free flour, are of great value. Regular monitoring of symptoms, weight and nutrition is essential. Patients who have an excellent clinical response, with disappearance of circulating anti-endomysial antibodies, probably do not need to undergo repeat jejunal biopsies. These should be reserved for patients who do not symptomatically improve or whose antibodies remain persistently positive.

Rarely, patients are 'refractory' and require treatment with corticosteroids or immunosuppressive drugs to induce remission. Dietary compliance should be carefully assessed in patients who fail to respond, but if their diet is satisfactory, other conditions such as pancreatic insufficiency or microscopic colitis should be sought, as should complications of coeliac disease such as ulcerative jejunitis or enteropathy-associated T-cell lymphoma.

Complications

A twofold increased risk of malignancy, particularly of enteropathy-associated T-cell lymphoma, small bowel carcinoma and squamous carcinoma of the oesophagus, has been reported, but recent studies have found only modest increases compared to the general population. A few patients develop ulcerative jejuno-ileitis; fever, pain, obstruction or perforation may then supervene. The diagnosis of small bowel complications is rarely made by barium studies or enteroscopy, and laparotomy and full-thickness biopsy are usually necessary.

Treatment is difficult. Corticosteroids are used with mixed success and some patients require surgical resection and parenteral nutrition. The course is often progressive and relentless.

Fig. 22.40 Jejunal mucosa. **A** Normal. **B** Subtotal villous atrophy in coeliac disease. There is blunting of villi (B), crypt hyperplasia (H) and inflammatory infiltration of the lamina propria (I).

Osteoporosis and osteomalacia may occur in patients with long-standing, poorly controlled coeliac disease. These complications are less common in patients who adhere strictly to a gluten-free diet.

Dermatitis herpetiformis

This is characterised by crops of intensely itchy blisters over the elbows, knees, back and buttocks (p. 1276). Immunofluorescence shows granular or linear IgA deposition at the dermo-epidermal junction. Almost all patients have partial villous atrophy on jejunal biopsy, even though they usually have no gastrointestinal symptoms. In contrast, fewer than 10% of coeliac patients have evidence of dermatitis herpetiformis, although both disorders are associated with the same histocompatibility antigen groups. The rash usually responds to a gluten-free diet but some patients require additional treatment with dapsone (100–150 mg daily).

Tropical sprue

Tropical sprue is defined as chronic, progressive malabsorption in a patient in or from the tropics, associated with abnormalities of small intestinal structure and function. The disease occurs mainly in the West Indies and in Asia, including southern India, Malaysia and Indonesia.

Pathophysiology

The epidemiological pattern and occasional epidemics suggest that an infective agent may be involved. Although no single bacterium has been isolated, the condition often begins after an acute diarrhoeal illness. Small bowel bacterial overgrowth with *Escherichia coli*, *Enterobacter* and *Klebsiella* is frequently seen. The changes closely resemble those of coeliac disease.

Clinical features

There is diarrhoea, abdominal distension, anorexia, fatigue and weight loss. In visitors to the tropics the onset of severe diarrhoea may be sudden and accompanied by fever. When the disorder becomes chronic, the features of megaloblastic anaemia (folic acid malabsorption) and other deficiencies, including ankle oedema, glossitis and stomatitis, are common. Remissions and relapses may occur. The differential diagnosis in the indigenous tropical population is an infective cause of diarrhoea. The important differential diagnosis in visitors to the tropics is giardiasis (p. 363).

Management

Tetracycline 250 mg 6-hourly for 28 days is the treatment of choice and brings about long-term remission or cure. In most patients pharmacological doses of folic acid (5 mg daily) improve symptoms and jejunal morphology. In some cases treatment must be prolonged before improvement occurs, and occasionally patients must leave the tropics.

Small bowel bacterial overgrowth ('blind loop syndrome')

The normal duodenum and jejunum contain less than 10^4 /mL organisms which are usually derived from saliva. The count of coliform organisms never exceeds 10^3 /mL. In bacterial overgrowth there may be 10^8 – 10^{10} /mL organisms, most of which are normally found only in the colon. Disorders which impair the normal physiological mechanisms controlling bacterial proliferation

22.50 Causes of small bowel bacterial overgrowth

Mechanism	Examples
Hypo- or achlorhydria	Pernicious anaemia Partial gastrectomy Long-term PPI therapy
Impaired intestinal motility	Scleroderma Diabetic autonomic neuropathy Chronic intestinal pseudo-obstruction
Structural abnormalities	Gastric surgery (blind loop after Billroth II operation) Jejunal diverticulosis Enterocolic fistulas (e.g. Crohn's disease) Extensive small bowel resection Strictures (e.g. Crohn's disease)
Impaired immune function	Hypogammaglobulinaemia

in the intestine predispose to bacterial overgrowth (Box 22.50). The most important are loss of gastric acidity, impaired intestinal motility and structural abnormalities which allow colonic bacteria to gain access to the small intestine or provide a secluded haven from the peristaltic stream.

Pathophysiology

Bacterial overgrowth can occur in patients with small bowel diverticuli. Another cause is diabetic autonomic neuropathy (p. 831), which reduces small bowel motility and affects enterocyte secretion. In scleroderma, bacterial overgrowth occurs because the circular and longitudinal layers of the intestinal muscle are fibrosed, and motility is abnormal. In idiopathic hypogammaglobulinaemia the IgA and IgM levels in serum and jejunal secretions are reduced. Chronic diarrhoea and malabsorption occur because of bacterial overgrowth and recurrent gastrointestinal infections (particularly giardiasis, p. 363).

Clinical features

The patient presents with watery diarrhoea and/or steatorrhoea with anaemia due to B_{12} deficiency. These arise because of deconjugation of bile acids, which impairs micelle formation, and because of bacterial utilisation of vitamin B_{12} . There may also be symptoms from the underlying intestinal cause.

Investigations

Serum vitamin B_{12} concentration is low, whilst folate levels are normal or elevated because the bacteria produce folic acid. Barium follow-through or small bowel enema may reveal blind loops or fistulas. Endoscopic duodenal biopsies exclude mucosal disease such as coeliac disease. Jejunal contents for bacteriological examination can be aspirated at endoscopy; the laboratory analysis requires anaerobic and aerobic culture techniques. The diagnosis can often be made non-invasively using the glucose hydrogen or ^{14}C -glycocholic acid breath tests. In these tests breath samples are serially measured after oral ingestion of the test material. Bacteria within the small bowel cause an early rise in breath hydrogen from glucose or ^{14}C from ^{14}C -glycocholate. Hypogammaglobulinaemia

can be diagnosed by measurement of serum immunoglobulins and by intestinal biopsy which shows reduced or absent plasma cells and nodules of lymphoid tissue (nodular lymphoid hyperplasia).

Management

The underlying cause of small bowel bacterial overgrowth should be addressed. Tetracycline 250 mg 6-hourly for 7 days is then the treatment of choice, although up to 50% of patients do not respond adequately. Metronidazole 400 mg 8-hourly or ciprofloxacin 250 mg 12-hourly is an alternative. Some patients require up to 4 weeks of treatment and, in a few, continuous rotating courses of antibiotics are necessary. Intramuscular vitamin B₁₂ supplementation is needed in chronic cases. Patients with motility disorders such as diabetes and scleroderma may benefit from antidiarrhoeal drugs (diphenoxylate 5 mg 8-hourly orally or loperamide 2 mg 4–6-hourly orally). In hypogammaglobulinaemia treatment should focus on control of giardiasis and, if necessary, immunoglobulin infusions.

Whipple's disease

This rare condition is characterised by infiltration of small intestinal mucosa by 'foamy' macrophages which stain positive with periodic acid-Schiff (PAS) reagent. The disease is a multisystem one and almost any organ can be affected, sometimes long before gastrointestinal involvement becomes apparent (Box 22.52).

Pathophysiology

The disease is caused by infection with the Gram-positive bacillus *Tropheryma whipplei* which is resident within macrophages in the bowel mucosa. Villi are widened and flattened; densely packed macrophages occur in the lamina propria. These may obstruct lymphatic drainage, causing fat malabsorption. Molecular characterisation of the bacillus has led to development of polymerase chain reaction (PCR)-based diagnosis.

Clinical features

Middle-aged men are most commonly affected and the presentation depends on the pattern of organ involvement. Low-grade fever is common and most patients have joint symptoms to some degree, often as the first manifestation. Occasionally, neurological manifestations may predominate.

Management

Whipple's disease is often fatal if untreated but responds well, at least initially, to intravenous ceftriaxone 2 g daily

22.52 Clinical features of Whipple's disease

Gastrointestinal (> 70%)
• Diarrhoea (75%), steatorrhoea, weight loss (90%), bloating, protein-losing enteropathy, ascites, hepatosplenomegaly (< 5%)
Musculoskeletal (65%)
• Seronegative large joint arthropathy, sacroiliitis
Cardiac (10%)
• Pericarditis, myocarditis, endocarditis, coronary arteritis
Neurological (10–40%)
• Apathy, fits, dementia, myoclonus, meningitis, cranial nerve lesions
Pulmonary (10–20%)
• Chronic cough, pleurisy, pulmonary infiltrates
Haematological (60%)
• Anaemia, lymphadenopathy
Other (40%)
• Fever, pigmentation

for 2 weeks, followed by oral co-trimoxazole for at least 1 year. Symptoms usually resolve quickly and biopsy changes revert to normal in a few weeks. Long-term follow-up is essential, as relapse occurs in up to one-third of patients. This often occurs within the central nervous system, in which case the same therapy is repeated or else treatment with doxycycline and hydroxychloroquine is necessary.

Ileal resection

Malabsorption may occur as a complication of small bowel resection. Ileal resection is usually found after surgery for Crohn's disease. Vitamin B₁₂ and bile salt malabsorption develops (Fig. 22.41). Unabsorbed bile salts pass into the colon, stimulating water and electrolyte secretion and resulting in diarrhoea. If hepatic synthesis of new bile salts cannot keep pace with faecal losses, fat malabsorption occurs. Another consequence is the formation of lithogenic bile, leading to gallstones. Renal calculi, rich in oxalate, develop. Normally, oxalate in the colon is bound to and precipitated by calcium. Unabsorbed bile salts preferentially bind calcium, leaving free oxalate to be absorbed with subsequent development of urinary oxalate calculi.

Patients have urgent watery diarrhoea or mild steatorrhoea. Contrast studies of the small bowel and tests of B₁₂ and bile acid absorption (p. 850) are useful investigations. Parenteral vitamin B₁₂ supplementation is necessary. Diarrhoea usually responds well to colestyramine, a resin which binds bile salts in the intestinal lumen. Aluminium hydroxide is an alternative therapy.

Short bowel syndrome

Short bowel syndrome is defined as malabsorption resulting from extensive small intestinal resection or disease. The syndrome has many causes (Box 22.53) but in adults it usually results from extensive surgery undertaken for Crohn's disease or mesenteric infarction. Irrespective of the cause, three main types of patient are seen:

22.51 Malabsorption in old age

- **Coeliac disease:** symptoms such as dyspepsia tend to be vague; only 25% present classically with diarrhoea and weight loss. Metabolic bone disease, folate or iron deficiency, coagulopathy and small bowel lymphoma are more common.
- **Small bowel bacterial overgrowth:** more prevalent: Atrophic gastritis resulting in hypo- or achlorhydria becomes more common
Jejunal diverticulosis is prevalent
The long-term effects of gastric surgery for ulcer disease are now being seen in older people.

Fig. 22.41 Consequences of ileal resection.

22

22.53 Aetiology of short bowel syndrome

Children

- Congenital anomalies (e.g. mid-gut volvulus, atresia)
- Necrotising enterocolitis

Adults

- Crohn's disease
- Mesenteric infarction
- Radiation enteritis
- Volvulus

- *Jejunal resection with intact ileum and colon.* This is uncommon and nutritional support is rarely needed.
- *Jejunum-colon patients* (jejunio-ileal resection with jejunocolic anastomosis).
- *Jejunostomy patients* (jejunio-ileal resection and colectomy).

Pathophysiology

Important differences occur between jejunum-colon and jejunostomy patients (Box 22.54) but in both groups loss of surface area for digestion and absorption is the key problem. These processes are normally completed within the first 100 cm of jejunum, and enteral feeding is usually possible if this amount of small intestine remains. The proximal small bowel normally reabsorbs most of the 8 L of fluid it receives daily, and patients with a high jejunostomy are at great risk of hypovolaemia, dehydration and electrolyte losses. The presence of some or all of the colon may markedly improve these losses by increased water reabsorption. The presence of an intact ileocaecal valve ameliorates the clinical picture by slowing small intestinal transit and reducing bacterial overgrowth.

Clinical features

Severely affected patients have large volumes of jejunostomy fluid losses or, if the colon is preserved, diarrhoea

and steatorrhoea. Dehydration and signs of hypovolaemia are common, as are weight loss, loss of muscle bulk and malnutrition. Some patients remain in satisfactory but precarious fluid balance until a minor intercurrent illness or intestinal upset occurs, when they can rapidly become dehydrated.

Management

In the immediate post-operative period, total parenteral nutrition (TPN) should be started. PPI therapy is given to reduce gastric secretions. Enteral feeding can be cautiously introduced after 1–2 weeks under careful supervision and slowly increased as tolerated. For patients with a jejunostomy, parenteral saline is likely to be necessary if less than 100 cm of jejunum remains. If less than 75 cm of small bowel remains, TPN is also needed.

22.54 Effects of a short bowel

	Jejunum-colon	Jejunostomy
Clinical	Gradual diarrhoea, weight loss	Rapid fluid losses
Water/electrolyte depletion	+/-	++
Malabsorption nutrients	++	+++
D-lactic acidosis	+/-	-
Oxalate renal calculi	++	-
Pigment gallstones	++	++
Gut adaptation	+	-
Impact on quality of life	Diarrhoea	High output, dehydration, parenteral nutrition

The principles of long-term management are:

- Detailed nutritional assessments at regular intervals.
- Monitoring of fluid and electrolyte balance. Patients can usually be taught how to do this for themselves. A readily available supply of oral rehydration solution is useful for intercurrent illness.
- Adequate calorie and protein intake. Fats are a good energy source and should be taken as tolerated. Medium-chain triglyceride supplements are often given first because they are more easily absorbed.
- Use of oral/enteral rather than parenteral nutrition whenever possible.
- Replacement of vitamin B₁₂, calcium, vitamin D, magnesium, zinc and folic acid.
- Antidiarrhoeal agents, e.g. loperamide (2–4 mg 6-hourly) or codeine phosphate (30 mg 4–6-hourly).

Some patients are unable to maintain positive fluid balance. Octreotide (50–200 µg 8–12-hourly by subcutaneous injection) reduces gastrointestinal secretions and is useful in such individuals. Despite these measures, some patients require long-term home TPN for survival and this is best managed in specialist centres. Small bowel transplantation is an option but rejection and 'graft-versus-host' disease (p. 1014) remain significant hurdles.

Radiation enteritis and proctocolitis

Intestinal damage occurs in 10–15% of patients undergoing radiotherapy for abdominal or pelvic malignancy. The risk varies with total dose, dosing schedule and the use of concomitant chemotherapy.

Pathophysiology

The rectum, sigmoid colon and terminal ileum are most frequently involved. Radiation causes acute inflammation, shortening of villi, oedema and crypt abscess formation. These usually resolve completely but in some patients an obliterative endarteritis affecting the endothelium of submucosal arterioles develops over 2–12 months. Fibroblastic proliferation produces progressive ischaemic fibrosis over years and may lead to adhesions, ulceration, strictures, obstruction or fistula to adjacent organs.

Clinical features

In the acute phase there is nausea, vomiting, cramping abdominal pain and diarrhoea. When the rectum and colon are involved, rectal mucus, bleeding and tenesmus occur. The chronic phase develops after 5–10 years in some patients and produces one or more of the problems listed in Box 22.55.

Investigations

In the acute phase the rectal changes at sigmoidoscopy resemble those of ulcerative proctitis (see Fig. 22.57, p. 900). The extent of the lesion is determined by colonoscopy. Barium follow-through examination shows small bowel strictures, ulcers and fistulas.

Management

Diarrhoea in the acute phase is treated with codeine phosphate, diphenoxylate or loperamide in standard dosage. Local corticosteroid enemas help proctitis, and antibiotics may be required for bacterial overgrowth. Nutritional supplements are necessary when malab-

22.55 Chronic complications of intestinal irradiation

- Proctocolitis
- Bleeding from telangiectasia
- Small bowel strictures
- Fistulas: rectovaginal, colovesical, enterocolic
- Adhesions
- Malabsorption: bacterial overgrowth, bile salt malabsorption (ileal damage)

sorption is present. Colestyramine (4 g as a single sachet) is useful for bile salt malabsorption. Endoscopic laser or argon plasma coagulation therapy may reduce bleeding from proctitis. Surgery should be avoided, if possible, because the injured intestine is difficult to resect and anastomose, but it may be necessary for obstruction, perforation or fistula.

Abetalipoproteinaemia

This rare autosomal recessive disorder is caused by deficiency of apolipoprotein B which results in failure of chylomicron formation. It leads to fat malabsorption and deficiency of fat-soluble vitamins. Jejunal biopsy reveals enterocytes distended with resynthesised triglyceride and normal villous morphology. Serum cholesterol and triglyceride levels are low. A number of other abnormalities occur in this syndrome, including acanthocytosis, retinitis pigmentosa and a progressive neurological disorder with cerebellar and dorsal column signs. Symptoms may be improved by a low-fat diet supplemented with medium-chain triglycerides and vitamins A, D, E and K.

Motility disorders

Chronic intestinal pseudo-obstruction

Small intestinal motility is disordered in conditions which affect the smooth muscle or nerves of the intestine. Many cases are 'primary' (idiopathic), while others are 'secondary' to a variety of disorders or drugs (Box 22.56).

Clinical features

There are recurrent episodes of nausea, vomiting, abdominal discomfort and distension, often worse after

22.56 Causes of chronic intestinal pseudo-obstruction

Primary or idiopathic

- Rare familial visceral myopathies or neuropathies
- Congenital aganglionosis

Secondary

- Drugs, e.g. opiates, tricyclic antidepressants, phenothiazines
- Smooth muscle disorders, e.g. scleroderma, amyloidosis, mitochondrial myopathies
- Myenteric plexus disorders, e.g. paraneoplastic syndrome in small-cell lung cancer
- CNS disorders, e.g. Parkinsonism, autonomic neuropathy
- Endocrine and metabolic disorders, e.g. hypothyroidism, pheochromocytoma, acute intermittent porphyria

food. Alternating constipation and diarrhoea occur and weight loss results from malabsorption (due to bacterial overgrowth) and fear of eating. There may also be symptoms of dysmotility affecting other parts of the gastrointestinal tract, such as dysphagia, and, in primary cases, features of bladder dysfunction. Some patients have obscure but severe abdominal pain which is extremely difficult to manage.

Investigations

The diagnosis is often delayed and a high index of suspicion is needed. Plain X-rays show distended loops of bowel and air-fluid levels, but barium studies demonstrate no mechanical obstruction. Laparotomy is sometimes performed to exclude obstruction and to obtain full-thickness biopsies of the intestine. Electron microscopy, histochemistry and special stains define rare, specific syndromes.

Management

This is often difficult. Underlying causes should be addressed and further surgery avoided if at all possible. Metoclopramide or domperidone may enhance motility, and antibiotics are given for bacterial overgrowth. Nutritional and psychological support is also necessary.

Miscellaneous disorders of the small intestine

Protein-losing enteropathy

This term is used when there is excessive loss of protein into the gut lumen, sufficient to cause hypoproteinaemia. Protein-losing enteropathy occurs in many gut disorders but is most common in those where ulceration occurs (Box 22.57). In other disorders protein loss results from increased mucosal permeability or obstruction of intestinal lymphatic vessels. Patients present with peripheral oedema and hypoproteinaemia in the presence of normal liver function and without proteinuria. The diagnosis is confirmed by measurement of faecal clearance of α_1 -antitrypsin or ^{51}Cr -labelled albumin after intravenous injection. Other investigations are performed to determine the underlying cause. Treatment is that of the underlying disorder, with nutritional support and measures to control peripheral oedema.

22.57 Causes of protein-losing enteropathy

With mucosal erosions or ulceration

- Crohn's disease
- Ulcerative colitis
- Radiation damage
- Oesophageal, gastric or colonic cancer
- Lymphoma

Without mucosal erosions or ulceration

- Ménétrier's disease
- Bacterial overgrowth
- Coeliac disease
- Tropical sprue
- Eosinophilic gastroenteritis
- SLE

With lymphatic obstruction

- Intestinal lymphangiectasia
- Constrictive pericarditis
- Lymphoma
- Whipple's disease

Intestinal lymphangiectasia

This may be primary, resulting from congenital malunion of lymphatics, or secondary to lymphatic obstruction due to lymphoma, filariasis or constrictive pericarditis. Impaired drainage of intestinal lymphatic vessels leads to discharge of protein and fat-rich lymph into the gastrointestinal lumen. The condition presents with peripheral lymphoedema, pleural effusions or chylous ascites, and steatorrhoea. Investigations reveal hypoalbuminaemia, lymphocytopenia and reduced serum immunoglobulin concentrations. Jejunal biopsies show greatly dilated lacteals, and lymphangiography shows lymphatic obstruction. Treatment consists of a low-fat diet with medium-chain triglyceride supplements.

Ulceration of the small intestine

Small bowel ulcers are uncommon and are either idiopathic or secondary to underlying intestinal disorders (Box 22.58). Ulcers are more common in the ileum, and cause bleeding, perforation, stricture formation or obstruction. Barium studies and enteroscopy confirm the diagnosis.

22.58 Causes of small intestinal ulcers

- Idiopathic
- Inflammatory bowel disease, e.g. Crohn's
- Drugs, e.g. NSAIDs, enteric-coated potassium tablets
- Ulcerative jejuno-ileitis
- Lymphoma and carcinoma
- Infections, e.g. tuberculosis, typhoid, *Yersinia enterocolitica*
- Others, e.g. radiation, vasculitis

NSAID-associated small intestinal toxicity

These drugs cause a spectrum of small intestinal lesions ranging from erosions and ulcers to mucosal webs, strictures and, rarely, a condition known as 'diaphragm disease' in which intense submucosal fibrosis results in circumferential stricturing. The condition can present with pain, obstruction, bleeding or anaemia, and may mimic Crohn's disease, carcinoma or lymphoma. Enteroscopy or capsule endoscopy can reveal the diagnosis but sometimes this is only discovered at laparotomy.

Eosinophilic gastroenteritis

This disorder of unknown aetiology can affect any part of the gastrointestinal tract; it is characterised by eosinophil infiltration affecting the gut wall in the absence of parasitic infection or eosinophilia of other tissues. Peripheral blood eosinophilia is present in 80% of cases.

Clinical features

There are features of obstruction and inflammation, such as colicky pain, nausea and vomiting, diarrhoea and weight loss. Protein-losing enteropathy occurs and up to 50% of patients have a history of other allergic disorders. Serosal involvement may produce eosinophilic ascites.

Diagnosis and management

The diagnosis is made by histological assessment of multiple endoscopic biopsies, although full-thickness biopsies are occasionally required. Other investigations are performed to exclude parasitic infection and other causes of eosinophilia. A raised serum IgE concentration is often seen. Dietary manipulations are rarely effective, although elimination diets, especially of milk, may benefit a few patients. Severe symptoms are treated with prednisolone 20–40 mg daily and/or sodium cromoglicate, which stabilises mast cell membranes. The prognosis is good in the majority of patients.

Meckel's diverticulum

This is the most common congenital anomaly of the gastrointestinal tract and occurs in 0.3–3% of people. Most patients are asymptomatic. The diverticulum results from failure of closure of the vitelline duct, with persistence of a blind-ending sac arising from the antimesenteric border of the ileum; it usually occurs within 100 cm of the ileocaecal valve, and is up to 5 cm long. Approximately 50% contain ectopic gastric mucosa; rarely, colonic, pancreatic or endometrial tissue is present. Complications most commonly occur in the first 2 years of life but are occasionally seen in young adults. Bleeding results from ulceration of ileal mucosa adjacent to the ectopic parietal cells and presents as recurrent melaena or altered blood per rectum. Diagnosis can be made by scanning the abdomen using a gamma counter following an intravenous injection of ^{99m}Tc -pertechnetate, which is concentrated by ectopic parietal cells. Other complications include intestinal obstruction, diverticulitis, intussusception and perforation. Intervention is unnecessary unless complications occur. The vast majority of patients remain asymptomatic throughout life.

Adverse food reactions

Adverse food reactions are common and are subdivided into food intolerance and food allergy, the former being much more common. In food intolerance there is an adverse reaction to food which is not immune-mediated and results from pharmacological (e.g. histamine, tyramine or monosodium glutamate), metabolic (e.g. lactase deficiency) or other mechanisms (e.g. toxins or chemical contaminants in food).

Lactose intolerance

Human milk contains around 200 mmol/L (68 g/L) of lactose which is normally digested to glucose and galactose by the brush border enzyme lactase prior to absorption. In most populations enterocyte lactase activity declines throughout childhood. The enzyme is deficient in up to 90% of adult Africans, Asians and South Americans, but only 5% of northern Europeans.

In cases of genetically determined (primary) lactase deficiency, jejunal morphology is normal. 'Secondary' lactase deficiency occurs as a consequence of disorders which damage the jejunal mucosa, such as coeliac disease and viral gastroenteritis. Unhydrolysed lactose enters the colon, where bacterial fermentation produces

volatile short-chain fatty acids, hydrogen and carbon dioxide.

Clinical features

In most people lactase deficiency is completely asymptomatic. However, some complain of colicky pain, abdominal distension, increased flatus, borborygmi and diarrhoea after ingesting milk or milk products. Irritable bowel syndrome is often suspected but the diagnosis is suggested by clinical improvement on lactose withdrawal. The lactose hydrogen breath test is a useful non-invasive confirmatory investigation.

Dietary exclusion of lactose is recommended, although most sufferers are able to tolerate small amounts of milk without symptoms. Addition of commercial lactase preparations to milk has been effective in some studies but is costly.

Intolerance of other sugars

'Osmotic' diarrhoea can be caused by sorbitol, an unabsorbable carbohydrate which is used as an artificial sweetener. Fructose may also cause diarrhoea if consumed in greater quantities than can be absorbed (e.g. in fruit juices).

Food allergy

Food allergies are immune-mediated disorders, most commonly due to IgE antibodies and type I hypersensitivity reactions, although type IV delayed reactions are also seen. Up to 20% of the population perceive themselves as suffering from food allergy but only 1–2% of adults and 5–7% of children have genuine food allergies. The most common culprits are peanuts, milk, eggs, soya and shellfish.

Clinical manifestations occur immediately on exposure and range from trivial to life-threatening or even fatal anaphylaxis. The common 'oral allergy syndrome' results from contact with benzoic acid in certain fresh fruit juices leading to urticaria and angioedema of the lips and oropharynx. This is not, however, an immune-mediated reaction. 'Allergic gastroenteropathy' has features similar to eosinophilic gastroenteritis, while 'gastrointestinal anaphylaxis' consists of nausea, vomiting, diarrhoea and sometimes cardiovascular and respiratory collapse. Fatal reactions to trace amounts of peanuts are well documented.

The diagnosis of food allergy is difficult to prove or refute. Skin prick tests and measurements of antigen-specific IgE antibodies in serum have limited predictive value. Double-blind placebo-controlled food challenges are the gold standard, but are laborious and are not readily available. In many cases clinical suspicion and trials of elimination diets are used.

Treatment of proven food allergy consists of detailed patient education and awareness, strict elimination of the offending antigen, and in some cases antihistamines or sodium cromoglicate. Anaphylaxis should be treated as a medical emergency with resuscitation, airway support and intravenous adrenaline (epinephrine). Teachers and other carers of affected children should be trained to deal with this. Patients should wear an information bracelet and be taught to carry and use a preloaded adrenaline (epinephrine) syringe.

Infections of the small intestine

Travellers' diarrhoea, giardiasis and amoebiasis

See pages 306, 363 and 362.

Abdominal tuberculosis

Mycobacterium tuberculosis is a rare cause of abdominal disease in Caucasians but must be considered in people in and from the developing world and in AIDS patients. Gut infection usually results from human *M. tuberculosis* which is swallowed after coughing. Many patients have no pulmonary symptoms and a normal chest X-ray.

The area most commonly affected is the ileocaecal region; presentation and radiological findings may be very similar to those of Crohn's disease. Abdominal pain can be acute or of several months' duration, but diarrhoea is less common in tuberculosis than in Crohn's disease. Low-grade fever is common but not invariable. Like Crohn's disease, tuberculosis can affect any part of the gastrointestinal tract, and perianal disease with fistula is recognised. Peritoneal tuberculosis may result in peritonitis with exudative ascites, associated with abdominal pain and fever. Granulomatous hepatitis occurs.

Diagnosis

Abdominal tuberculosis causes an elevated ESR; a raised serum alkaline phosphatase concentration suggests hepatic involvement. Histological confirmation should be sought by endoscopy, laparoscopy or liver biopsy. Caseation of granulomas is not always seen and acid- and alcohol-fast bacteria are often scanty. Culture may be helpful but identification of the organism may take 6 weeks and diagnosis is now possible on biopsy specimens by PCR-based techniques.

Management

When the presentation is very suggestive of abdominal tuberculosis, chemotherapy with four drugs—isoniazid, rifampicin, pyrazinamide and ethambutol (p. 694)—should be commenced, even if bacteriological or histological proof is lacking.

Cryptosporidiosis

Cryptosporidiosis and other protozoal infections, including isosporiasis (*Isospora belli*) and microsporidiosis, are dealt with on pages 393–394.

Tumours of the small intestine

The small intestine is rarely affected by neoplasia, and fewer than 5% of all gastrointestinal tumours occur here.

Benign tumours

The most common are adenomas, GIST, lipomas and hamartomas. Adenomas are most often found in the periampullary region and are usually asymptomatic, although occult bleeding or obstruction due to intussusception may occur. Transformation to adenocarcinoma is rare. Multiple adenomas are common in the duodenum of patients with familial adenomatous

polyposis (FAP), who merit regular endoscopic surveillance. Hamartomatous polyps with almost no malignant potential occur in Peutz–Jeghers syndrome (p. 909).

Malignant tumours

These are rare and include, in decreasing order of frequency, adenocarcinoma, carcinoid tumour, malignant GIST and lymphoma. The majority occur in middle age or later. Kaposi's sarcoma is seen in patients with AIDS.

Adenocarcinomas occur with increased frequency in patients with FAP, coeliac disease and Peutz–Jeghers syndrome. The non-specific presentation and rarity of these lesions often lead to delay in diagnosis. Barium follow-through examination or small bowel enema studies will demonstrate most lesions of this type. Enteroscopy, capsule endoscopy, mesenteric angiography and CT also play a role in investigation. Treatment is by surgical resection.

Carcinoid tumours

These are derived from enterochromaffin cells and are most common in the appendix. Localised spread and the potential for metastasis to the liver increase with primary lesions over 2 cm in diameter. Carcinoid tumours also occur in the rectum and in the appendix; those in the latter are usually benign. Overall, these tumours are less aggressive than carcinomas and their growth is usually slow.

The term 'carcinoid syndrome' refers to the systemic symptoms produced when secretory products of the neoplastic enterochromaffin cells reach the systemic circulation (Box 22.59). When produced by the primary tumour they are usually metabolised in the liver and do not reach the systemic circulation. The syndrome is therefore only seen when 5-HT, bradykinin and other peptide hormones are released by hepatic metastases.

Management

The treatment of a carcinoid tumour is surgical resection. The treatment of carcinoid syndrome is palliative because hepatic metastases have occurred, although prolonged survival is common. Surgical removal of the primary tumour is usually attempted and the hepatic metastases can be excised as reduction of tumour mass improves symptoms. Hepatic artery embolisation retards growth of hepatic deposits. Octreotide 200 µg 8-hourly by subcutaneous injection is used to reduce tumour release of secretagogues. Cytotoxic chemotherapy has only a minor role.

22.59 Clinical features of carcinoid tumours*

- Small-bowel obstruction due to the tumour mass
- Intestinal ischaemia (due to mesenteric infiltration or vasospasm)
- Hepatic metastases causing pain, hepatomegaly and jaundice
- Flushing and wheezing
- Diarrhoea
- Cardiac involvement (tricuspid regurgitation, pulmonary stenosis, right ventricular endocardial plaques) leading to heart failure
- Facial telangiectasia

*The diagnosis is made by detecting excess levels of the 5-HT metabolite, 5-HIAA, in a 24-hour urine collection.

Lymphoma

Non-Hodgkin lymphoma (p. 1039) may involve the gastrointestinal tract as part of more generalised disease or may rarely arise in the gut, with the small intestine being most commonly affected. Lymphomas occur with increased frequency in patients with coeliac disease, AIDS and other immunodeficiency states. Most are of B-cell origin, although lymphoma associated with coeliac disease is derived from T cells (enteropathy-associated T-cell lymphoma).

Colicky abdominal pain, obstruction and weight loss are the usual presenting features, and perforation is also occasionally seen. Malabsorption is only a feature of diffuse bowel involvement and hepatosplenomegaly is rare.

The diagnosis is made by small bowel biopsy, radiological contrast studies and CT. Staging investigations are performed. Surgical resection where possible is the treatment of choice, with radiotherapy and combination chemotherapy reserved for those with advanced disease. The prognosis depends largely on the stage at diagnosis, cell type, patient age and the presence of 'B' symptoms (fever, weight loss, night sweats).

Immunoproliferative small intestinal disease (IPSID)

Also known as 'alpha heavy chain disease', this rare condition occurs mainly in the Mediterranean, Middle East, India and Pakistan, and North America. The aetiology is unknown but it may be a response to chronic stimulation by bacterial antigens. The condition varies in severity from relatively benign to frankly malignant.

The small intestinal mucosa is diffusely affected, especially proximally, by a dense lymphoplasmacytic infiltrate. Enlarged mesenteric lymph nodes are also common. Most patients are young adults who present with malabsorption, anorexia and fever. Serum electrophoresis confirms the presence of alpha heavy chains (from the F_c portion of IgA). Prolonged remissions can be obtained with long-term antibiotic therapy, but chemotherapy is required for those who fail to respond or who have aggressive disease.

DISEASES OF THE PANCREAS

Acute pancreatitis

Acute pancreatitis accounts for 3% of all cases of abdominal pain admitted to hospital. It affects 2–28 per 100 000 of the population and may be increasing in incidence. Despite recent advances in management, mortality has remained unchanged at 10%. About 80% of all cases are mild with a mortality of less than 5%; 98% of deaths occur in the 20% of severe cases. One-third occur within the first week, usually from multi-organ failure. After this time the majority of deaths result from sepsis, especially that complicating infected necrosis. At admission it is possible to predict patients at risk of these complications (Box 22.60). Patients with predicted or actual severe pancreatitis (Box 22.61), those with necrosis or other complications should be managed in a specialist centre with an intensive therapy unit and multidisciplinary hepatobiliary specialists.

22.60 Adverse prognostic factors in acute pancreatitis (Glasgow criteria)*

- Age > 55 years
- $PO_2 < 8$ kPa (60 mmHg)
- White blood cell count (WBC) > $15 \times 10^9/L$
- Albumin < 32 g/L
- Serum calcium < 2 mmol/L (8 mg/dL) (corrected)
- Glucose > 10 mmol/L (180 mg/dL)
- Urea > 16 mmol/L (45 mg/dL) (after rehydration)
- Alanine aminotransferase (ALT) > 200 U/L
- Lactate dehydrogenase (LDH) > 600 U/L

*Severity and prognosis worsen as the number of these factors increases. More than three implies severe disease.

22.61 Factors that may predict severe pancreatitis within 48 hours of admission

Initial assessment

- Clinical impression of severity
- Body mass index > 30
- Pleural effusion on chest X-ray
- APACHE II score > 8

24 hrs after admission

- Clinical impression of severity
- APACHE II score > 8
- Glasgow score ≥ 3
- Persisting organ failure, especially if multiple
- CRP > 150 mg/L

48 hrs after admission

- Clinical impression of severity
- Glasgow score ≥ 3
- CRP > 150 mg/L
- Persisting organ failure for 48 hrs
- Multiple or progressive organ failure

Pathophysiology

Acute pancreatitis occurs as a consequence of premature activation of zymogen granules, releasing proteases which digest the pancreas and surrounding tissue (Fig. 22.42). The normal pancreas has only a poorly developed capsule, and adjacent structures, including the common bile duct, duodenum, splenic vein and transverse colon, are commonly involved in the inflammatory process. The severity of acute pancreatitis is dependent upon the balance between activity of released proteolytic enzymes and antiproteolytic factors. The latter comprise an intracellular pancreatic trypsin inhibitor protein and circulating β_2 -macroglobulin, α_1 -antitrypsin and Cl-esterase inhibitors. Causes of acute pancreatitis are given in Box 22.62. Acute pancreatitis is often self-limiting. In some patients, however, it is severe, with local complications such as necrosis, pseudocyst or abscess, and systemic complications leading to multi-organ failure.

Clinical features

Severe, constant upper abdominal pain which radiates to the back in 65% of cases builds up over 15–60 minutes. Nausea and vomiting are common. There is marked epigastric tenderness, but in the early stages (and in contrast to a perforated peptic ulcer) guarding and rebound tenderness are absent because the inflammation is principally retroperitoneal. Bowel sounds become quiet

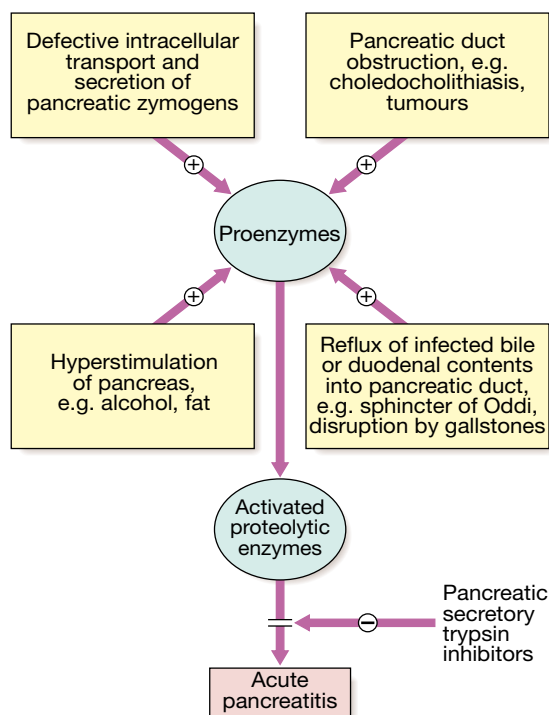

Fig. 22.42 Pathophysiology of acute pancreatitis.

22.62 Causes of acute pancreatitis

Common (90% of cases)

- Gallstones
- Alcohol
- Idiopathic
- Post-ERCP

Rare

- Post-surgical (abdominal, cardiopulmonary bypass)
- Trauma
- Drugs (azathioprine, thiazide diuretics, sodium valproate)
- Metabolic (hypercalcaemia, hypertriglyceridaemia)
- Pancreas divisum (p. 893)
- Sphincter of Oddi dysfunction
- Infection (mumps, Coxsackie virus)
- Hereditary
- Renal failure
- Organ transplantation (kidney, liver)
- Severe hypothermia
- Petrochemical exposure

or absent as paralytic ileus develops. In severe cases the patient becomes hypoxic and develops hypovolaemic shock with oliguria. Discoloration of the flanks (Grey Turner's sign) or the periumbilical region (Cullen's sign) is a feature of severe pancreatitis with haemorrhage. The differential diagnosis includes a perforated viscus, acute cholecystitis and myocardial infarction. Various complications may occur and these are listed in Box 22.63. An acute pancreatic pseudocyst is a localised peripancreatic collection of pancreatic juice and debris which usually develops in the lesser sac following inflammatory rupture of the pancreatic duct. The pseudocyst is initially contained within a poorly defined, fragile wall of granulation tissue which matures over a 6-week period to form a fibrous capsule (Fig. 22.43). Small intrapancreatic cysts

22.63 Complications of acute pancreatitis

Complication	Cause
Systemic	
Systemic inflammatory response syndrome (SIRS)	Increased vascular permeability from cytokine, platelet aggregating factor and kinin release
Hypoxia	Acute respiratory distress syndrome (ARDS) due to microthrombi in pulmonary vessels
Hyperglycaemia	Disruption of islets of Langerhans with altered insulin/glucagon release
Hypocalcaemia	Sequestration of calcium in fat necrosis, fall in ionised calcium
Reduced serum albumin concentration	Increased capillary permeability
Pancreatic	
Necrosis	Non-viable pancreatic tissue and peripancreatic tissue death; frequently infected
Abscess	Circumscribed collection of pus close to the pancreas and containing little or no pancreatic necrotic tissue
Pseudocyst	Disruption of pancreatic ducts
Pancreatic ascites or pleural effusion	Disruption of pancreatic ducts
Gastrointestinal	
Upper gastrointestinal bleeding	Gastric or duodenal erosions
Variceal haemorrhage	Splenic or portal vein thrombosis
Erosion into colon	
Duodenal obstruction	Compression by pancreatic mass
Obstructive jaundice	Compression of common bile duct

Fig. 22.43 CT showing large pancreatic pseudocyst (arrow) developing from the body of the pancreas (P).

and pseudocysts are common and resolve as the pancreatitis recovers, but those greater than 6 cm seldom disappear spontaneously and can cause abdominal pain and may compress or erode surrounding structures including blood vessels to form pseudoaneurysms. Pancreatic ascites occurs when fluid leaks from a disrupted pancreatic duct into the peritoneal cavity. Leakage into the thoracic cavity can result in a pleural effusion or a pleuro-pancreatic fistula.

Investigations

The diagnosis of acute pancreatitis is based upon finding raised serum amylase or lipase concentrations and ultrasound or CT evidence of pancreatic swelling. Plain X-rays are taken to exclude other diagnoses such as perforation or obstruction and to identify pulmonary complications. Amylase is efficiently excreted by the kidneys, and concentrations may have returned to normal if measured 24–48 hours after the onset of pancreatitis. In this situation the diagnosis can be made by demonstrating an elevated urinary amylase:creatinine ratio. A persistently elevated serum amylase concentration suggests pseudocyst formation. Peritoneal amylase concentrations are massively elevated in pancreatic ascites. Serum amylase concentrations are also elevated (but less so) in intestinal ischaemia, perforated peptic ulcer and ruptured ovarian cyst, whilst the salivary isoenzyme of amylase is elevated in parotitis. If available, serum lipase measurements are preferable to amylase as they have greater diagnostic accuracy for acute pancreatitis.

Ultrasound scanning confirms the diagnosis, although in the earlier stages the gland may not be grossly swollen. The ultrasound scan is also useful because it may show gallstones, biliary obstruction or pseudocyst formation.

Contrast-enhanced pancreatic CT 6–10 days after admission is used to define the viability of the pancreas if persisting organ failure, sepsis or clinical deterioration is present, as these may indicate pancreatic necrosis. Necrotising pancreatitis is associated with decreased pancreatic enhancement following intravenous injection of contrast material. The presence of gas within necrotic material (Fig. 22.44) suggests infection and impending abscess formation, in which case percutaneous aspira-

Fig. 22.44 Pancreatic necrosis. Lack of vascular enhancement of the pancreas during contrast-enhanced CT indicates necrosis (arrow). The presence of gas suggests infection has occurred.

tion of material for bacterial culture should be carried out and appropriate antibiotics prescribed. Involvement of the colon, blood vessels and other adjacent structures by the inflammatory process is best seen by CT.

Certain investigations stratify the severity of acute pancreatitis and have important prognostic value at the time of presentation (Box 22.64). In addition, serial assessment of C-reactive protein (CRP) is a useful indicator of progress. A peak CRP > 210 mg/L in the first 4 days predicts severe acute pancreatitis with 80% accuracy. It is worth noting that the serum amylase concentration has no prognostic value.

Management

Management of acute pancreatitis comprises several related steps:

- establishing the diagnosis and stratifying disease severity
- early treatment (resuscitation) according to whether the disease is mild or severe
- detection and treatment of complications
- treating the underlying cause—specifically gallstones.

The initial management is based upon analgesia using pethidine and correction of hypovolaemia using normal saline and/or colloids. All severe cases should be managed in a high-dependency or intensive care unit. A central venous line or Swan-Ganz catheter and urinary catheter are used to monitor patients with shock. Hypoxic patients need oxygen and patients who develop acute respiratory distress syndrome (ARDS) may require ventilatory support. Hyperglycaemia is corrected using insulin, but it is not necessary to correct hypocalcaemia by intravenous calcium injection unless tetany occurs.

Nasogastric aspiration is only necessary if paralytic ileus is present. Enteral feeding, if tolerated, should be started at an early stage in patients with severe pancreatitis because they are in a severely catabolic state and need nutritional support (Box 22.65). In addition enteral feeding decreases endotoxaemia and thereby may

EBM 22.64 ERCP in acute pancreatitis

'In patients with actual or predicted severe pancreatitis of suspected biliary origin, emergency ERCP with biliary sphincterotomy improves outcome and is best undertaken within 72 hours of onset. Greatest benefit occurs in those patients who have ascending cholangitis.'

- UK Working Party on Acute Pancreatitis. Gut 2005; 54(Suppl III):iii1–iii9.

For further information:  www.bsg.org.uk

EBM 22.65 Nutritional support in acute pancreatitis

'Nutritional support is not necessary in all patients with severe pancreatitis. If it is required, the enteral route (if tolerated) is superior to parenteral feeding, and the nasogastric route can be used as it appears to be effective in 80% of cases.'

- UK Working Party on Acute Pancreatitis. Gut 2005; 54(Suppl III):iii1–iii9

For further information:  www.bsg.org.uk

reduce systemic complications. Nasogastric feeding is just as effective as the nasojejunal route. Prophylaxis of thromboembolism with low-dose subcutaneous heparin is also advisable. The use of prophylactic, broad-spectrum intravenous antibiotics such as imipenem or cefuroxime to prevent infection of pancreatic necrosis is controversial but they are often given.

Patients who present with cholangitis or jaundice in association with severe acute pancreatitis should undergo urgent ERCP to diagnose and treat choledocholithiasis. In less severe cases of gallstone pancreatitis, biliary imaging (using MRCP or EUS) can be carried out after the acute phase has resolved. If the liver function tests return to normal and ultrasound has not demonstrated a dilated biliary tree, laparoscopic cholecystectomy with an on-table cholangiogram is appropriate because any common bile duct stones have probably passed. When the operative cholangiogram detects residual common bile duct stones, these are removed by laparoscopic exploration of the duct or by post-operative ERCP. Cholecystectomy should be undertaken within 2 weeks following resolution of pancreatitis—and preferably during the same admission—to prevent further potentially fatal attacks of pancreatitis. Patients who have developed necrotising pancreatitis or pancreatic abscess require urgent endoscopic or surgical necrosectomy to debride all cavities of necrotic material. Pancreatic pseudocysts are treated by drainage into the stomach, duodenum or jejunum (Roux en Y). This is usually performed after an interval of at least 6 weeks, once a pseudocapsule has matured, using open surgery or endoscopic methods.

Chronic pancreatitis

Chronic pancreatitis is a chronic inflammatory disease characterised by fibrosis and destruction of exocrine pancreatic tissue. Diabetes mellitus occurs in advanced cases because the islets of Langerhans are involved.

22.66 Causes of chronic pancreatitis ('TIGAR-0')

Toxic-metabolic

- Alcohol
- Tobacco
- Hypercalcaemia
- Chronic renal failure

Idiopathic

- Tropical
- Early/late onset types

Genetic

- Hereditary pancreatitis (cationic trypsinogen mutation)
- *SPINK-1* mutation
- Cystic fibrosis

Autoimmune

- Isolated or as part of multi-organ problem

Recurrent and severe acute pancreatitis

- Post-necrotic
- Recurrent acute pancreatitis

Obstructive

- Ductal adenocarcinoma
- Intraductal papillary mucinous neoplasia
- Pancreas divisum
- Sphincter of Oddi stenosis

N.B. Many patients have gallstones but these do not cause chronic pancreatitis.

Pathophysiology

Around 80% of cases in Western countries result from alcohol misuse. In southern India severe chronic calcific pancreatitis occurs in non-alcoholics, possibly as a result of malnutrition and cassava consumption. Other causes are listed in Box 22.66. The pathophysiology of chronic pancreatitis is shown in Figure 22.45.

Clinical features

Chronic pancreatitis predominantly affects middle-aged alcoholic men. Almost all present with abdominal pain. In

Fig. 22.45 Pathophysiology of chronic pancreatitis. Alcohol and other risk factors may trigger acute pancreatitis (AP) through multiple mechanisms. The first (or 'sentinel') episode of acute pancreatitis initiates an inflammatory response involving T-helper cells. Ongoing exposure to alcohol drives further inflammation but this is modified by regulatory T cells with subsequent fibrosis, via activation of pancreatic stellate cells. A cycle of inflammation and fibrosis ensues, with development of chronic pancreatitis. Alcohol is the most relevant risk factor as it is involved at multiple steps.

50% this occurs as episodes of 'acute pancreatitis', although each attack results in a degree of permanent pancreatic damage. Relentless, slowly progressive chronic pain without acute exacerbations affects 35% of patients, whilst the remainder have no pain but present with diarrhoea. Pain is due to a combination of increased pressure within the pancreatic ducts and direct involvement of pancreatic and peripancreatic nerves by the inflammatory process. Pain may be relieved by leaning forwards or by drinking alcohol. Approximately one-fifth of patients chronically consume opiate analgesics. Weight loss is common and results from a combination of anorexia, avoidance of food because of post-prandial pain, malabsorption and/or diabetes. Steatorrhoea occurs when more than 90% of the exocrine tissue has been destroyed; protein malabsorption only develops in the most advanced cases. Overall, 30% of patients are diabetic, but this figure rises to 70% in those with chronic calcific pancreatitis. Physical examination reveals a thin, malnourished patient with epigastric tenderness. Skin pigmentation over the abdomen and back is common and results from chronic use of a hot water bottle (erythema ab igne). Many patients have features of other alcohol- and smoking-related diseases. Complications are listed in Box 22.67.

Investigations

Investigations (Box 22.68 and Fig. 22.46) are carried out to:

- make a diagnosis of chronic pancreatitis
- define pancreatic function
- demonstrate anatomical abnormalities prior to surgical intervention.

22.67 Complications of chronic pancreatitis

- Pseudocysts and pancreatic ascites, which occur in both acute and chronic pancreatitis
- Extrahepatic obstructive jaundice due to a benign stricture of the common bile duct as it passes through the diseased pancreas
- Duodenal stenosis
- Portal or splenic vein thrombosis leading to segmental portal hypertension and gastric varices
- Peptic ulcer

22.68 Investigations in chronic pancreatitis

Tests to establish the diagnosis

- Ultrasound
- CT (may show atrophy, calcification or ductal dilatation)
- Abdominal X-ray (may show calcification)
- MRCP
- Endoscopic ultrasound

Tests of pancreatic function

- Collection of pure pancreatic juice after secretin injection (gold standard but invasive and seldom used)
- Pancreolauryl or PABA test (Box 22.12, p. 850)
- Faecal pancreatic elastase

Tests of anatomy prior to surgery

- MRCP

Management

Alcohol misuse

Alcohol avoidance is crucial in halting the progression of the disease and reducing pain.

Pain relief

A range of analgesic drugs, particularly NSAIDs, are valuable, but the severe and unremitting nature of the pain often leads to opiate use with the risk of addiction. Oral pancreatic enzyme supplements suppress pancreatic secretion and their regular use reduces analgesic consumption in some patients. Patients who are abstinent from alcohol and who have severe chronic pain which is resistant to conservative measures are considered for surgical or endoscopic pancreatic therapy (Box 22.69). Coeliac plexus neurolysis or minimally invasive thoracoscopic splanchnicectomy sometimes produces long-lasting pain relief, although relapse eventually occurs in the majority of cases. In some patients MRCP does not show a surgically or endoscopically correctable abnormality and in these patients the only surgical approach is total pancreatectomy. Unfortunately, even after this operation, some patients will continue to experience pain. Moreover, the procedure causes diabetes which may be difficult to control, with a high risk of

Fig. 22.46 Imaging in chronic pancreatitis. **[A]** CT scan showing a grossly dilated and irregular duct with a calcified stone (arrow A). Note the calcification in the head of the gland (arrow B). **[B]** MRCP of the same patient showing marked ductal dilatation with abnormal dilated side branches (arrows A). A small cyst is also present (arrow B).

22.69 Intervention in chronic pancreatitis

Endoscopic therapy

- Dilatation or stenting of pancreatic duct strictures
- Removal of calculi (mechanical or shock-wave lithotripsy)
- Drainage of pseudocysts

Surgical methods

- Partial pancreatic resection, preserving the duodenum
- Pancreatico-jejunostomy

hypoglycaemia (since both insulin and glucagon release are absent), and significant morbidity and mortality.

Malabsorption

This is treated by dietary fat restriction (with supplementary medium-chain triglyceride therapy in malnourished patients) and oral pancreatic enzyme supplements. A PPI is added to optimise duodenal pH for pancreatic enzyme activity.

Management of complications

Surgical or endoscopic therapy may be necessary for the management of pseudocysts, pancreatic ascites, common bile duct or duodenal stricture and the consequences of portal hypertension. Many patients with chronic pancreatitis also require treatment for other alcohol- and smoking-related diseases and for the consequences of self-neglect and malnutrition.

Autoimmune pancreatitis (AIP)

This is a form of chronic pancreatitis that can mimic cancer but which responds to corticosteroids. AIP is characterised by abdominal pain, weight loss or obstructive jaundice, without acute attacks of pancreatitis. Blood tests reveal increased serum immunoglobulin G (IgG) or IgG4, and the presence of other autoantibodies. Imaging shows a diffusely enlarged pancreas, narrowing of the pancreatic duct and stricturing of the lower bile duct on ERCP. AIP may occur alone or in association with other autoimmune disorders such as Sjögren's syndrome, primary sclerosing cholangitis (PSC) or inflammatory bowel disease. The response to steroids is usually excellent but some patients require azathioprine.

Congenital abnormalities of the pancreas

Pancreas divisum

This is due to failure of the primitive dorsal and ventral ducts to fuse during embryonic development of the pancreas. As a consequence, most of the pancreatic drainage occurs through the smaller accessory ampulla rather than through the major ampulla. The condition occurs in 7–10% of the normal population and is usually asymptomatic, but some patients develop acute pancreatitis, chronic pancreatitis or atypical abdominal pain.

Annular pancreas

In this congenital anomaly, the pancreas encircles the second/third part of the duodenum, leading to gastric

outlet obstruction. Annular pancreas is associated with malrotation of the intestine, atresias and cardiac anomalies.

Cystic fibrosis

This disease is considered in detail on page 678. The major gastrointestinal manifestations of cystic fibrosis are pancreatic insufficiency and meconium ileus. Peptic ulcer, and hepatic and biliary disease also occur. In cystic fibrosis pancreatic secretions are protein- and mucus-rich. The resultant viscous juice forms plugs which obstruct the pancreatic ductules, leading to progressive destruction of acinar cells. Steatorrhoea is universal and the large-volume bulky stools predispose to rectal prolapse. Malnutrition is compounded by the metabolic demands of respiratory failure and by diabetes which develops in 40% of patients by adolescence.

The majority of patients now survive well into adulthood and heart/lung transplantation can further prolong life. Optimal treatment of the cystic fibrosis patient depends upon an assiduous team approach to respiratory, nutritional and hepatobiliary complications. Nutritional counselling and supervision are important to ensure intake of high-energy foods, providing 120–150% of the recommended intake for normal subjects. Fats are an important calorie source and, despite the presence of steatorrhoea, fat intake should not be restricted. Supplementary fat-soluble vitamins are also necessary. High-dose oral pancreatic enzymes are required, in doses sufficient to control steatorrhoea and stool frequency. A PPI aids fat digestion by producing an optimal duodenal pH. Diabetic patients usually require insulin injections rather than oral hypoglycaemic agents.

Meconium ileus

Mucus-rich plugs within intestinal contents can obstruct the small or large intestine. Meconium ileus is treated by the mucolytic agent N-acetylcysteine given orally, by gastrografin enema or by gut lavage using polyethylene glycol. In resistant cases of meconium ileus surgical resection may be necessary.

Tumours of the pancreas

Pancreatic carcinoma affects 10–15 per 100 000 in Western populations, rising to 100 per 100 000 in those over the age of 70. Men are affected twice as often as women. The disease is associated with increasing age, smoking and chronic pancreatitis. Between 5 and 10% of patients have a genetic predisposition (hereditary pancreatitis, MEN, hereditary non-polyposis colon cancer (HNPCC) and familial atypical mole multiple melanoma syndrome (FAMMM)). Overall survival is only 3–5% with median survival of 6–10 months for those with locally advanced disease and 3–5 months if metastases are present.

Pathophysiology

Approximately 90% of pancreatic neoplasms are adenocarcinomas which arise from the pancreatic ducts. These tumours involve local structures and metastasise to regional lymph nodes at an early stage. The majority of patients have advanced disease at the time of presentation.

Clinical features

The clinical features of pancreatic cancer are pain, weight loss and obstructive jaundice (Fig. 22.47). The pain results from invasion of the coeliac plexus and is characteristically incessant and boring. It often radiates from the upper abdomen through to the back and may be eased a little by bending forwards. Almost all patients lose weight and many are cachectic. Around 60% of tumours arise from the head of the pancreas, and involvement of the common bile duct results in the development of obstructive jaundice, often with severe pruritus. A few patients present with diarrhoea, vomiting from duodenal obstruction, diabetes mellitus, recurrent venous thrombosis, acute pancreatitis or depression. Physical examination reveals clear evidence of weight loss. An abdominal mass due to the tumour itself, a palpable gallbladder or hepatic metastasis is commonly found. A palpable gallbladder in a jaundiced patient is usually the consequence of distal biliary obstruction by a pancreatic cancer (Courvoisier's sign).

Investigations

When a patient presents with biochemically confirmed obstructive jaundice, the diagnosis is usually made

by ultrasound and contrast-enhanced CT (Fig. 22.48). Diagnosis in non-jaundiced patients is often delayed because presenting symptoms are relatively non-specific. Fit patients with small localised tumours should undergo staging to define operability. EUS or laparoscopy with laparoscopic ultrasound will define tumour size, involvement of blood vessels and metastatic spread. In patients unsuitable for surgery because of advanced disease, frailty or comorbidity, endoscopic ultrasound (EUS) or CT-guided cytology or biopsy may be used to confirm the diagnosis. MRCP and ERCP are sensitive methods of diagnosing pancreatic cancer and are valuable when the diagnosis is in doubt, although differentiation between cancer and localised chronic pancreatitis can be difficult. The main role of ERCP is to insert a stent into the common bile duct to relieve obstructive jaundice in inoperable patients.

Management

Surgical resection is the only method of effecting cure, and 5-year survival in patients undergoing a complete resection is around 12%. Recent trials have demonstrated improved survival (21–29%) with adjuvant chemotherapy using 5-fluorouracil and folinic acid or gemcitabine.

Fig. 22.47 Features of pancreatic cancer.

Fig. 22.48 Carcinoma of the pancreatic head. A large mass (M) in the head of pancreas involves the portal vein (PV) and obstructs the common bile duct (CBD). (GB = gallbladder)

Unfortunately, a mere 10–15% of tumours are amenable to curative resection since most neoplasms are locally advanced at the time of diagnosis. For the great majority of patients treatment is palliative. Pain relief is achieved using analgesic drugs and, in some patients, coeliac plexus neurolysis by a percutaneous or EUS-guided alcohol injection. Jaundice is relieved by choledochojejunostomy in fit patients; percutaneous or endoscopic stenting is used in the elderly or in patients who have very advanced disease. Ampullary or periampullary adenocarcinomas are rare neoplasms which arise from the ampulla of Vater or adjacent duodenum. They are often polypoid and may ulcerate; they frequently infiltrate the duodenum but behave less aggressively than pancreatic adenocarcinoma. Around 25% of patients undergoing resection of ampullary or periampullary tumours survive for 5 years in contrast to patients with pancreatic ductal cancer.

Cystic neoplasms of the pancreas are increasingly being seen with widespread use of CT. These are a heterogeneous group; serous cystadenomas rarely, if ever, become malignant and do not require surgery. Mucinous cysts occur more often in women, are usually in the pancreatic head and display a spectrum of behaviour from benign to borderline to frankly malignant. EUS with aspiration of cyst contents for cytology and measurement of carcinoembryonic antigen (CEA) and amylase concentrations can help determine whether a lesion is mucinous or not. In fit patients, all mucinous lesions should be resected. A variant, called intraductal papillary mucinous neoplasia (IPMN) is often discovered coincidentally on CT, often in elderly men. IPMN may affect the main pancreatic duct with marked dilatation and plugs of mucus, or may affect a side-branch. The histology varies from villous adenomatous change to dysplasia to carcinoma. IPMN is premalignant but indolent, and the decision to resect or to monitor depends on many factors, including age and fitness of the patient and location, size and evolution of lesions.

Endocrine tumours

These arise from neuroendocrine tissue within the pancreas and can occur in association with parathyroid and

pituitary adenomas (MEN 1, p. 793). The majority of endocrine tumours are non-secretory and, although malignant, grow slowly and metastasise late. Other tumours secrete hormones and present because of their endocrine effects (see Box 20.52, p. 782). Neuroendocrine pancreatic tumours may be single, but are frequently multifocal and arise from other clusters of neuroendocrine cells derived from neural crest tissues. They are localised by CT and endoscopic ultrasound. ¹¹¹In-labelled DTPA is very sensitive in the diagnosis of glucagonoma.

INFLAMMATORY BOWEL DISEASE

Ulcerative colitis and Crohn's disease are chronic inflammatory bowel diseases which pursue a protracted relapsing and remitting course, usually extending over years. The diseases have many similarities and it is sometimes impossible to differentiate between them. A crucial distinction is that ulcerative colitis only involves the colon, while Crohn's disease can involve any part of the gastrointestinal tract from mouth to anus. A summary of the main features of ulcerative colitis and Crohn's disease is provided in Box 22.70.

i	22.70 Comparison of ulcerative colitis and Crohn's disease	
	Ulcerative colitis	Crohn's disease
Age group	Any	Any
Gender	M = F	M = F
Ethnic group	Any	Any; more common in Ashkenazi Jews
Genetic factors	<i>HLA-DR103</i> associated with severe disease	<i>CARD 15/NOD-2</i> mutations predispose
Risk factors	More common in non-/ex-smokers Appendectomy protects	More common in smokers
Anatomical distribution	Colon only; begins at anorectal margin with variable proximal extension	Any part of gastrointestinal tract; perianal disease common; patchy distribution—'skip lesions'
Extraintestinal manifestations	Common	Common
Presentation	Bloody diarrhoea	Variable; pain, diarrhoea, weight loss all common
Histology	Inflammation limited to mucosa; crypt distortion, cryptitis, crypt abscesses, loss of goblet cells	Submucosal or transmural inflammation common; deep fissuring ulcers, fistulas; patchy changes; granulomas
Management	5-ASA; corticosteroids; azathioprine; colectomy is curative	Corticosteroids; azathioprine; methotrexate; biologic therapy (anti-TNF); nutritional therapy; surgery for complications is not curative

The incidence of inflammatory bowel disease (IBD) varies widely between populations. Crohn's disease appears to be very rare in the developing world yet ulcerative colitis, although still unusual, is becoming more common. In the West, the incidence of ulcerative colitis is stable at 10–20 per 100 000, with a prevalence of 100–200 per 100 000, while the incidence of Crohn's disease is increasing and is now 5–10 per 100 000, with a prevalence of 50–100 per 100 000. Both diseases most commonly start in young adults, with a second smaller incidence peak in the seventh decade. Approximately 240 000 people are affected by IBD in the UK. Life expectancy in patients with IBD is similar to that of the general population. Although many patients require surgery and admission to hospital for other reasons, the majority have an excellent work record and pursue a normal life. Around 90% of ulcerative colitis patients have intermittent disease activity, whilst 10% have continuous symptoms.

Pathophysiology

It is thought that IBD develops because of an abnormal host response to an environmental trigger in genetically susceptible individuals (Box 22.71). This causes inflammation of the intestine and release of inflammatory mediators, such as TNF, IL-12 and IL-23, which cause tissue damage. These mediators are targets for therapeutic intervention (Fig. 22.49). In both diseases the intestinal wall is infiltrated with acute and chronic inflammatory cells. There are important differences in the distribution of disease and in histological features (Fig. 22.50).

Ulcerative colitis

Inflammation invariably involves the rectum (proctitis) but can spread to involve the sigmoid colon (proctosigmoiditis) or the whole colon (pancolitis). Inflammation is confluent and is more severe distally. In long-standing pancolitis the bowel can become shortened and 'pseudopolyps' develop which are normal or hypertrophied residual mucosa within areas of atrophy. The inflammatory process

Fig. 22.49 Pathogenesis of inflammatory bowel disease.

(1) Bacterial antigens are taken up by specialised M cells, pass between leaky epithelial cells or enter the lamina propria through ulcerated mucosa. (2) After processing they are presented to type 1 T-helper cells by antigen-presenting cells (APC) in the lamina propria. (3) T-cell activation and differentiation results in a Th1 T cell-mediated cytokine response (4) with secretion of cytokines including gamma interferon (IFN- γ). Further amplification of T cells perpetuates the inflammatory process with activation of non-immune cells and release of other important cytokines, e.g. interleukin (IL)-12, IL-23, IL-1, IL-6 and tumour necrosis factor (TNF). These pathways occur in all normal individuals exposed to an inflammatory insult and this is self-limiting in healthy subjects. In genetically predisposed persons, dysregulation of innate immunity may trigger inflammatory bowel disease.

is limited to the mucosa and spares the deeper layers of the bowel wall (Fig. 22.51). Both acute and chronic inflammatory cells infiltrate the lamina propria and the crypts ('cryptitis'). Crypt abscesses are typical. Goblet cells lose their mucus and in long-standing cases glands become distorted. Dysplasia, characterised by heaping of cells within the crypts, nuclear atypia and increased mitotic rate may herald the development of colon cancer.

Crohn's disease

The sites most commonly involved, in order of frequency, are terminal ileum and right side of colon, colon alone, terminal ileum alone, ileum and jejunum. The entire wall of the bowel is oedematous and thickened, and there are deep ulcers which often appear as linear fissures; thus the mucosa between them is described as 'cobblestone'. These may penetrate through the bowel wall to initiate abscesses or fistulas involving the bowel, bladder, uterus, vagina and skin of the perineum. The mesenteric lymph nodes are enlarged and the mesentery is thickened. Crohn's disease has a patchy distribution and the inflammatory process is interrupted by islands of normal mucosa. On histological examination, the bowel wall is thickened with a chronic inflammatory infiltrate throughout all layers (Fig. 22.52).

Clinical features

Ulcerative colitis

The major symptom is bloody diarrhoea. The first attack is usually the most severe and thereafter the disease is followed by relapses and remissions. Emotional stress,

22.71 Factors associated with the development of inflammatory bowel disease

Genetic

- More common in Ashkenazi Jews
- 10% have a first-degree relative or at least one close relative with IBD
- High concordance between identical twins
- Both ulcerative colitis and Crohn's disease are associated with the HLA locus and the genes encoding MST-1 and IL-23
- Crohn's disease is associated with the *NOD2*, *ATG16L1* and *IRGM* genes
- Ulcerative colitis is associated with the *ECM-1* gene
- Associated with autoimmune thyroiditis and SLE
- HLA-DR103 associated with severe ulcerative colitis
- Ulcerative colitis and Crohn's patients with HLA-B27 commonly develop ankylosing spondylitis

Environmental

- Ulcerative colitis is more common in non-smokers and ex-smokers
- Most Crohn's patients are smokers (relative risk = 3)
- Associated with low-residue, high refined sugar diet
- Appendectomy protects against ulcerative colitis

Fig. 22.50 Common patterns of disease distribution in inflammatory bowel disease.

Fig. 22.51 Histology of ulcerative colitis. There is surface ulceration and inflammation is confined to the mucosa with excess inflammatory cells in the lamina propria, loss of goblet cells, and crypt abscesses (arrows). (SM = submucosa)

intercurrent infection, gastroenteritis, antibiotics or NSAID therapy may all provoke a relapse. Proctitis causes rectal bleeding and mucus discharge, sometimes accompanied by tenesmus. Some patients pass frequent, small-volume fluid stools, while others are constipated and pass pellety stools. Constitutional symptoms do not occur. Proctosigmoiditis causes bloody diarrhoea with mucus. Almost all patients are constitutionally well, but a small minority who have very active, limited disease develop fever, lethargy and abdominal discomfort.

Extensive colitis causes bloody diarrhoea with passage of mucus. In severe cases anorexia, malaise, weight loss and abdominal pain occur, and the patient is toxic with fever, tachycardia and signs of peritoneal inflammation (Box 22.72).

Crohn's disease

The major symptoms are abdominal pain, diarrhoea and weight loss. Ileal Crohn's disease (Figs 22.53 and 22.54)

Fig. 22.52 Histology of Crohn's disease. **A** Inflammation is 'transmural'; there is fissuring ulceration (arrow) with inflammation extending into the submucosa (SM). **B** At higher power a characteristic non-caseating granuloma is seen.

22.72 Factors considered for disease severity assessment in ulcerative colitis

	Mild	Severe
Daily bowel frequency	< 4	> 6
Blood in stools	+/-	+++
Stool volume	< 200 g/24 hrs	> 400 g/24 hrs
Pulse	< 90 bpm	> 90 bpm
Temperature	Normal	> 37.8°C, 2 days out of 4
Sigmoidoscopy	Normal or granular mucosa	Blood in lumen
Abdominal X-ray	Normal	Dilated bowel and/or mucosal islands
Haemoglobin	Normal	< 100 g/L (< 10 g/dL)
ESR	Normal	> 30 mm/hr
Serum albumin	> 35 g/L (> 3.5 g/dL)	< 30 g/L (< 3 g/dL)

may cause subacute or even acute intestinal obstruction. The pain is often associated with diarrhoea which is usually watery and does not contain blood or mucus. Almost all patients lose weight because they avoid food since eating provokes pain. Weight loss may also be due to malabsorption, and some patients present with features of fat, protein or vitamin deficiencies. Crohn's colitis presents in an identical manner to ulcerative colitis, but rectal sparing and the presence of perianal disease are features which favour a diagnosis of Crohn's disease. Many patients present with symptoms of both small bowel and colonic disease. A few have isolated perianal disease, vomiting from jejunal strictures or severe oral ulceration.

Fig. 22.53 Ileal Crohn's disease. MRI scan showing a thickened, narrowed loop of ileum with enhancement after MR contrast (arrows), consistent with active Crohn's disease. Normal small bowel can be seen at the top right of the image. (C = caecum)

Fig. 22.54 Barium follow-through showing terminal ileal Crohn's disease. A long stricture is present (arrow A), and more proximally there is ulceration with characteristic 'rose thorn' ulcers (arrow B).

Physical examination often reveals evidence of weight loss, anaemia with glossitis and angular stomatitis. There is abdominal tenderness, most marked over the inflamed area. An abdominal mass due to matted loops of thickened bowel or an intra-abdominal abscess may occur. Perianal skin tags, fissures or fistulas are found in at least 50% of patients.

Differential diagnosis

The differential diagnosis is summarised in Box 22.73. The most important issue is to distinguish the first attack of an acute colitis from infection. In general, diarrhoea lasting longer than 10 days in Western countries is

22.73 Conditions which can mimic ulcerative or Crohn's colitis

unlikely to be the result of infection, whereas a history of foreign travel, antibiotic exposure (pseudomembranous colitis) or homosexual contact increases the possibility of infection, which should be excluded by the appropriate investigations (see below). The diagnosis of Crohn's disease is usually more straightforward on the basis of imaging and clinical presentation, but in atypical cases biopsy or surgical resection is necessary to exclude other diseases (Box 22.74).

Complications

Life-threatening colonic inflammation

This can occur in both ulcerative colitis and Crohn's disease. In the most extreme cases the colon dilates (toxic megacolon) and bacterial toxins pass freely across the diseased mucosa into the portal then systemic circulation. This complication occurs most commonly during the first attack of colitis and is recognised by the features described in Box 22.72. An abdominal X-ray should be taken daily because when the transverse colon is dilated to more than 6 cm (Fig. 22.55) there is a high risk of colonic

Fig. 22.55 Plain abdominal X-ray showing a grossly dilated colon due to severe ulcerative colitis. There is also marked mucosal oedema and 'thumb-printing' (arrows).

perforation, although this complication can also occur in the absence of toxic megacolon.

Haemorrhage

Haemorrhage due to erosion of a major artery is rare but can occur in both conditions.

Fistulas

These are specific to Crohn's disease. Enteroenteric fistulas can cause diarrhoea and malabsorption due to blind loop syndrome. Enterovesical fistulation causes recurrent urinary infections and pneumaturia. An enterovaginal fistula causes a feculent vaginal discharge. Fistulation from the bowel may also cause perianal or ischiorectal abscesses, fissures and fistulas.

Cancer

The risk of colon cancer is increased in patients with active colitis of more than 8 years' duration. The cumulative risk for ulcerative colitis may be as high as 20% after 30 years but is probably lower for Crohn's colitis. Tumours develop in areas of dysplasia and may be multiple. Patients with long-standing, extensive colitis are therefore entered into surveillance programmes beginning 8–10 years after diagnosis during which biopsies are taken throughout the colon at colonoscopy. If mild to moderate dysplastic changes are identified, the frequency of screening is increased to 1–2-yearly, but if high-grade dysplasia is found, panproctocolectomy should be considered because of the high risk of colon cancer.

Extraintestinal

Extraintestinal complications are common in IBD and may dominate the clinical picture. Some of these occur during relapse of intestinal disease; others appear unrelated to intestinal disease activity (Fig. 22.56).

Investigations

These are necessary to confirm the diagnosis, define disease distribution and activity, and identify complications. Full blood count may show anaemia resulting from bleeding or malabsorption of iron, folic acid or vitamin B₁₂. Serum albumin concentration falls as a consequence of protein-losing enteropathy, inflammatory disease or poor nutrition. The ESR and CRP are elevated in exacerbations and in response to abscess formation.

Bacteriology

At the time of initial presentation, stool microscopy, culture and examination for *Clostridium difficile* toxin or for ova and cysts, blood cultures and serological tests should be performed to exclude infection. These investigations may need to be repeated in established disease to exclude superimposed enteric infection in patients who present with exacerbations of IBD.

Endoscopy

Sigmoidoscopy (Fig. 22.57) with biopsy is an essential investigation in all patients who present with diarrhoea. In ulcerative colitis sigmoidoscopy is almost always abnormal with loss of vascular pattern, granularity, friability and ulceration. In Crohn's disease patchy inflammation with discrete, deep ulcers, perianal disease (fissures, fistulas and skin tags) or rectal sparing occurs. Colonoscopy may show active inflammation with pseudopolyps or a complicating carcinoma. Biopsies are

Occur during the active phase of inflammatory bowel disease

Unrelated to inflammatory bowel disease activity

Fig. 22.56 Systemic complications of inflammatory bowel disease. (See also Chs 19 and 20.)

taken to define disease extent, as this is underestimated by endoscopic appearances alone, and to seek dysplasia in patients with long-standing colitis. In ulcerative colitis the macroscopic and histological abnormalities are

Fig. 22.57 Sigmoidoscopic view of moderately active ulcerative colitis. Mucosa is erythematous and friable with contact bleeding. Submucosal blood vessels are no longer visible.

confluent and most severe in the distal colon and rectum. Stricture formation does not occur in the absence of a carcinoma. In Crohn's colitis the endoscopic abnormalities are patchy, with normal mucosa between the areas of abnormality. Aphthoid or deeper ulcers and strictures are common. Capsule endoscopy is useful in the identification of small bowel inflammation, but should be avoided in the presence of strictures.

Radiology

Barium enema is a less sensitive investigation than colonoscopy in patients with colitis and is now little used. Contrast studies of the small bowel can be helpful in the investigation of Crohn's disease; affected areas are narrowed and ulcerated, and multiple strictures are common (see Fig. 22.54). MRI scans provide comparable information without radiation exposure or risking small bowel obstruction and are useful in delineating pelvic or perineal involvement. A plain abdominal X-ray is essential in the management of patients who present with severe active disease. Dilatation of the colon (see Fig. 22.55), mucosal oedema ('thumb-printing') or evidence of perforation may be found. In small bowel Crohn's disease there may be evidence of intestinal obstruction or displacement of bowel loops by a mass. Ultrasound may identify thickened small bowel loops and abscess development in Crohn's disease.

Management

For optimal treatment, a team-based approach should be employed involving physicians, surgeons, radiologists, nurse specialists and dietitians. Both ulcerative colitis and Crohn's disease are life-long conditions and have psychosocial implications; counsellors and patient support groups have important roles in education, reassurance and coping. The key aims are to:

- treat acute attacks
- prevent relapses
- detect carcinoma at an early stage
- select patients for surgery.

Drugs used in the treatment of IBD are listed in Box 22.75.

Ulcerative colitis

Active proctitis In mild to moderate disease mesalazine enemas or suppositories combined with oral mesalazine are effective first-line therapy. Topical corticosteroids are less effective and are reserved for patients who are intolerant of topical mesalazine. Patients who fail to respond are treated with oral prednisolone 40 mg daily.

Active left-sided or extensive ulcerative colitis In mildly active cases, high-dose aminosalicylates combined with topical aminosalicylate and corticosteroids are effective. Oral prednisolone 40 mg daily is indicated for more active disease or when initial aminosalicylate therapy is ineffective.

22.75 Drugs used in the treatment of inflammatory bowel disease

Class	Mechanism of action	Notes
Aminosalicylates (mesalazine (Asacol, Salofalk, Pentasa), olsalazine, sulfasalazine, balsalazide)	Modulate cytokine release from mucosa Delivered to colon by one of three mechanisms: (1) pH-dependent (Asacol, Salofalk) (2) time-dependent (Pentasa) (3) bacterial breakdown by colonic bacteria from a carrier molecule (sulfasalazine, balsalazide)	No proven value in Crohn's Available as oral or topical (enema/suppository) preparation Sulfasalazine causes side-effects in 10–45%: headache, nausea, diarrhoea, blood dyscrasias Other aminosalicylates much better tolerated; diarrhoea, headache in 2–5% Rarely, renal impairment All safe during pregnancy
Corticosteroids (prednisolone, hydrocortisone, budesonide)	Anti-inflammatory Budesonide is a potent corticosteroid efficiently cleared from circulation by liver, thereby minimising adrenocortical suppression and steroid side-effects	Topical, oral or i.v., according to disease severity Bisphosphonates are co-prescribed to prevent osteopenia Budesonide considered for active ileitis and ileocolitis
Thiopurines (azathioprine, 6-mercaptopurine)	Immunomodulation by inducing T-cell apoptosis Azathioprine is metabolised in the liver to 6-mercaptopurine, then by thiopurine methyltransferase (TPMT) to thioguanine nucleotides	Effective after 12 weeks of starting therapy Complications in 20%. Flu-like syndrome with myalgia Leucopenia in 3%, particularly in inherited TPMT deficiency No increased risk of cancer but probable increase in lymphoma Safe during pregnancy
Methotrexate	Anti-inflammatory	Intolerance in 10–18%. Nausea, stomatitis, diarrhoea, hepatotoxicity and pneumonitis
Ciclosporin	Suppresses T-cell expansion	'Rescue' therapy to prevent surgery in ulcerative colitis responding poorly to corticosteroids. No value in Crohn's disease Major side-effects in 0–17%: nephrotoxicity, infections, neurotoxicity (including fits) Minor complications in up to 50%: tremor, paraesthesiae, abnormal liver function tests, hirsutism
Anti-TNF antibodies (infliximab and adalimumab)	Suppress inflammation and induce apoptosis of inflammatory cells	Moderately to severely active Crohn's disease, especially fistulating Severe active ulcerative colitis Anaphylactic reactions after multiple infusions Contraindicated in the presence of infections; reactivation of tuberculosis Increased risk of infections and malignancy
Antibiotics	Antibacterial	Useful in perianal Crohn's disease Major concern is peripheral neuropathy with long-term metronidazole
Antidiarrhoeal agents (codeine phosphate, loperamide, lomotil)	Reduce gut motility and small bowel secretion Loperamide improves anal function	Avoided in acute flare-ups of disease May precipitate colonic dilatation

Severe ulcerative colitis Patients who fail to respond to maximal oral therapy and those who present with severe colitis are best managed in hospital and should be monitored jointly by a physician and surgeon:

- clinically: for the presence of abdominal pain, temperature, pulse rate, stool blood and frequency
- in the laboratory; haemoglobin, white cell count, albumin, electrolytes, ESR and CRP
- radiologically: for colonic dilatation on plain abdominal X-rays.

Supportive treatment includes intravenous fluids to correct dehydration along with nutritional support, usually as enteral rather than intravenous feeding, for malnourished patients (Box 22.76).

Intravenous corticosteroids (methylprednisolone 60 mg or hydrocortisone 400 mg/day) are given as a constant infusion. Topical and oral aminosalicylates are also used, although their value in severe disease is unclear. Patients who do not promptly respond to corticosteroids are considered for intravenous ciclosporin or infliximab, which, in approximately 30% of cases, overcomes the need for urgent colectomy.

Patients who develop colonic dilatation (> 6 cm), those whose clinical and laboratory measurements deteriorate and those who do not respond after 7–10 days' maximal medical treatment usually require urgent colectomy.

Maintenance of remission Life-long maintenance therapy is recommended for all patients with extensive disease and patients with distal disease who relapse more than once a year. Oral aminosalicylates—either mesalazine or balsalazide—are first-line agents (Box 22.77). Sulfasalazine has a higher incidence of side-effects, but should be considered in patients with co-existent arthropathy. Patients who frequently relapse despite aminosalicylate drugs are treated with thiopurines.

22.76 Medical management of fulminant ulcerative colitis

- Intravenous fluids
- Transfusion if Hb < 100 g/L
- I.v. methylprednisolone (60 mg daily) or hydrocortisone (400 mg daily)
- Antibiotics for proven infection
- Nutritional support
- Subcutaneous heparin for prophylaxis of venous thromboembolism
- Avoidance of opiates and antidiarrhoeal agents
- Consider infliximab (5 mg/kg) in stable patients not responding to 3–5 days of corticosteroids

EBM 22.77 Aminosalicylates and remission in ulcerative colitis

'Higher doses of 5-ASA (4 g/day) are superior to placebo at inducing remission in mild ulcerative colitis and Crohn's disease. Maintenance with 5-ASA reduces the risk of colorectal cancer by 75% in ulcerative colitis.'

- Carter MJ, et al. Gut 2004; 53 (suppl. V):1–16.

Crohn's disease

Active disease Patients with active colitis or ileocolitis are initially treated in a similar manner to those with active ulcerative colitis. Aminosaliculates and corticosteroids are both effective and usually induce remission in active ileocolitis and colitis. In severe disease intravenous steroids are indicated, but abscess or fistulating disease should be excluded before instituting therapy. In contrast to ulcerative colitis, nutritional therapy using polymeric or elemental diets induces remission in Crohn's disease. Possible mechanisms include avoidance of dietary antigens, other ill-defined immunological effects and the non-specific effects of nutritional support. Prolonged nutritional therapy, which involves exclusion of a normal diet, is onerous for the patient; remission rates are comparable to those achieved by corticosteroids but relapse rates are higher and, except in paediatric practice, primary nutritional therapy is now seldom used.

Patients with isolated ileal disease should be treated with corticosteroids. Budesonide is appropriate for treating moderately active disease, although it is marginally less effective than prednisolone. Aminosaliculates have little added value but there is some evidence to support the use of oral metronidazole. Poorly responding patients should, at an early stage, be considered for surgical resection since this is associated with prolonged remission in most cases.

Therapy with the anti-TNF antibodies infliximab (given as an intravenous infusion 4–8-weekly on three occasions) or adalimumab (a subcutaneous injection given two weekly) can induce remission in patients with active Crohn's disease at any site within the gastrointestinal tract (Box 22.78). Interestingly, however, etanercept (a decoy receptor for TNF) is ineffective in Crohn's disease. These drugs also effectively treat some extraintestinal complications, including pyoderma gangrenosum and inflammatory arthritis. Infliximab and adalimumab are contraindicated in the presence of infection, including tuberculosis, and may be complicated by allergic reactions (Box 22.79). Relapse commonly occurs approximately 12 weeks after treatment and for this reason biological agents are usually combined with immunosuppressive drugs such as the thiopurines (azathioprine and 6-mercaptopurine) or methotrexate, to maintain remission. These drugs can induce remarkable mucosal healing but scarring can occur, and they should therefore be used with caution in patients with stenosing disease. Biological agents, particularly when combined with thiopurines, predispose to malignancy. Although this risk is relatively small and has to be balanced against the considerable value in transforming the quality of life for

EBM 22.78 Infliximab in Crohn's disease

22.79 Biological drugs and inflammatory bowel disease

- Inhibit activity of TNF- α , resulting in suppression of T-cell-mediated immunity
- Two commercially available agents are infliximab and adalimumab
- Induce remission in 70% of cases of active Crohn's disease, with mucosal healing
- Fistulas heal in most patients
- Clinical relapse is frequent after about 12 weeks
- Efficacy is improved by corticosteroid co-treatment
- Maintenance therapy is necessary for aggressive disease
- Side-effects may be serious and related to suppression of cell-mediated immunity
 - Infection: tuberculosis and active sepsis of any sort are absolute contraindications
 - Malignancy: avoid in patients with a history of cancer or lymphoma. Increased incidence of malignant disease in patients on maintenance therapy, particularly if combined with thiopurines

many sufferers, the risk-benefit analysis should be discussed with all patients before therapy is started.

Patients with diffuse and extensive ileocolonic involvement present considerable therapeutic challenges. A combination of drug therapies, nutritional support (which in the most severe cases involves prolonged parenteral nutrition), surgical intervention and endoscopic balloon dilatation of strictures may all be needed at different times.

Fistulas and perianal disease Fistulas usually develop in association with active Crohn's disease and are often associated with sepsis. The first step in management is to define the site of fistulation by imaging. Surgical intervention is then required, although treatment of underlying active disease with corticosteroids and nutritional support, usually by TPN, are required in many cases. For simple perianal disease metronidazole and/or ciprofloxacin are first-line therapies. Thiopurines are used in chronic disease. In many patients examination under anaesthetic is needed to determine the site of complicating abscess, fissure and fistula. Infliximab and adalimumab heal enterocutaneous fistulas and perianal disease in many patients.

Maintenance of remission The most effective step, and one greater than any pharmacological intervention, is smoking cessation. Aminosalicylates have minimal efficacy. Patients who relapse more than once a year should be treated with thiopurines (Box 22.80). Patients who are intolerant of or resistant to thiopurines should be treated with once-weekly methotrexate combined with folic acid. Patients with aggressive disease are managed using a combination of immunosuppressives and anti-TNF therapy. Chronic use of corticosteroids should be

avoided since this leads to osteoporosis and other side-effects, without preventing relapse.

Surgical treatment

Ulcerative colitis

Up to 60% of patients with extensive ulcerative colitis eventually require surgery. The indications are listed in Box 22.81. Impaired quality of life, with impact upon occupation and on social and family life, is the most important of these. Surgery involves removal of the entire colon and rectum, and cures the patient. One-third of those with pancolitis undergo colectomy within 5 years of diagnosis. Before surgery, patients must be counselled by doctors, stoma nurses and patients who have undergone similar surgery. The choice of procedure is either panproctocolectomy with ileostomy, or proctocolectomy with ileal-anal pouch anastomosis. The sister surgical text to this book, *Principles and Practice of Surgery*, should be consulted for further details.

Crohn's disease

The indications for surgery are similar to those for ulcerative colitis. Operations are often necessary to deal with fistulas, abscesses and perianal disease, and may also be required to relieve small or large bowel obstruction. In contrast to ulcerative colitis, surgery is not curative and disease recurrence is the rule. Surgical intervention should therefore be as conservative as possible in order to minimise loss of viable intestine and to avoid creation of a short bowel syndrome. Obstructing or fistulating small bowel disease may require resection of affected tissue. Patients who have localised segments of Crohn's colitis may be managed by segmental resection and/or multiple stricturoplasties in which the stricture is not resected but instead incised in its longitudinal axis and sutured transversely. Others who have extensive colitis require total colectomy but ileal-anal pouch formation should be avoided because of the high risk of disease recurrence within the pouch and subsequent fistulas, abscess formation and pouch failure.

Patients who have perianal Crohn's disease should be managed as conservatively as possible. Seton drainage, fistulectomy and use of advancement flaps are appropriate for complex fistulas in combination with medical therapies. Around 80% of Crohn's patients undergo surgery at some stage, and 70% of these require more than one operation during their lifetime. Clinical recurrence following resectional surgery is present in 50% of all cases at 10 years.

22.81 Indications for surgery in ulcerative colitis

Impaired quality of life

- Loss of occupation or education
- Disruption of family life

Failure of medical therapy

- Dependence upon oral corticosteroids
- Complications of drug therapy

Fulminant colitis

Disease complications unresponsive to medical therapy

- Arthritis
- Pyoderma gangrenosum

Colon cancer or severe dysplasia

IBD in special circumstances

Childhood

Ulcerative colitis and Crohn's disease can develop before adolescence. Chronic ill health results in growth failure, metabolic bone disease and delayed puberty. Loss of schooling and social contact, as well as frequent hospitalisation, can have important psychosocial consequences. Treatment is similar to that described for adults and may require the use of corticosteroids, immunosuppressive drugs, biological agents and surgery. Monitoring of height, weight and sexual development is crucial.

Pregnancy

The activity of IBD is not usually affected by pregnancy, although relapse may be more common after parturition. Drug therapy, including aminosalicylates, corticosteroids and azathioprine, can be safely continued throughout the pregnancy (Box 22.82).

Metabolic bone disease

Patients with IBD are prone to developing osteoporosis due to effects of chronic inflammation, corticosteroids, weight loss, malnutrition and malabsorption. Osteomalacia can also occur in Crohn's disease which is complicated by malabsorption, but is less common than osteoporosis. The risk of osteoporosis increases with age and with the dose and duration of corticosteroid therapy.

22.82 Pregnancy and inflammatory bowel disease

Pre-conception

- Outcomes are best when pregnancy is carefully planned and disease is in remission
- IBD drugs should be continued until discussed with a specialist
- Aminosalicylates, antidiarrhoeals and azathioprine are safe in pregnancy
- Corticosteroids are probably safe
- Safety of biological therapy in pregnancy is unclear; use only when absolutely necessary
- Daily folic acid supplements are recommended

Pregnancy

- Two-thirds of patients in remission will remain so during pregnancy
- Active disease is likely to remain active
- Severe active disease carries an increased risk of premature delivery and low birth weight
- Gentle flexible sigmoidoscopy is safe after the first trimester
- Colonoscopy and X-rays should be avoided

Labour

- Needs careful discussion between patient, gastroenterologist and obstetrician
- Normal labour and vaginal delivery are possible for most women
- Caesarean section may be preferred for patients with perianal Crohn's or an ileo-anal pouch to reduce risks of pelvic floor damage, fistulation and late incontinence

Breastfeeding

- Safe and does not exacerbate IBD
- Data on the risk to babies from drugs excreted in breast milk are limited; most are probably safe
- Patients should discuss breastfeeding and drug therapy carefully with their doctor

Diagnosis and management of osteomalacia and osteoporosis are discussed in Chapter 25.

Microscopic colitis

Some patients experience watery diarrhoea as a consequence of microscopic ('lymphocytic') colitis. The colonoscopic appearances are normal but histological examination of biopsies shows a range of abnormalities.

Collagenous colitis is characterised by the presence of a thick submucosal band of collagen; a chronic inflammatory infiltrate is usually seen. The disease is more common in women and is associated with rheumatoid arthritis, diabetes and coeliac disease. Patients have a history of intermittent watery diarrhoea and treatment is based on antidiarrhoeal drugs and budesonide.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a functional bowel disorder in which abdominal pain is associated with defecation or a change in bowel habit. Approximately 20% of the general population fulfil diagnostic criteria for IBS but only 10% of these consult their doctors because of gastrointestinal symptoms. Nevertheless, IBS is the most common cause of gastrointestinal referral and accounts for frequent absenteeism from work and impaired quality of life. Young women are affected 2–3 times more often than men. Co-existing conditions such as non-ulcer dyspepsia, chronic fatigue syndrome, dysmenorrhoea and fibromyalgia are common. A significant proportion of patients have a history of physical or sexual abuse.

Pathophysiology

IBS encompasses a wide range of symptoms and a single cause is unlikely. It is generally believed that most patients develop symptoms in response to psychosocial factors, altered gastrointestinal motility, altered visceral sensation or luminal factors.

Psychosocial factors

Most patients seen in general practice do not have psychological problems but about 50% of patients referred to hospital meet the criteria for a psychiatric diagnosis. A range of disturbances are identified, including anxiety, depression, somatisation and neurosis. Panic attacks are also common. Acute psychological stress and overt psychiatric disease are known to alter visceral perception and gastrointestinal motility in both irritable bowel patients and healthy people. There is an increased prevalence of abnormal illness behaviour with frequent consultations for minor symptoms and reduced coping ability (p. 238). These factors contribute to but do not cause IBS.

Altered gastrointestinal motility

A range of motility disorders are found but none is diagnostic. Patients with diarrhoea as a predominant symptom exhibit clusters of rapid jejunal contraction waves, rapid intestinal transit and an increased number of fast and propagated colonic contractions. Those who are predominantly constipated have decreased oro-caecal transit and a reduced number of high-amplitude, propagated colonic contraction waves but there is no consistent evidence of abnormal motility.

Abnormal visceral perception

IBS is associated with increased sensitivity to intestinal distension induced by inflation of balloons in the ileum, colon and rectum, a consequence of altered central nervous system processing of visceral sensation. This is more common in women and in diarrhoea-predominant IBS.

Infection and allergy

Between 7 and 32% of patients develop IBS following an episode of gastroenteritis, more commonly young women and those with existing background psychological problems. Others may be intolerant of specific dietary components, particularly lactose and wheat. Abnormalities of gut microflora leading to increased fermentation and gas production and minimal inflammation have also been postulated. Some patients have subtle, histologically undetectable mucosal inflammation, possibly leading to activation of inflammatory cells and release of cytokines, nitric oxide and histamine. These may trigger abnormal secretomotor function and sensitise enteric sensory nerve endings.

Clinical features

The most common presentation is that of recurrent abdominal pain (Box 22.83). This is usually colicky or 'cramping', felt in the lower abdomen and relieved by defecation. Abdominal bloating worsens throughout the day; the cause is unknown but it is not due to excessive intestinal gas. The bowel habit is variable. Most patients alternate between episodes of diarrhoea and constipation, but it is useful to classify patients as having predominantly constipation or predominantly diarrhoea. Those with constipation tend to pass infrequent pellet stools, usually in association with abdominal pain or proctalgia. Those with diarrhoea have frequent defecation but produce low-volume stools and rarely have nocturnal symptoms. Passage of mucus is common but rectal bleeding does not occur. Despite apparently severe symptoms, patients do not lose weight and are constitutionally well. Physical examination is generally unremarkable, with the exception of variable tenderness to palpation.

Diagnosis

The diagnosis is clinical in nature and can be made confidently in most patients under the age of 40 years without resorting to complicated tests (Box 22.84). Full blood count, faecal calprotectin and sigmoidoscopy are usually done routinely and are normal in IBS. Colonoscopy should be undertaken in older patients to exclude colorectal cancer. Those who present atypically require investigations to exclude organic gastrointestinal disease. Diarrhoea-predominant patients justify investigations to exclude microscopic colitis (p. 904), lactose intolerance (p. 886), bile acid malabsorption (p. 850),

**22.83 Features of irritable bowel syndrome**

- Colicky abdominal pain
- Altered bowel habit
- Abdominal distension
- Rectal mucus
- Feeling of incomplete defecation

**22.84 Supporting diagnostic features and alarm features in IBS****Features supporting a diagnosis of IBS**

- Symptoms > 6 months
- Frequent consultations for non-GI problems
- Previous medically unexplained symptoms
- Stress worsens symptoms

Alarm features

- Age > 50 years; male gender
- Weight loss
- Nocturnal symptoms
- Family history of colon cancer
- Anaemia
- Rectal bleeding

coeliac disease (p. 879), thyrotoxicosis and, in developing countries, parasitic infection. All patients who give a history of rectal bleeding should undergo colonoscopy to exclude colonic cancer or IBD.

Management

The most important steps are to make a positive diagnosis and reassure the patient. Many patients are concerned that they have developed cancer, and a cycle of anxiety leading to colonic symptoms, which further heighten anxiety, can be broken by explanation that symptoms are not due to organic disease but are the result of altered bowel motility and sensation. In patients who fail to respond to reassurance, treatment is tailored to the predominant symptoms (Fig. 22.58). Elimination diets are generally unhelpful but up to 20% may benefit from a wheat-free diet, some may respond to lactose exclusion, and excess intake of caffeine or artificial sweeteners such as sorbitol should be addressed. The role of probiotics has yet to be clearly established.

Patients with intractable symptoms sometimes benefit from several months of therapy with amitriptyline (10–25 mg orally at night) (Box 22.85). Side-effects include dry mouth and drowsiness but these are usually mild and the drug is generally well tolerated, although patients with features of somatisation tolerate the drug poorly and lower doses should be used. It may act by reducing visceral sensation and by altering gastrointestinal motility. Other drugs may overcome abnormalities of 5-HT signalling which have been identified in some IBS patients. These include 5-HT₄ agonists. Active anxiety or affective disorders should be separately treated. Psychological interventions such as cognitive behavioural therapy, relaxation and gut-directed hypnotherapy are reserved for the most difficult cases. A range of complementary and alternative therapies exist; most lack a good evidence base but are popular and help some patients (Box 22.86).

EBM 22.85 Drug therapy for IBS

'Evidence for efficacy of drug therapy for IBS is weak. There is evidence of benefit for antispasmodic drugs for abdominal pain and overall response but there is no clear evidence of benefit for antidepressants or bulking agents. For each individual, treatment should be aimed at the most debilitating symptom.'

AIDS AND THE GASTROINTESTINAL TRACT

See page 393.

ISCHAEMIC GUT INJURY

Ischaemic gut injury is usually the result of arterial occlusion. Severe hypotension and venous insufficiency are less frequent causes (p. 199). The presentation is variable depending on the different vessels involved and the acuteness of the event. Diagnosis is often difficult.

Acute small bowel ischaemia

An embolus from the heart or aorta to the superior mesenteric artery is responsible for 40–50% of cases, thrombosis of underlying atheromatous disease for approximately 25% and non-occlusive ischaemia due to hypotension complicating myocardial infarction, heart failure, arrhythmias or sudden blood loss for approximately 25%. Vasculitis or venous occlusion is a rare cause. The pathological spectrum ranges from transient alteration of bowel function to transmural haemorrhagic

necrosis and gangrene. Patients usually have evidence of cardiac disease and arrhythmia. Almost all develop abdominal pain that is more impressive than the physical findings. In the early stages the only physical signs may be a silent, distended abdomen or diminished bowel sounds, peritonitis only developing later.

Leucocytosis, metabolic acidosis, hyperphosphataemia and hyperamylasaemia are typical. Plain abdominal X-rays show 'thumb-printing' due to mucosal oedema. Mesenteric or CT angiography reveals an occluded or narrowed major artery with spasm of arterial arcades, although most patients undergo laparotomy on the basis of a clinical diagnosis without angiography. Resuscitation, management of cardiac disease and intravenous antibiotic therapy, followed by laparotomy, are key steps. If treatment is instituted early, embolectomy and vascular reconstruction may salvage some small bowel. In these rare cases a 'second look' laparotomy is undertaken 24 hours later and further necrotic bowel resected. In patients at high surgical risk thrombolysis may sometimes be effective. The results of therapy depend on early intervention; patients treated late have a 75% mortality rate. Survivors often have nutritional failure from short bowel syndrome (p. 882) and require intensive nutritional support, sometimes including home parenteral nutrition, as well as anticoagulation. Small bowel transplantation is promising in selected patients. Patients with mesenteric venous thrombosis also require surgery if there are signs of peritonitis but are otherwise treated with anticoagulation. Investigations for underlying prothrombotic disorders should be performed (p. 1049).

Acute colonic ischaemia

The splenic flexure and descending colon have little collateral circulation and lie in 'watershed' areas of arterial supply. The spectrum of injury ranges from reversible colopathy to transient colitis, colonic stricture, gangrene and fulminant pancolitis. Arterial thromboembolism is usually responsible but colonic ischaemia can also follow severe hypotension, colonic volvulus, strangulated hernia, systemic vasculitis or hypercoagulable states. Ischaemia of the descending and sigmoid colon is also a complication of abdominal aortic aneurysm surgery (where the inferior mesenteric artery is ligated). The patient is usually elderly and presents with sudden onset of cramping left-sided lower abdominal pain and rectal bleeding. Symptoms usually resolve spontaneously over 24–48 hours and healing occurs within 2 weeks. Some have a residual fibrous stricture or segment of colitis. A minority develop gangrene and peritonitis. The diagnosis is established by colonoscopy within 48 hours of presentation; otherwise, mucosal ulceration and oedema may have resolved. Resection is required for peritonitis.

Chronic mesenteric ischaemia

This results from atherosclerotic stenosis affecting at least two of the coeliac axis, superior mesenteric and inferior mesenteric arteries. Dull but severe mid- or upper abdominal pain develops about 30 minutes after eating. Patients lose weight because of reluctance to eat, and some experience diarrhoea. Physical examination invariably shows evidence of generalised arterial disease. An abdominal bruit is sometimes audible but is non-specific. Mesenteric angiography confirms at least two affected mesenteric arteries. Vascular reconstruction

or percutaneous angioplasty is sometimes possible. Left untreated, many patients eventually develop intestinal infarction.

DISORDERS OF THE COLON AND RECTUM

Tumours of the colon and rectum

Polyps and polyposis syndromes

Polyps may be neoplastic or non-neoplastic. The latter include hamartomas, metaplastic ('hyperplastic') polyps and inflammatory polyps. These have no malignant potential. Polyps may be single or multiple and vary from a few millimetres to several centimetres in size.

Colorectal adenomas are extremely common in the Western world and the prevalence rises with age; 50% of people over 60 years of age have adenomas, and in half of these the polyps are multiple. They are more common in the rectum and distal colon and are either pedunculated or sessile. Histologically, they are classified as either tubular, villous or tubulovillous, according to the glandular architecture. Nearly all forms of colorectal carcinoma develop from adenomatous polyps over 5–10 years, although not all polyps carry the same degree of risk. Features associated with a higher risk of subsequent malignancy in colonic polyps are listed in Box 22.87.

Adenomas are usually asymptomatic and discovered incidentally. Occasionally, they cause bleeding and anaemia. Villous adenomas sometimes secrete large amounts of mucus, causing diarrhoea and hypokalaemia.

Discovery of a polyp at sigmoidoscopy is an indication for colonoscopy because proximal polyps are present in 40–50% of such patients. Colonoscopic polypectomy should be carried out wherever possible, as this considerably reduces subsequent colorectal cancer risk (Fig. 22.59). Very large or sessile polyps can sometimes be removed safely by endoscopic mucosal resection (EMR) but will otherwise require surgery. Once all polyps have been removed, patients should undergo surveillance colonoscopy at 3–5-year intervals, as new polyps develop in 50% of patients. Patients over 75 years of age do not require repeated colonoscopies, as their subsequent lifetime cancer risk is low.

Between 10 and 20% of polyps show histological evidence of malignancy. When cancer cells are found within 2 mm of the resection margin of the polyp, when the polyp cancer is poorly differentiated or when lymphatic invasion is present, segmental colonic resection is recommended because residual tumour or lymphatic spread (in up to 10%) may be present. Malignant polyps without these features can be followed up by surveillance colonoscopy.

Polyposis syndromes are classified by histopathology (Box 22.88). It should be noted that, while the hamarto-

22.87 Risk factors for malignant change in colonic polyps

matous polyps in Peutz–Jeghers syndrome and juvenile polyposis are not themselves neoplastic, these disorders are associated with an increased risk of certain malignancies, e.g. breast, colon, ovary and thyroid.

Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is an uncommon autosomal dominant disorder affecting 1 in 13 000 of the population and accounting for 1% of all colorectal cancer. It results from germline mutation of the tumour suppressor *APC* gene followed by acquired mutation of the remaining allele (Ch. 3). *APC* is a large gene and over 1400 different mutations have been reported, but most result in a truncated *APC* protein. This protein has many functions in the regulation of colonic epithelial turnover. It normally binds to and sequesters β -catenin and is unable to do so when mutated, allowing β -catenin to translocate to the nucleus where it upregulates the expression of many genes.

Around 20% of cases arise as new mutations and have no family history. Hundreds to thousands of adeno-

matous colonic polyps will develop in 80% of patients by age 15 (Fig. 22.60), with symptoms such as rectal bleeding beginning a few years later. In those affected, cancer will develop within 10–15 years of the appearance of adenomas and 90% of patients will develop colorectal cancer by the age of 50 years. Despite surveillance, approximately 1 in 4 patients with FAP has cancer by the time they undergo colectomy.

Recently, a second gene involved in base excision repair (MutY homolog, *MYH*) has been identified which may give rise to colonic polyposis. *MYH* displays autosomal recessive inheritance and leads to tens to hundreds of polyps and a tendency to proximal colon cancer. This variant is referred to as *MYH*-associated polyposis (MAP).

Non-neoplastic cystic fundic gland polyps occur in the stomach but adenomatous polyps also occur uncommonly. Duodenal adenomas occur in over 90% and are most common around the ampulla of Vater. Malignant transformation to adenocarcinoma occurs in 10% and is the leading cause of death in those who have had

Fig. 22.60 Familial adenomatous polyposis. There are hundreds of adenomatous polyps throughout the colon.

prophylactic colectomy. Many extraintestinal features are also seen in FAP and these are summarised in Box 22.89.

Desmoid tumours occur in up to one-third of patients and usually arise in the mesentery or abdominal wall. Although benign, they may become very large, causing compression of adjacent organs, intestinal obstruction or vascular compromise, and are difficult to remove. They sometimes respond to hormonal therapy with tamoxifen, and the NSAID sulindac may lead to regression in some, by unknown mechanisms. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in some and is seen as dark, round, pigmented retinal lesions. When present in an at-risk individual, they are 100% predictive of the presence of FAP. A variant, Turcot's syndrome, is characterised by FAP with primary central nervous system tumours (astrocytoma or medulloblastoma).

Early identification of affected individuals before symptoms develop is essential. The diagnosis can be excluded if sigmoidoscopy is normal. In newly diagnosed cases with new mutations, genetic testing confirms the diagnosis, and all first-degree relatives should also undergo testing (p. 57). In families with known FAP, at-risk family members should undergo direct mutation testing at 13–14 years of age. This is less invasive than regular sigmoidoscopy, which is reserved for those known to have the mutation. Affected individuals should undergo colectomy after school or college education has been completed. The operation of choice is total proctocolectomy with ileal pouch–anal anastomosis. Periodic upper gastrointestinal endoscopy is recommended to detect duodenal adenomas.

22.89 Extraintestinal features of familial adenomatous polyposis

- Congenital hypertrophy of the retinal pigment epithelium (CHRPE, 70–80%)
- Epidermoid cysts (extremities, face, scalp)* (50%)
- Benign osteomas, especially skull and angle of mandible* (50–90%)
- Dental abnormalities (15–25%)*
- Desmoid tumours (10–15%)
- Other malignancies (brain, thyroid, liver, 1–3%)

*Gardner's syndrome.

Peutz–Jeghers syndrome

This is characterised by multiple hamartomatous polyps in the small intestine and colon, as well as melanin pigmentation of the lips, mouth and digits (Fig. 22.61). Most cases are asymptomatic, although chronic bleeding, anaemia or intussusception can be seen. There is a significant risk of small bowel or colonic adenocarcinoma and of cancer of the pancreas, lung, ovary, breast and endometrium. It is an autosomal dominantly inherited disorder most commonly resulting from truncating mutations in a serine-threonine kinase gene on chromosome 19p (*STK11-LKB1*).

Diagnosis requires two of the following:

- small bowel polyposis
- mucocutaneous pigmentation
- a family history suggesting autosomal dominant inheritance.

Genetic testing is also available but may be inconclusive since mutants in genes other than *STK11-LKB1* can cause the disorder. Affected people should undergo regular upper endoscopy, colonoscopy, and small bowel and pancreatic imaging. Polyps > 1 cm in size should be removed. Testicular examination is essential for men while women should undergo pelvic examination, cervical smears and regular mammography. Asymptomatic relatives of affected patients should also undergo screening.

Fig. 22.61 Peutz–Jeghers syndrome. Typical lip pigmentation.

Juvenile polyposis (JPS)

In this condition, tens to hundreds of mucus-filled hamartomatous polyps are found in the colorectum. One-third of cases are inherited in an autosomal dominant manner and up to 20% of patients develop colorectal cancer before the age of 40. The criteria for diagnosis are:

- 10 or more colonic juvenile polyps
- juvenile polyps elsewhere in the gut, or
- any number of polyps in those with a family history.

Germline mutations in the tumour suppressor gene *SMAD4* are often found, as are *PTEN* mutations. Colonoscopy with polypectomy should be performed every 1–3 years and colectomy considered for extensive involvement.

Colorectal cancer

Although relatively rare in the developing world, colorectal cancer is the second most common internal malignancy and the second leading cause of cancer deaths in Western countries. In the UK the incidence is 50–60 per 100 000, equating to 30 000 cases per year. The condition becomes increasingly common over the age of 50.

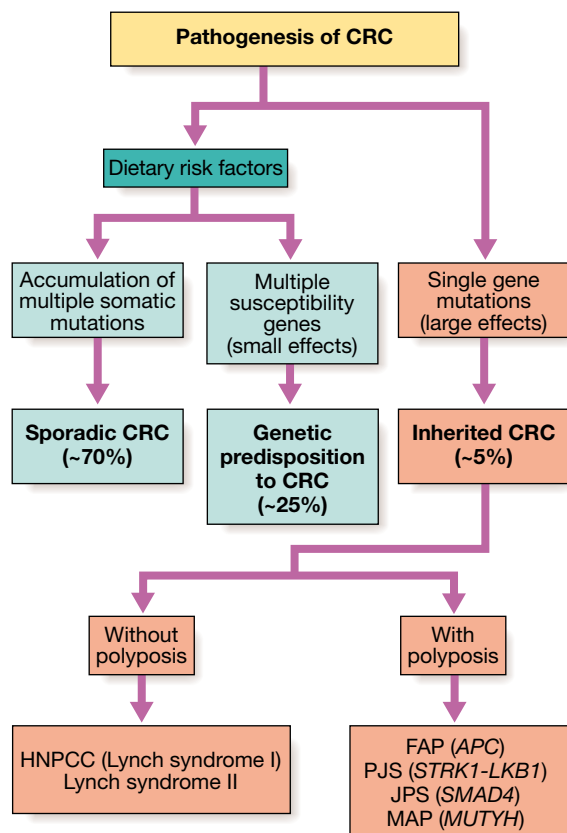

Fig. 22.62 Pathogenesis of colorectal cancer (CRC). (FAP = familial adenomatous polyposis; HNPCC = hereditary non-polyposis colon cancer); JPS = juvenile polyposis syndrome; MAP = *MUTYH*-associated polyposis; PJS = Peutz-Jeghers syndrome

Pathophysiology

Both environmental and genetic factors are important in colorectal carcinogenesis (Fig. 22.62).

Environmental factors probably account for 70% of all 'sporadic' colorectal cancers. This figure is based on the

22.90 Dietary risk factors for colorectal cancer development

Risk factor	Comments
Increased risk	
Red meat*	High saturated fat and protein content. Carcinogenic amines formed during cooking
Saturated animal fat*	High faecal bile acid and fatty acid levels. May affect colonic prostaglandin turnover
Decreased risk	
Dietary fibre*	Effects vary with fibre type; shortened transit time, binding of bile acids and effects on bacterial flora proposed
Fruit and vegetables	Green vegetables contain anticarcinogens, such as glucosinolates and flavonoids. Little evidence for protection from vitamins A, C, E
Calcium	Binds and precipitates faecal bile acids
Folic acid	Reverses DNA hypomethylation
Omega-3 fatty acids	May be of modest benefit; trials awaited

*Evidence is inconsistent and a clear relationship is unproven.

22.91 Non-dietary risk factors in colorectal cancer

Medical conditions

- Colorectal adenomas (p. 907)
- Long-standing extensive ulcerative colitis or Crohn's colitis (p. 895), especially if associated with primary sclerosing cholangitis (PSC)
- Ureterosigmoidostomy
- Acromegaly
- Pelvic radiotherapy

Others

- Obesity and sedentary lifestyle—may be related to dietary factors
- Smoking (relative risk 1.5–3.0)
- Alcohol (weak association)
- Cholecystectomy (effect of bile acids in right colon)
- Type 2 diabetes (hyperinsulinaemia)
- Use of aspirin or NSAIDs (COX-2 inhibition) and perhaps statins associated with *reduced* risk

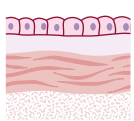

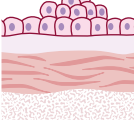

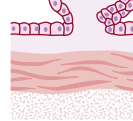

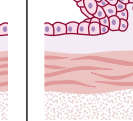

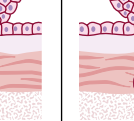

wide geographic variation in incidence and the decrease in risk seen in migrants who move from high- to low-risk countries. Dietary factors are believed to be most important and these are summarised in Box 22.90; other recognised risk factors are listed in Box 22.91.

Colorectal cancer development results from the accumulation of multiple genetic mutations arising from two major pathways: chromosomal instability and microsatellite instability (Fig. 22.63).

- **Chromosomal instability.** This involves mutations or deletions of portions of chromosomes with loss of heterozygosity (LOH) and inactivation of specific tumour suppressor genes. In LOH, one allele of a gene is deleted but gene inactivation only occurs when a subsequent unrelated mutation affects the other allele.
- **Microsatellite instability.** This involves germline mutations in one of six genes encoding enzymes involved in repairing errors that occur normally during DNA replication (DNA mismatch repair); these genes are designated *hMSH2*, *hMSH6*, *hMLH1*, *hMLH3*, *hPMS1* and *hPMS2*. Replication errors accumulate and can be detected in 'microsatellites' of repetitive DNA sequences. Replication errors also occur in important regulatory genes, resulting in a genetically unstable phenotype and accumulation of multiple somatic mutations throughout the genome that eventually lead to cancer formation. A minority of sporadic cancers develop this way, as do almost all cases of HNPCC.

HNPCC accounts for 5–10% of cancers; it occurs in those with a family history and often at a young age. Pedigrees of HNPCC families indicate an autosomal dominant pattern of inheritance. The criteria necessary for diagnosing this condition are given in Box 22.92. The lifetime risk of colorectal cancer in affected individuals is 80%. The mean age of cancer development is 45 years, and in contrast to sporadic colon cancer two-thirds of tumours occur proximally. In a subset of patients, there is also an increased incidence of cancers of the endometrium, ovary, urinary tract, stomach, pancreas, small intestine and central nervous system, related to inheritance of different mismatch repair gene mutations.

Those who fulfil the criteria for diagnosis should be referred for pedigree assessment, genetic testing and

Normal	Early adenoma	Intermediate adenoma	Late adenoma	Carcinoma
				
Key gene	APC (adenomatous polyposis coli)	K-ras	DCC (SMAD4) (deleted in colon cancer)	p53
Chromosome	5q	12p	18q	17p
Normal function	'Gatekeeper'	Transmembrane GTP-binding protein mediating mitogenic signals (p21)	Multiple: role in apoptosis, tumour suppressor gene; TGF signalling	Upregulated during cell damage to arrest cell cycle and allow DNA repair or apoptosis to occur
Alteration	Truncating mutations	Gain in function mutations	Allelic deletion	Allelic deletion; gain in function mutations
Effect	Progression to early adenoma development	Cell proliferation	? Role in invasion and metastasis	Cell proliferation; impaired apoptosis

Further mutations

- Anchorage independence
- Protease synthesis
- Telomerase synthesis
- Multidrug resistance
- Evasion of immune system

Fig. 22.63 The multistep origin of cancer: molecular events implicated in colorectal carcinogenesis. (GTP = guanine triphosphate)

i	<p>22.92 Criteria for the diagnosis of hereditary non-polyposis colon cancer ('modified Amsterdam II criteria')*</p> <ul style="list-style-type: none"> • Three or more relatives with colon cancer (at least one first-degree) • Colorectal cancer in two or more generations • At least one member affected under 50 years of age • FAP excluded <p><small>*These criteria are strict and may miss some families with mutations. HNPCC should also be considered in individuals with colorectal or endometrial cancer under 45 years of age.</small></p>
----------	---

colonoscopy. These should begin around 25 years of age or 5–10 years earlier than the youngest case of cancer in the family. Colonoscopy needs to be repeated every 1–2 years, but even then, interval cancers can still occur.

A further 20% of patients who do not have HNPCC still have a family history of colorectal cancer. The lifetime risk of developing cancer with one or two affected first-degree relatives is 1 in 12 and 1 in 6, respectively. The risk is even higher if relatives were affected at an early age. The genes mediating this increased risk are unknown. Most tumours arise from malignant transformation of a benign adenomatous polyp. Over 65% occur in the rectosigmoid and a further 15% recur in the caecum or ascending colon. Synchronous tumours are present in 2–5% of patients. Macroscopically, the majority of cancers are either polypoid and 'fungating', or annular and constricting. Spread occurs through the bowel wall. Rectal cancers may invade the pelvic viscera and side walls. Lymphatic invasion is common at presentation, as is spread through both portal and systemic circulations to reach the liver and, less commonly, the lungs. Tumour stage at diagnosis is the most important determinant of prognosis (see Fig. 22.65, p. 912).

Clinical features

Symptoms vary depending on the site of the carcinoma. In tumours of the left colon, fresh rectal bleeding is common and obstruction occurs early. Tumours of the right colon present with anaemia from occult bleeding or with altered bowel habit, but obstruction is a late feature. Colicky lower abdominal pain is present in two-thirds of patients and rectal bleeding occurs in 50%. A minority present with features of either obstruction or perforation, leading to peritonitis, localised abscess or fistula formation. Carcinoma of the rectum usually causes early bleeding, mucus discharge or a feeling of incomplete emptying. Between 10 and 20% of patients present with iron deficiency anaemia or weight loss. On examination there may be a palpable mass, signs of anaemia or hepatomegaly from metastases. Low rectal tumours may be palpable on digital examination.

Investigations

Colonoscopy (Fig. 22.64) is the investigation of choice because it is more sensitive and specific than barium enema. Furthermore, lesions can be biopsied and polyps removed. Rigid sigmoidoscopy will detect less than one-third of tumours. Endoanal ultrasound or pelvic MRI stages rectal cancers accurately. CT colonography ('virtual colonoscopy') is a sensitive non-invasive technique for diagnosing tumours and polyps greater than 1 cm that can be used if colonoscopy is incomplete or high-risk. CT is valuable for detecting hepatic metastases, although intraoperative ultrasound is increasingly being used for this purpose. A proportion of patients have raised serum carcinoembryonic antigen (CEA) concentrations but this is variable and so of little use in diagnosis. Measurements of CEA are valuable, however, during follow-up and can help to detect early recurrence.

Fig. 22.64 Colonoscopic view of a polypoid rectal carcinoma undergoing laser therapy (arrow) in a patient unfit for surgery.

Management

Surgery

The tumour is removed, along with adequate resection margins and pericolic lymph nodes. Continuity is restored by direct anastomosis wherever possible. Carcinomas within 2 cm of the anal verge may require abdominoperineal resection and formation of a colostomy. All patients should be counselled pre-operatively about the possible need for a stoma. Total mesorectal excision (TME) reduces recurrence rates and increases survival in rectal cancer. Solitary hepatic or lung metastases are sometimes resected at a later stage. Post-operatively, patients should undergo colonoscopy after 6–12 months and periodically thereafter to search for local recurrence or development of new 'metachronous' lesions, which occur in 6% of cases.

Adjuvant therapy

Two-thirds of patients have lymph node or distant spread (Dukes stage C, Fig. 22.65) at presentation and are, therefore, beyond cure with surgery alone. Most recurrences are within 3 years of diagnosis. Colonic cancers recur locally at the site of resection, in lymph

nodes, liver and peritoneum. Adjuvant chemotherapy with 5-fluorouracil and folinic acid (to reduce toxicity) for 6 months improves both disease-free and overall survival in patients with Dukes C colon cancer by around 4–13%. Pre-operative radiotherapy can be given to patients with large, fixed rectal cancers to 'down-stage' the tumour, making it resectable and reducing local recurrence. Dukes C and some Dukes B rectal cancers are given post-operative radiotherapy to reduce the risk of local recurrence if operative resection margins are involved. In some countries, patients with metastatic disease are treated with monoclonal antibodies using bevacizumab or cetuximab either alone or with chemotherapeutic agents such as irinotecan.

Chemotherapy

Surgical resection of the primary tumour is appropriate for some patients with metastases to treat obstruction, bleeding or pain. Palliative chemotherapy with 5-fluorouracil and folinic acid improves survival, and second-line therapy with irinotecan is used when this fails. Pelvic radiotherapy is sometimes useful for distressing rectal symptoms such as pain, bleeding or severe tenesmus. Endoscopic laser therapy or insertion of an expandable metal stent can be used to relieve obstruction.

Prevention and screening

Secondary prevention aims to detect and remove lesions at an early or pre-malignant stage. Several potential methods exist:

- Widespread screening by regular *faecal occult blood (FOB) testing* reduces colorectal cancer mortality (Box 22.93) and increases the proportion of early cancers detected. These tests currently lack sensitivity and specificity and need to be improved. FOB screening is recommended after the age of 50 years.
- *Colonoscopy* remains the gold standard but is expensive and carries risks; many countries lack the resources to offer this form of screening.
- *Flexible sigmoidoscopy* is an alternative option and has been shown to reduce overall colorectal cancer mortality by approximately 35% (70% for cases arising in the rectosigmoid). It is recommended in the USA every 5 years in all persons over the age of 50.

Fig. 22.65 Staging and survival in colorectal cancer. (Modified Dukes classification. *Dukes' original staging only had stages A–C.)

EBM 22.93 Faecal occult blood (FOB) testing and colon cancer mortality

'Combined results from four randomised controlled trials show that participants allocated to screening by FOB testing had a 16% reduction in the relative risk of colorectal cancer mortality (RR 0.84, CI: 0.78–0.90). When adjusted for screening attendance, there was a 25% relative risk reduction (RR 0.75, CI: 0.66–0.84) for those attending at least one round of FOB screening.'

• (Cochrane Review). Cochrane Library, issue 4, 2006. Oxford: Update Software.

For further information:  www.cochrane.org/reviews

- Screening for high-risk patients by *molecular genetic analysis* is an exciting prospect but is not yet available.

Diverticulosis

Diverticula are acquired and are most common in the sigmoid and descending colon of middle-aged people. Asymptomatic diverticula (diverticulosis) are present in over 50% of people above the age of 70. Symptomatic diverticular disease supervenes in 10–25% of cases while complicated diverticulosis (acute diverticulitis, pericolic abscess, bleeding, perforation or stricture) is uncommon.

Pathophysiology

A life-long refined diet with a relative deficiency of fibre is widely thought to be responsible and the condition is rare in populations with a high dietary fibre intake, such as in Asia, where it more often affects the right side of the colon. It is postulated that small-volume stools require high intracolonic pressures for propulsion and this leads to herniation of mucosa between the taeniae coli (Fig. 22.66). Diverticula consist of protrusions of

Fig. 22.66 The human colon in diverticulosis. The colonic wall is weak between the taeniae. The blood vessels that supply the colon pierce the circular muscle and weaken it further by forming tunnels. Diverticula usually emerge through these points of least resistance.

mucosa covered by peritoneum. There is commonly hypertrophy of the circular muscle coat. Inflammation is thought to result from impaction of diverticula with faecoliths. This may resolve spontaneously or progress to cause haemorrhage, perforation, local abscess formation, fistula and peritonitis. Repeated attacks of inflammation lead to thickening of the bowel wall, narrowing of the lumen and eventual obstruction.

Clinical features

Symptoms are usually the result of associated constipation or spasm. Colicky pain is usually suprapubic or felt in the left iliac fossa. The sigmoid colon may be palpable and, in attacks of diverticulitis, there is local tenderness, guarding, rigidity ('left-sided appendicitis') and sometimes a palpable mass. During these episodes there may also be diarrhoea, rectal bleeding or fever. The differential diagnosis includes colorectal cancer, ischaemic colitis, inflammatory bowel disease and infection. Diverticular disease is complicated by perforation, pericolic abscess, fistula formation (usually colovesical) and acute rectal bleeding. These complications are more common in patients who take NSAIDs or aspirin. After one attack of diverticulitis, the recurrence rate is around 3% per year. Over 10–30 years, perforation, obstruction or bleeding will each affect around 5% of patients.

Investigations

These are usually performed to exclude colorectal neoplasia. Barium enema confirms the presence of diverticula (see Fig. 22.11C, p. 845). Strictures and fistulas may also be seen. Flexible sigmoidoscopy is performed to exclude a coexisting neoplasm which is easily missed radiologically. Colonoscopy requires expertise and carries a risk of perforation. CT is used to assess complications.

Management

Diverticulosis which is asymptomatic and discovered coincidentally requires no treatment. Constipation can be relieved by a high-fibre diet with or without a bulking laxative (ispaghula husk, 1–2 sachets daily) taken with plenty of fluids. Stimulants should be avoided. Antispasmodics may sometimes help. An acute attack of diverticulitis requires 7 days of metronidazole (400 mg 8-hourly orally), along with either a cephalosporin or ampicillin (500 mg 6-hourly orally). Severe cases require intravenous fluids, intravenous antibiotics, analgesia and nasogastric suction, but randomised trials show no benefit from acute resection compared to conservative management, and emergency surgery is reserved for severe haemorrhage or perforation. Percutaneous drainage of acute paracolic abscesses can be effective and avoids the need for emergency surgery. Elective surgery is performed in patients after recovery from repeated acute attacks of obstruction, and resection of the affected segment with primary anastomosis is the procedure of choice.

Constipation and disorders of defecation

The clinical approach to patients with constipation and its aetiology have been described on page 859.

Simple constipation

This is extremely common and does not imply underlying organic disease. It usually responds to increased dietary fibre or the use of bulking agents; an adequate fluid intake is also essential. Many types of laxative are available, and these are listed in Box 22.94.

Severe idiopathic constipation

This occurs almost exclusively in young women and often begins in childhood or adolescence. The cause is unknown but some have 'slow transit' with reduced motor activity in the colon. Others have 'obstructed defecation' resulting from inappropriate contraction of the external anal sphincter and puborectalis muscle (anismus). The condition is often resistant to treatment. Bulking agents may exacerbate symptoms but prokinetic agents or balanced solutions of polyethylene glycol '3350' benefit some patients with slow transit. Glycerol suppositories and biofeedback techniques are used for those with obstructed defecation. Rarely, subtotal colectomy is necessary as a last resort.

Faecal impaction

In faecal impaction a large, hard mass of stool fills the rectum. This tends to occur in disabled, immobile or institutionalised patients, especially the frail elderly or those with dementia. Constipating drugs, autonomic neuropathy and painful anal conditions also contribute. Megacolon, intestinal obstruction and urinary tract infections may supervene. Perforation and bleeding from pressure-induced ulceration are occasionally seen. Treatment involves adequate hydration and careful digital disimpaction after softening the impacted stool with arachis oil enemas. Stimulants should be avoided.

Melanosis coli and laxative misuse syndromes

Long-term consumption of stimulant laxatives leads to accumulation of lipofuscin pigment in macrophages in the lamina propria. This imparts a brown discoloration to the colonic mucosa, often described as resembling 'tiger

22.95 Constipation in old age

- **Evaluation:** particular attention should be paid to immobility, dietary fluid and fibre intake, drugs and depression.
- **Immobility:** predisposes to constipation by increasing the colonic transit time; the longer this is, the greater the fluid absorption and the harder the stool.
- **Bulking agents:** can make matters worse in patients with slow transit times and should be avoided.
- **Overflow diarrhoea:** if faecal impaction develops, paradoxical overflow diarrhoea may occur. If antidiarrhoeal agents are given, the underlying impaction may worsen and result in serious complications such as stercoral ulceration and bleeding.

skin'. The condition is benign and resolves when the laxatives are stopped. Prolonged laxative use may rarely result in megacolon or 'cathartic colon', in which barium enema demonstrates a featureless mucosa, loss of haustra and shortening of the bowel. Surreptitious laxative misuse is a psychiatric condition seen in young women, some of whom have a history of bulimia or anorexia nervosa (pp. 249–250). They complain of refractory watery diarrhoea. Laxative use is usually denied and may continue even when patients are undergoing investigation. Screening of urine for laxatives may reveal the diagnosis.

Hirschsprung's disease

This disease is characterised by constipation and colonic dilatation (megacolon) due to congenital absence of ganglion cells in the large intestine. The incidence is 1:5000 and a family history is present in one-third of cases. The main gene contributing to susceptibility is the *RET* gene, but often other genetic mutations need to be present for the disease to occur. These genes are implicated in the regulation of enteric neurogenesis, and the mutations cause failure of migration of neuroblasts into the gut wall during embryogenesis. Ganglion cells are absent from nerve plexuses, most commonly in a short segment of the rectum and/or sigmoid colon. As a result, the internal anal sphincter fails to relax. Constipation, abdominal distension and vomiting usually develop immediately after birth but a few cases do not present until childhood or adolescence. The rectum is empty on digital examination.

Barium enema shows a small rectum and colonic dilatation above the narrowed segment. Full-thickness biopsies are required to demonstrate nerve plexuses and confirm the absence of ganglion cells. Histochemical stains for acetylcholinesterase are also used. Anorectal manometry demonstrates failure of the rectum to relax with balloon distension. Treatment involves resection of the affected segment.

Acquired megacolon

This may develop in childhood as a result of voluntary withholding of stool during toilet training. In such cases it presents after the first year of life and is distinguished from Hirschsprung's disease by the urge to defecate and the presence of stool in the rectum. It usually responds to osmotic laxatives.

In adults, acquired megacolon has several causes. It is seen in depressed or demented patients, either as part of

22.94 Laxatives

Class	Examples
Bulk-forming	Ispaghula husk Methylcellulose
Stimulants	Bisacodyl Dantrol (only for terminally ill patients) Docusate Senna
Faecal softeners	Docusate Arachis oil enema
Osmotic laxatives	Lactulose Lactitol Magnesium salts
Others	Polyethylene glycol (PEG)* Phosphate enema*

*Used mainly for bowel preparation prior to investigation or surgery.

the condition or as a side-effect of antidepressant drugs. Prolonged misuse of stimulant laxatives may cause degeneration of the myenteric plexus, while interruption of sensory or motor innervation may be responsible in a number of neurological disorders. Scleroderma and hypothyroidism are other recognised causes.

Most patients can be managed conservatively by treatment of the underlying cause, high-residue diets, laxatives and the judicious use of enemas. Prokinetics are helpful in a minority of patients. Subtotal colectomy is a last resort for the most severely affected patients.

Acute colonic pseudo-obstruction (Ogilvie's syndrome)

This condition has many causes (Box 22.96) and is characterised by relatively sudden onset of painless, massive enlargement of the proximal colon accompanied by distension; there are no features of mechanical obstruction. Bowel sounds are normal or high-pitched rather than absent. Left untreated, it may progress to perforation, peritonitis and death.

Plain abdominal X-rays show colonic dilatation with air extending to the rectum. A caecal diameter greater than 10–12 cm is associated with a high risk of perforation. Single-contrast or water-soluble barium enemas demonstrate the absence of mechanical obstruction.

Management consists of treating the underlying disorder and correcting any biochemical abnormalities. The anticholinesterase, neostigmine, is often effective in enhancing parasympathetic activity and gut motility. Decompression either with a rectal tube or by careful colonoscopy may be effective but needs to be repeated until the condition resolves. In severe cases, surgical or fluoroscopic defunctioning caecostomy is necessary.

22.96 Causes of acute colonic pseudo-obstruction

- Trauma, burns
- Recent surgery
- Drugs, e.g. opiates, phenothiazines
- Respiratory failure
- Electrolyte and acid–base disorders
- Diabetes mellitus
- Uraemia

Colonic infections

These are discussed on pages 302–305.

Anorectal disorders

Faecal incontinence

The normal control of anal continence is described on page 842. Common causes of incontinence are listed in Box 22.97.

Patients are often embarrassed to admit incontinence and may complain only of 'diarrhoea'. A careful history and examination, especially of the anorectum and perineum, may help to establish the underlying cause. Endoanal ultrasound is valuable for defining the integrity of the anal sphincters, while anorectal manometry and electrophysiology are also useful investigations if available.

22.97 Causes of faecal incontinence

- Obstetric trauma: childbirth, hysterectomy
- Severe diarrhoea
- Faecal impaction
- Congenital anorectal anomalies
- Anorectal disease: haemorrhoids, rectal prolapse, Crohn's disease
- Neurological disorders: spinal cord or cauda equina lesions, dementia

Management

This is often very difficult. Underlying disorders should be treated and diarrhoea managed with loperamide, diphenoxylate or codeine phosphate. Pelvic floor exercises and biofeedback techniques help some patients, and those with confirmed anal sphincter defects may benefit from sphincter repair operations.

Haemorrhoids ('piles')

Haemorrhoids arise from congestion of the internal and/or external venous plexuses around the anal canal (Fig. 22.67). They are extremely common in adults. The aetiology is unknown, although they are associated with constipation and straining and may develop for the first time during pregnancy. First-degree piles bleed, while second-degree piles prolapse but retract spontaneously. Third-degree piles are those which require manual replacement after prolapsing. Bright red rectal bleeding occurs after defecation. Other symptoms include pain, pruritus ani and mucus discharge. Treatment involves measures to prevent constipation and straining. Injection sclerotherapy or band ligation is effective for most, but a minority of patients require haemorrhoidectomy, which is usually curative.

Pruritus ani

This is common and can stem from many causes (Box 22.98), most of which result in contamination of the perianal skin with faecal contents.

Fig. 22.67 Internal haemorrhoids seen as bluish cushions of prominent veins at sigmoidoscopy.

22.98 Causes of pruritus ani

Local anorectal conditions

- Haemorrhoids
- Poor hygiene
- Fistula, fissures

Infections

- Threadworms
- Candidiasis

Skin disorders

- Contact dermatitis
- Lichen planus
- Psoriasis

Other

- Diarrhoea or incontinence of any cause
- Anxiety
- Irritable bowel syndrome

Itching may be trivial or severe, and results in an itch-scratch-itch cycle which exacerbates the problem. When no underlying cause is found, all local barrier ointments and creams must be stopped. Good personal hygiene is essential, with careful washing after defecation. The perineal area must be kept dry and clean. Bulk-forming laxatives may reduce faecal soiling.

Solitary rectal ulcer syndrome

This is most common in young adults and occurs on the anterior rectal wall. It is thought to result from localised chronic trauma and/or ischaemia associated with disordered puborectalis function and mucosal prolapse. The ulcer is seen at sigmoidoscopy and biopsies show a characteristic accumulation of collagen.

Symptoms include minor bleeding and mucus per rectum, tenesmus and perineal pain. Treatment is often difficult but avoidance of straining at defecation is important and treatment of constipation may help. Marked mucosal prolapse is treated surgically.

Anal fissure

In this common problem traumatic or ischaemic damage to the anal mucosa results in a superficial mucosal tear, most commonly in the midline posteriorly. Spasm of the internal anal sphincter exacerbates the condition. Severe pain occurs on defecation and there may be minor bleeding, mucus discharge and pruritus. The skin may be indurated and an oedematous skin tag, or 'sentinel pile', adjacent to the fissure is common.

Avoidance of constipation with bulk-forming laxatives and increased fluid intake is important. Relaxation of the internal sphincter is normally mediated by nitric oxide, and 0.2% glyceryl trinitrate or diltiazem ointment, which donates nitric oxide and improves mucosal blood flow, is effective in 60–80% of patients. Resistant cases may respond to injection of botulinum toxin into the internal anal sphincter to induce sphincter relaxation. Manual dilatation under anaesthesia leads to long-term incontinence and should not be considered. The majority of cases can now be treated without surgery, but where these measures fail, healing can usually be achieved surgically by lateral internal anal sphincterotomy or advancement anoplasty.

Anorectal abscesses and fistulas

Perianal abscesses develop between the internal and external anal sphincters and may point at the perianal skin. Ischiorectal abscesses occur lateral to the sphincters in the ischiorectal fossa. They usually result from infection of anal glands by normal intestinal bacteria. Crohn's disease (p. 895) is sometimes responsible.

Patients complain of extreme perianal pain, fever and/or discharge of pus. Spontaneous rupture may also lead to the development of fistulas. These may be superficial or may track through the anal sphincters to reach the rectum. Abscesses are drained surgically and superficial fistulas are laid open with care to avoid sphincter damage.

Diseases of the peritoneal cavity

Peritonitis

Surgical peritonitis occurs as the result of a ruptured viscus (see surgical textbooks). Peritonitis may also complicate ascites (spontaneous bacterial peritonitis) or may occur in children in the absence of ascites, due to infection with pneumococci or β -haemolytic streptococci.

Chlamydial peritonitis is a complication of pelvic inflammatory disease. The affected woman presents with right upper quadrant abdominal pain, pyrexia and a hepatic rub (the Fitz-Hugh-Curtis syndrome). Tuberculosis may cause peritonitis and ascites.

Tumours

The most common is secondary adenocarcinoma from the ovary or gastrointestinal tract. Mesothelioma is a rare tumour complicating asbestos exposure. It presents as a diffuse abdominal mass, due to omental infiltration, and with ascites. The prognosis is extremely poor.

Other disorders

Endometriosis

Ectopic endometrial tissue can become embedded on the serosal aspect of the intestine, most frequently in the sigmoid and rectum. The overlying mucosa is usually intact. Cyclical engorgement and inflammation result in pain, bleeding, diarrhoea, constipation, and adhesions or obstruction. Low backache is frequent. The onset is usually between 20 and 45 years and is more common in nulliparous women. Bimanual examination may reveal tender nodules in the pouch of Douglas. Endoscopic studies only reveal the diagnosis if carried out during menstruation, when a bluish mass with intact overlying mucosa is apparent. In some patients laparoscopy is required. Treatment options include laparoscopic diathermy and hormonal therapy with progestogens (e.g. norethisterone), gonadotrophin-releasing hormone analogues or danazol.

Pneumatosis cystoides intestinalis

In this rare condition multiple gas-filled submucosal cysts line the colonic and small bowel walls. The cause is unknown, but the condition may be seen in patients with chronic cardiac or pulmonary disease, pyloric obstruction, scleroderma or dermatomyositis. Most patients are asymptomatic, although there may be abdominal

cramp, diarrhoea, tenesmus, rectal bleeding and mucus discharge. The cysts are recognised on sigmoidoscopy, plain abdominal X-rays or barium enema. Fasting breath hydrogen levels are elevated and fall with treatment. Therapies reported to be effective include prolonged high-flow oxygen, elemental diets and antibiotics.

History and significance of abdominal signs

1 Flapping tremor

Jerky forward movements every 2–3 minutes when arms are outstretched and hands are dorsiflexed suggest hepatic encephalopathy.

5 Assessment of liver size

- Start in the right iliac fossa.
- Progress up the abdomen 2 cm with each breath (through open mouth).
- Confirm the lower border of the liver by percussion.
- Detect if smooth or irregular, tender or non-tender; ascertain shape.
- Identify the upper border by percussion.
- Clinical assessment of hepatomegaly important in diagnosing liver disease

Liver size

Large liver (hepatomegaly)

- Liver metastases
- Multiple or large hepatic cysts
- Cirrhosis
 - Alcohol
 - Haemochromatosis
- Hepatic vein outflow obstruction
- Infiltration
 - Amyloid

Small liver

- Cirrhosis

Ascites

Causes	Associated clinical findings
Exudative (high protein)*	
Carcinoma	Weight loss ± hepatomegaly
Tuberculosis	Weight loss + fever
Transudative (low protein)	
Cirrhosis	Hepatomegaly Splenomegaly Spider naevi
Renal failure (including nephrotic syndrome)	Generalised oedema
Congestive heart failure	Peripheral oedema Elevated jugular venous pulse (JVP)

*See ascites (p. 936)

Kayser–Fleischer rings in Wilson's disease.

Key history points

Symptoms*

- Itching preceding jaundice
- Abdominal pain (suggests stones)
- Weight loss (chronic liver disease and malignancy)
- Dark urine and pale stools
- Fever ± rigors
- Dry eyes/dry mouth
- Fatigue

Recent drug history

Other

- Exposure to intravenous drug or blood transfusions
- Travel history and country of birth
- Family history of liver disease
- Autoimmune disease history
- Alcohol history
- Inflammatory bowel disease
- Metabolic syndrome (increased body mass index ± type 2 diabetes/hypertension)

*Symptoms may be absent and abnormal liver function tests detected incidentally.

The liver is the largest organ in the body. It plays a central role in digestion and in the regulation of protein, carbohydrate and lipid metabolism, and is responsible for the metabolism of drugs and environmental toxins. In view of this, it is not surprising that diseases of the liver are a major cause of morbidity and mortality; worldwide, 1 in 40 deaths are due to liver disease or primary liver cell cancer. In developed countries, the most common cause of liver disease is alcohol abuse, although in keeping with the rise in obesity rates, the incidence of non-alcoholic fatty liver disease (NAFLD) is rapidly increasing. In the developing world, infections caused by hepatitis viruses, often complicated by hepatobiliary cancer, and those caused by parasites, are responsible for most chronic liver disease. In the UK, liver disease is responsible for about 5000 deaths per year and is the fifth most common cause of death. This figure has doubled over the last decade. About a quarter of liver disease in the UK is due to chronic viral hepatitis, and alcohol is responsible for 70% of deaths from cirrhosis.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Applied anatomy

Normal liver structure and blood supply

The liver is one of the heaviest organs in the body, weighing 1.2–1.5 kg. It is classically divided into left and right lobes by the falciform ligament, but a more useful functional division is into the right and left hemilivers, based on the hepatic blood supply (Fig. 23.1). The right and left hemilivers are further divided into a total of eight segments in accordance with subdivisions of the hepatic and portal veins. Each segment has its own branch of the hepatic artery and biliary tree, and this segmental classification is used clinically to describe the position of

Fig. 23.1 Liver blood supply.

liver tumours on radiological imaging. A liver segment is made up of multiple smaller units known as lobules, comprised of a central vein, radiating sinusoids separated from each other by single liver cell (hepatocyte) plates, and peripheral portal tracts. The functional unit of the liver is the hepatic acinus (Fig. 23.2).

Blood flows into the hepatic acinus via a single branch of the portal vein and hepatic artery situated centrally in the portal tracts. The blood flows outwards along the hepatic sinusoids into one of several tributaries of the hepatic vein at the periphery of the acinus. Bile flows in the opposite direction from the periphery of the acinus through channels termed cholangioles, which converge in interlobular bile ducts in the portal tracts. The hepatocytes in each acinus lie in three zones, depending on their position relative to the portal tract. The hepatocytes in zone 1 are closest to the terminal branches of the portal vein and hepatic artery, and are richly supplied with oxygenated blood, and blood containing the highest concentration of nutrients and toxins. Conversely, hepatocytes in zone 3 are furthest from the portal tracts and closest to the hepatic veins, and are therefore relatively hypoxic and exposed to lower concentrations of nutrients and toxins compared with the zone 1 hepatocytes.

Liver cells

Hepatocytes comprise 80% of liver cells and the remainder is made up of sinusoidal endothelial cells (10%), bile duct endothelial cells (1%) and cells of the immune system (9%). Endothelial cells line the hepatic sinusoids (Fig. 23.3), which constitute a network of capillary vessels that differ from other capillary beds in the body in that there is no basement membrane. The endothelial cells have gaps between them (fenestrae) of about 0.1 micron in diameter, allowing free flow of fluid and particulate matter to the hepatocytes.

Individual hepatocytes are separated from the leaky endothelial lining of the sinusoids by the space of Disse, which contains non-parenchymal cells called stellate (Ito) cells (see Fig. 23.3). Stellate cells store vitamin A and play an important part in regulating liver blood flow. They also have a role in causing hepatic fibrosis, since they differentiate into myofibroblasts in response to cytokines produced by Kupffer cells and hepatocytes following liver injury (Fig. 23.4).

Blood supply

The liver receives 80% of its blood supply via the hepatic artery and 20% via the portal vein, which drains blood from the gut via the splanchnic circulation. The normal portal venous pressure is 2–5 mmHg and is determined by the portal blood flow and portal vascular resistance. When portal venous pressure rises above 12 mm, portal hypertension is said to be present.

Biliary system and gallbladder

Hepatocytes provide the driving force for bile flow by creating osmotic gradients of bile acids, which form micelles in bile (bile acid-dependent bile flow), and of sodium (bile acid-independent bile flow). Bile is secreted by hepatocytes and flows from cholangioles to the biliary canaliculi in the portal tracts. The canaliculi join together to form larger intrahepatic bile ducts, which in turn merge to form the right and left hepatic ducts. These ducts join as they emerge from the liver to form

Fig. 23.2 Liver structure and microstructure. **A** Liver anatomy showing relationship with pancreas, bile duct and duodenum. **B** Hepatic lobule. **C** Hepatic acinus.

the common hepatic duct, which becomes the common bile duct after joining the cystic duct (see Fig. 23.2). The common bile duct is approximately 5 cm long and 4–6 mm wide. The distal portion of the duct passes through the head of the pancreas and usually joins the pancreatic duct before entering the duodenum through the sphincter of Oddi. Common bile duct pressure is maintained by rhythmic contraction and relaxation of the ampullary sphincter (sphincter of Oddi); this pressure exceeds gallbladder pressure in the fasting state, so that bile normally flows into the gallbladder, where it is concentrated tenfold by resorption of water and electrolytes.

The gallbladder is a pear-shaped sac lying under the right hemiliver, with its fundus located anteriorly behind the tip of the 9th costal cartilage. Its function is to concentrate and provide a reservoir for bile. Gallbladder tone is maintained by vagal activity, and cholecystokinin released from the duodenal mucosa during feeding causes gallbladder contraction and reduces sphincter pressure, so that bile flows into the duodenum. The body and neck of the gallbladder pass posteromedially towards the porta hepatis, and the cystic duct then joins it to the common hepatic duct. The cystic duct mucosa has prominent crescentic folds (valves of Heister), giving it a beaded appearance on cholangiography.

Fig. 23.3 Non-parenchymal liver cells. (NK= natural killer cells; PMN= polymorphonuclear leucocytes; B = B lymphocytes; T = T lymphocytes)

Hepatic function

Carbohydrate, amino acid and lipid metabolism

The liver plays a central role in carbohydrate, lipid and amino acid metabolism, and is involved in metabolising drugs and environmental toxins (Fig. 23.5).

- Amino acids from dietary proteins are used by hepatocytes for endogenous protein synthesis and for production of plasma proteins including albumin. The liver produces 8–14 g of albumin per day. Albumin plays a critical role in maintaining oncotic pressure in the vascular space and in the transport of small molecules like bilirubin, hormones and drugs throughout the body. Amino acids which are not required for the production of new proteins are broken down to urea. Production of urea and endogenous liver proteins is suppressed during fasting and hepatic amino acid release is reduced.

Fig. 23.4 Pathogenic mechanisms in hepatic fibrosis. Stellate cell activation occurs under the influence of cytokines released by other cell types in the liver, including hepatocytes, Kupffer cells (tissue macrophages), platelets and lymphocytes. Once stellate cells become activated, they can perpetuate their own activation by synthesis of transforming growth factor-beta (TGF- β_1) and platelet-derived growth factor (PDGF) through autocrine loops. Activated stellate cells produce TGF- β_1 , stimulating the production of collagen matrix as well as inhibitors of collagen breakdown. The inhibitors of collagen breakdown, matrix metalloproteinase 2 and 9 (MMP2 and MMP9), are inactivated in turn by tissue inhibitors TIMP1 and TIMP2, which are increased in fibrosis. Inflammation also contributes to fibrosis with the cytokine profile produced by Th2 lymphocytes, such as interleukin-6 and 13 (IL-6 and IL-13). Activated stellate cells also produce endothelin 1 (ET1), which may contribute to portal hypertension. (ROS = reactive oxygen species; IGF₁ = insulin-like growth factor 1; EGF = epidermal growth factor)

Fig. 23.5 Important liver functions.

- Following a meal, more than half of the glucose absorbed is taken up by the liver and stored as glycogen or converted to glycerol and fatty acids, thus preventing hyperglycaemia. During fasting, glycogen in the liver and that in other tissues, such as skeletal muscle, is broken down to release glucose (gluconeogenesis), thereby preventing hypoglycaemia (p. 798).
- The liver plays a central role in lipid metabolism, producing very low-density lipoproteins and further metabolising low- and high-density lipoproteins (p. 449).

Clotting factors

The liver plays a key role in the regulation of blood clotting by producing proteins that are involved in the coagulation cascade. Many of these coagulation factors (II, VII, IX and X) are post-translationally modified by vitamin K-dependent enzymes, and their synthesis is impaired in the presence of vitamin K deficiency (p. 993).

Bilirubin metabolism and bile

The liver plays a central role in the metabolism of bilirubin and is responsible for the production of bile (Fig. 23.6). Between 425 and 510 mmol (250–300 mg) of

Fig. 23.6 Pathway of bilirubin excretion.

unconjugated bilirubin is produced from the catabolism of haem every day. Bilirubin in the blood is normally almost all unconjugated and, because it is not water-soluble, is bound to albumin and does not pass into the urine. Unconjugated bilirubin is taken up by hepatocytes at the sinusoidal membrane, where it is conjugated in the endoplasmic reticulum by UDP-glucuronyl transferase, producing bilirubin mono- and diglucuronide. Impaired conjugation by this enzyme is a cause of inherited hyperbilirubinaemias (see Box 23.10, p. 932). These bilirubin conjugates are water-soluble and are exported into the bile canaliculus by specific carriers on the hepatocyte membrane. The conjugated bilirubin is excreted in the bile and passes into the bowel lumen.

Once in the bowel, conjugated bilirubin is metabolised by colonic bacteria to form stercobilinogen, which may be further oxidised to stercobilin. Both stercobilinogen and stercobilin are then excreted in the stool, contributing to its brown colour. Blockage to the biliary system results in reduced stercobilinogen in the stool, and the stools become pale. A small amount of stercobilinogen (4 mg/day) is absorbed from the bowel, passes through the liver and is excreted in the urine, where it is known as urobilinogen or, following further oxidation, urobilin. The liver secretes 1–2 L of bile daily. Bile contains bile acids (formed from cholesterol), phospholipids, bilirubin and cholesterol. Several biliary transporter proteins have now been identified that are involved in transporting bilirubin and bile acids from the hepato-

Fig. 23.7 Biliary transporter proteins. On the hepatocyte basolateral membrane, NTCP (sodium taurocholate cotransporting polypeptide) mediates uptake of conjugated bile acids from portal blood. At the canalicular membrane, these bile acids are secreted via BSEP (bile salt export pump) into bile. MDR3 (multidrug resistance protein 3), also situated on the canalicular membrane, transports phospholipid to the outer side of the membrane. This solubilises bile acids, forming micelles and protecting bile duct membranes from bile salt damage. FIC1 (familial intrahepatic cholestasis 1) moves phosphatidylserine from the inside to the outside of the canalicular membrane; mutations result in familial cholestasis syndrome in childhood. MDR2 (multidrug resistance 2) regulates transport of glutathione. MRP2 (multidrug resistance protein 2) transports bilirubin and is induced by rifampicin. OATP (organic anion transporter protein) transports bilirubin and organic anions.

cyte and into the biliary system (Fig. 23.7). Mutations in the genes encoding these proteins have been identified in inherited intrahepatic biliary diseases presenting in childhood, as well as in adult-onset disease such as intrahepatic cholestasis of pregnancy and gallstone formation.

Storage of vitamins and minerals

Vitamins A, D and B₁₂ are stored by the liver in large amounts, while others, such as vitamin K and folate, are stored in smaller amounts and disappear rapidly if dietary intake is reduced. The liver is also able to metabolise vitamins to more active compounds, e.g. 7-dehydrocholesterol to 25(OH) vitamin D. Vitamin K is a fat-soluble vitamin and so the inability to absorb fat-soluble vitamins, as occurs in biliary obstruction, results in a coagulopathy. The liver also stores minerals such as iron, in ferritin and haemosiderin, and copper, which is excreted in bile.

Immune regulation

Approximately 9% of the normal liver is composed of immune cells (see Fig. 23.3). Cells of the innate immune system include Kupffer cells derived from blood monocytes (4%), the liver macrophages and natural killer (NK) cells (2.5%), as well as B and T cells of the adaptive immune response (p. 74). Kupffer cells constitute the largest single mass of tissue-resident macrophages in the body and account for 80% of the phagocytic capacity of this system. They remove aged and damaged red blood cells, bacteria, viruses, antigen-antibody complexes and endotoxin. In addition, they are able to produce a wide variety of inflammatory mediators that can act locally or may be released into the systemic circulation.

The immunological environment of the liver is unique in that antigens presented within it tend to induce immunological tolerance. This is of importance in liver transplantation, where classical major histocompatibility (MHC) barriers may be crossed, and also in chronic viral infections, when immune responses may be attenuated. The mechanisms which underlie this phenomenon have not been fully defined but include a significant role for the liver sinusoidal endothelial cells, which may present antigen to T cells, as well as specialist innate subsets within the organ.

INVESTIGATION OF HEPATOBILIARY DISEASE

The aims of investigation in patients with suspected liver disease are shown in Box 23.1.

Liver function tests

Liver function tests (LFTs) include the measurement of serum bilirubin, aminotransferases, alkaline phosphatase, gamma-glutamyl transferase and albumin. Most analytes measured by LFTs are not truly 'function' tests, but rather provide biochemical markers of liver cell damage. Liver function is best assessed by the serum albumin, prothrombin time and bilirubin. Although abnormalities on LFTs are often non-specific, the patterns are frequently helpful in directing further investigations. Also levels of bilirubin, albumin and the prothrombin are related to clinical outcome in patients with severe liver disease, reflected by their use in several prognostic scores: the Child-Pugh and MELD score in cirrhosis (see Boxes 23.29 and 23.31, p. 945), the Maddrey score in alcoholic hepatitis (see Box 23.49, p. 956) and the King's College Hospital criteria for liver transplantation in acute liver failure (see Box 23.16, p. 935).

Bilirubin and albumin

The degree of elevation of bilirubin reflects the degree of liver damage. A raised bilirubin often occurs earlier in the natural history of biliary disease (e.g. primary biliary cirrhosis) than in disease of the liver parenchyma (e.g. cirrhosis) where the hepatocytes are primarily involved.

Serum albumin levels are often reduced in patients with liver disease. This is due to a change in the volume of distribution of albumin, as well as a reduction in synthesis. Since the plasma half-life of albumin is about 2 weeks, serum albumin levels may be normal in acute liver failure but are almost always reduced in chronic liver failure.

23.1 Aims of investigations in patients with suspected liver disease

- Detect hepatic abnormality
- Measure the severity of liver damage
- Detect the pattern of liver function test abnormality: hepatic or obstructive/cholestatic
- Identify the specific cause
- Investigate possible complications

Alanine aminotransferase and aspartate aminotransferase

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) normally transfer the amino group from an amino acid—alanine in the case of ALT and aspartate in the case of AST—to a ketoacid, producing pyruvate and oxalo-acetate respectively. Both ALT and AST are located in the cytoplasm of the hepatocyte; AST is also located in the hepatocyte mitochondria. Although both transaminase enzymes are widely distributed, expression of ALT outside the liver is relatively low and therefore this enzyme is considered more specific for hepatocellular damage. Large increases of aminotransferase activity favour hepatocellular damage, and this pattern of LFT abnormality is known as 'hepatic'.

Alkaline phosphatase and gamma-glutamyl transferase

Alkaline phosphatase (ALP) is the collective name given to several different enzymes that are capable of hydrolysing phosphate esters at alkaline pH. These enzymes are widely distributed in the body, but the main sites of production are the liver, gastrointestinal tract, bone, placenta and kidney. ALPs are post-translationally modified, resulting in the production of several different isoenzymes which differ in abundance in different tissues. ALP enzymes in the liver are located in cell membranes of the hepatic sinusoids and the biliary canaliculi. Accordingly, levels rise with intrahepatic and extrahepatic biliary obstruction and with sinusoidal obstruction, as occurs in infiltrative liver disease.

Gamma-glutamyl transferase (GGT) is a microsomal enzyme found in many cells and tissues of the body. The highest concentrations are found in the liver, where it is produced by hepatocytes and by the epithelium lining small bile ducts. The function of GGT is to transfer glutamyl groups from gamma-glutamyl peptides to other peptides and amino acids.

The pattern of a modest increase in aminotransferase activity and large increases in ALP and GGT activity favours biliary obstruction and is commonly described as 'cholestatic' or 'obstructive' (Box 23.2). Isolated elevation of the serum GGT is relatively common, and may occur during ingestion of microsomal enzyme-inducing drugs (Box 23.3), including alcohol.

Other biochemical tests

Other widely available biochemical tests may become altered in patients with liver disease:

- Hyponatraemia occurs in severe liver disease due to increased production of antidiuretic hormone (ADH) (p. 944).

23.2 'Hepatic' and 'cholestatic'/'obstructive' LFTs

Pattern	AST/ALT	GGT	ALP
Biliary obstruction	↑	↑↑	↑↑↑
Hepatitis	↑↑↑	↑	↑
Alcohol/enzyme-inducing drugs	N/↑	↑↑	N

N = normal; ↑ mild elevation (< twice normal); ↑↑ moderate elevation (2–5 times normal); ↑↑↑ marked elevation (> 5 times normal).

23.3 Drugs that increase levels of GGT

- Barbiturates
- Carbamazepine
- Ethanol
- Griseofulvin
- Isoniazid
- Rifampicin
- Phenytoin

- Serum urea may be reduced in hepatic failure, whereas levels of urea may be increased following gastrointestinal haemorrhage.
- When high levels of urea are accompanied by raised bilirubin, high serum creatinine and low urinary sodium, this suggests hepatorenal failure, which carries a grave prognosis.

Haematological tests

Routine haematology

Routine haematological investigations are often abnormal in patients with liver disease and can give a clue to the underlying diagnosis:

- *A normochromic normocytic anaemia* may reflect recent gastrointestinal haemorrhage, whereas chronic blood loss is characterised by a hypochromic microcytic anaemia secondary to iron deficiency. A high erythrocyte mean cell volume (macrocytosis) is associated with alcohol misuse, but target cells in any jaundiced patient also result in a macrocytosis.
- *Leucopenia* may complicate portal hypertension and hypersplenism, whereas leucocytosis may occur with cholangitis, alcoholic hepatitis and hepatic abscesses. Atypical lymphocytes are seen in infectious mononucleosis, which may be complicated by an acute hepatitis.
- *Thrombocytopenia* is common in cirrhosis and is due to reduced platelet production, and increased breakdown because of hypersplenism. Thrombopoietin, required for platelet production, is produced in the liver and levels fall with worsening liver function. Thus platelet levels are usually more depressed than white cells and haemoglobin in the presence of hypersplenism in patients with cirrhosis. A low platelet count is often an indicator of chronic liver disease, particularly in the context of hepatomegaly. Thrombocytosis is unusual in patients with liver disease but may occur in those with active gastrointestinal haemorrhage and, rarely, in association with hepatocellular carcinoma.

Coagulation tests

Tests of the coagulation system are often abnormal in patients with liver disease. The normal half-lives of the vitamin K-dependent coagulation factors in the blood are short (5–72 hours) and so changes in the prothrombin time occur relatively quickly following liver damage; these changes provide valuable prognostic information in patients with both acute and chronic liver failure. An increased prothrombin time is evidence of severe liver damage in chronic liver disease. Vitamin K does not reverse this deficiency if it is due to liver disease, but will reverse the prothrombin time if due to vitamin K deficiency, as may occur with biliary obstruction due to non-absorption of fat-soluble vitamins.

23.4 Chronic liver disease screen

- Hepatitis B surface antigen
- Hepatitis C antibody
- Liver autoantibodies (antinuclear factor, smooth muscle antibody, antimitochondrial antibody)
- Immunoglobulins
- Ferritin
- α_1 -antitrypsin
- Caeruloplasmin

Immunological tests

A variety of immunological tests, often known as a 'chronic liver disease screen' (Box 23.4), are available to evaluate the aetiology of hepatic disease (Box 23.5). These are discussed in more detail under specific diseases later in this chapter. In certain clinical situations, positive blood tests may require further assessment by performing a liver biopsy to confirm the diagnosis and assess the degree of liver scarring.

Radiological imaging

Several imaging techniques can be used to determine the site and general nature of structural lesions in the liver and biliary tree.

Ultrasound

Ultrasound is a non-invasive technique most commonly used to identify gallstones (Fig. 23.8) and biliary obstruction. It is also very useful in the initial assessment of patients with liver disease to determine whether further, more invasive investigations are required. Ultrasound is good for the identification of splenomegaly and abnormalities in liver texture, but is less effective at identifying diffuse parenchymal disease. Focal lesions, such as

Fig. 23.8 Ultrasound showing a stone in the gallbladder. Stone (arrow) with acoustic shadow (S).

23.5 How to identify the cause of LFT abnormality

Diagnosis	Clinical clue	Initial test	Additional tests
Alcoholic liver disease	History	LFTs AST > ALT; high MCV	Random blood alcohol
Non-alcoholic fatty liver disease (NAFLD)	Metabolic syndrome (central obesity, diabetes, hypertension)	LFTs	Liver biopsy
Chronic hepatitis B	Injection drug use; blood transfusion	HBsAg	HBeAg, HBeAb HBV-DNA HCV-RNA
Chronic hepatitis C		HCV antibody	
Primary biliary cirrhosis	Itching; raised ALP	AMA	Liver biopsy
Primary sclerosing cholangitis	Inflammatory bowel disease	MRCP	ANCA
Autoimmune hepatitis	Other autoimmune diseases	ASMA, ANA, LKM, immunoglobulin	Liver biopsy
Haemochromatosis	Diabetes/joint pain	Transferrin saturation, ferritin	HFE gene test
Wilson's disease	Neurological signs; haemolysis	Caeruloplasmin	24-hr urinary copper
α_1-antitrypsin	Lung disease	α_1 -antitrypsin level	α_1 -antitrypsin genotype
Drug-induced liver disease	Drug/herbal remedy history	LFTs	Liver biopsy
Coeliac disease	Malabsorption	Endomysial antibody	Small bowel biopsy

(ALP = alkaline phosphatase; ALT = alanine aminotransferase; AMA = antimitochondrial antibody; ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibodies; ASMA = anti-smooth muscle antibody; AST = aspartate aminotransferase; HBeAb = antibody to hepatitis B e antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; LKM = liver-kidney microsomal antibody; MCV = mean cell volume; MRCP = magnetic resonance cholangiopancreatography)

tumours, may not be detected unless they are more than 2 cm in diameter and have echogenic characteristics sufficiently different from normal liver tissue. Colour Doppler ultrasound allows blood flow in the hepatic artery, portal vein and hepatic veins to be investigated. Endoscopic and laparoscopic ultrasound provides high-resolution images of the pancreas, biliary tree and liver.

Computed tomography and magnetic resonance imaging

Computed tomography (CT) can be used for the same purpose as ultrasound but detects smaller focal lesions in the liver, especially when combined with contrast injection (Fig. 23.9). Magnetic resonance imaging (MRI) can also be

Fig. 23.9 CT scan in a patient with cirrhosis. The liver is small and has an irregular outline (black arrow), the spleen is enlarged (long white arrow), fluid (ascites) is seen around the liver, and collateral vessels are present around the proximal stomach (short white arrow).

used to localise and confirm the aetiology of focal liver lesions, particularly primary and secondary tumours.

Hepatic angiography is seldom used nowadays as a diagnostic tool, since CT and MRI are both able to provide images of hepatic vasculature, but it still has a therapeutic role in the embolisation of vascular tumours such as hepatoma. Hepatic venography is also rarely performed, but may be necessary to image the hepatic veins further in patients with suspected hepatic venous outflow obstruction (Budd–Chiari syndrome, p. 973).

Cholangiography

Cholangiography can be undertaken by magnetic resonance cholangiopancreatography (MRCP, Fig 23.10)

Fig. 23.10 MRCP showing a cholangiocarcinoma in the distal common bile duct (C). The proximal common bile duct (B) is dilated but the pancreatic duct (P) is normal.

Fig. 23.11 ERCP showing the normal biliary (B) and pancreatic (P) duct system.

endoscopy (endoscopic retrograde cholangiopancreatography, ERCP, Fig 23.11) or the percutaneous approach (percutaneous transhepatic cholangiography, PTC). The latter does not allow the ampulla of Vater or pancreatic duct to be visualised. MRCP is as good as ERCP at providing images of the biliary tree but has fewer complications and is the diagnostic test of choice. Both endoscopic and percutaneous approaches allow therapeutic interventions such as the insertion of biliary stents across malignant bile duct strictures. The percutaneous approach is only used if it is not possible to access the bile duct endoscopically.

Liver biopsy

An ultrasound-guided liver biopsy can confirm the severity of liver damage and provide aetiological information; it is performed percutaneously with a Trucut or Menghini needle, usually through an intercostal space, under local anaesthesia.

Percutaneous liver biopsy is a relatively safe procedure if the conditions detailed in Box 23.6 are met, but carries a mortality of about 0.01% and should never be undertaken lightly. The main complications are abdominal and/or shoulder pain, bleeding and biliary peritonitis. Biliary peritonitis is rare and usually occurs when a biopsy is performed in a patient with obstruction of a large bile duct. Liver biopsies can be carried out in patients with defective haemostasis if:

- the defect is corrected with fresh frozen plasma and platelet transfusion

23.6 Conditions required for safe percutaneous liver biopsy

- Cooperative patient
- Prothrombin time < 4 seconds prolonged
- Platelet count > $80 \times 10^9/L$
- Exclusion of bile duct obstruction, localised skin infection, advanced chronic obstructive pulmonary disease, marked ascites and severe anaemia

- the biopsy is obtained by the transjugular route, *or*
- the procedure is conducted percutaneously under ultrasound control and the needle track is then plugged with procoagulant material.

In patients with potentially resectable malignancy, biopsy should be avoided due to the potential risk of tumour dissemination. Operative or laparoscopic liver biopsy may sometimes be valuable.

Histological assessment of liver biopsy tissue is enhanced by discussion between clinicians and pathologists. Although the pathological features of liver disease are complex with several features occurring together, liver disorders can be broadly classified histologically into fatty liver (steatosis), hepatitis and cirrhosis. The use of special histological stains can help in determining the aetiology of liver disorders. The clinical features and prognosis of these changes are dependent on the underlying aetiology, and are discussed in the relevant sections below.

Non-invasive markers of hepatic fibrosis

Non-invasive markers of liver fibrosis have been developed and can obviate the need for liver biopsy when it is being used to evaluate progression of liver fibrosis or where the underlying diagnosis, such as hepatitis C or non-alcoholic fatty liver disease, is clear.

Serological markers of hepatic fibrosis, such as procollagen-type peptide and metalloproteinases (see Fig. 23.4, p. 924), are used in the 'Fibrotest'. The ELF (European Liver Fibrosis) serological assay uses a combination of hyaluronic acid, procollagen peptide III (PIIINP) and tissue inhibitor of metalloproteinase 1 (TIMP1). All these tests are good at differentiating severe fibrosis from mild scarring, but are limited in their ability to detect subtle changes.

An alternative to serological markers is the 'Fibroscan' test, in which ultrasound-based shock waves are sent through the liver, allowing hepatic fibrosis to be detected and quantitated.

PRESENTING PROBLEMS IN LIVER DISEASE

Liver injury may be either acute or chronic. The main causes are listed in Figure 23.12 and discussed in detail later in the chapter.

Acute liver injury	Chronic liver injury
Viral hepatitis (A, B, E)	Chronic viral hepatitis (B + C)
Alcoholic liver disease*	Alcoholic liver disease*
Drugs	NAFLD Haemochromatosis Wilson's disease α_1 -antitrypsin deficiency Cryptogenic (unknown)
Autoimmune hepatitis*	Autoimmune hepatitis*
	PBC PSC

Fig. 23.12 Causes of acute and chronic liver injury. *Although there is often evidence of chronic liver disease at presentation, may present acutely with jaundice. In alcoholic liver disease this is due to superimposed alcoholic hepatitis (NAFLD = non-alcoholic fatty liver disease; PBC = primary biliary cirrhosis; PSC = primary sclerosing cholangitis).

- *Acute liver injury* may present with non-specific symptoms of fatigue and abnormal LFTs, or with jaundice and acute liver failure.
- *Chronic liver injury* is defined as hepatic injury, inflammation and/or fibrosis occurring in the liver for more than 6 months. In the early stages patients can be asymptomatic with abnormal LFTs. With more severe liver damage, however, the presentation can be with jaundice, portal hypertension or other signs of cirrhosis (Box 23.7).

Abnormal liver function tests

Frequently, LFTs are requested in patients who have no symptoms or signs of liver disease, as part of routine health checks, insurance medicals and drug monitoring. When abnormal results are found, it is important for the clinician to be able to interpret them and to investigate patients appropriately. Many patients with chronic liver disease are asymptomatic or have vague non-specific symptoms. Since effective medical treatments are now available for many types of chronic liver disease, further evaluation is often warranted to make sure the patient does not have a treatable condition. Indeed, when thorough investigations are performed, the majority of

patients with abnormal LFTs will be found to have significant liver disease that merits treatment or follow-up, whereas those who do not have significant disease can be reassured and safely discharged.

Asymptomatic abnormal LFTs are quite common. When LFTs are measured routinely prior to elective surgery, 3.5% of patients have elevated transaminase concentrations and 0.3% have values greater than twice normal. The prevalence of abnormal LFTs has been reported to be as high as 10% in some studies. Although transient mild abnormalities in LFTs are seldom clinically significant, the majority of patients with persistently abnormal LFTs have significant liver disease. The most common abnormality is alcoholic or non-alcoholic fatty liver disease (pp. 954–958).

When abnormal LFTs are detected, a thorough history should be taken to determine the patient's alcohol consumption, drug use (prescribed or otherwise), risk factors for viral hepatitis (e.g. blood transfusion, injection drug use), the presence of autoimmune diseases, family history, neurological symptoms, and the presence of diabetes and/or obesity (see Box 23.5). Surprisingly, the presence or absence of stigmata of chronic liver disease (pp. 920 and 943) does not reliably identify patients with significant chronic liver disease, and further investigations may be indicated, even in absence of these signs.

Most hepatologists investigate patients with LFTs that are greater than twice the normal range. Both the pattern of LFT abnormality, hepatic or obstructive, and the degree of elevation are helpful in determining the cause of underlying liver disease (Boxes 23.8 and 23.9). The investigations that make up a standard liver screen and additional or confirmatory tests are shown in Boxes 23.4 and 23.5. An algorithm for investigating abnormal LFTs is provided in Figure 23.13.

Jaundice

Jaundice is usually detectable clinically when the plasma bilirubin exceeds 50 $\mu\text{mol/L}$ ($\sim 3 \text{ mg/dL}$). The causes of jaundice overlap with the causes of abnormal LFTs, discussed above. In a patient with jaundice it is useful to consider whether the cause might be pre-hepatic, hepatic or post-hepatic.

23.7 Presentation of liver disease

Severity	Acute liver injury	Chronic liver injury
Mild/moderate	Abnormal LFTs	Abnormal LFTs
Severe	Jaundice	Signs of cirrhosis \pm portal hypertension
Very severe	Acute liver failure	Chronic liver failure* Jaundice Ascites Hepatic encephalopathy Portal hypertension with variceal bleeding

*May not occur until several years after cirrhosis has presented.

23.8 Common causes of elevated serum transaminases

Minor elevation (< 100 U/L)

- Chronic hepatitis C
- Chronic hepatitis B
- Haemochromatosis
- Fatty liver disease

Moderate elevation (100–300 U/L)

As above plus:

- Alcoholic hepatitis
- Non-alcoholic steatohepatitis
- Autoimmune hepatitis
- Wilson's disease

Major elevation (> 300 U/L)

- Drugs (e.g. paracetamol)
- Acute viral hepatitis
- Autoimmune liver disease
- Ischaemic liver
- Toxins (e.g. *Amanita phalloides* poisoning)
- Flare of chronic hepatitis B

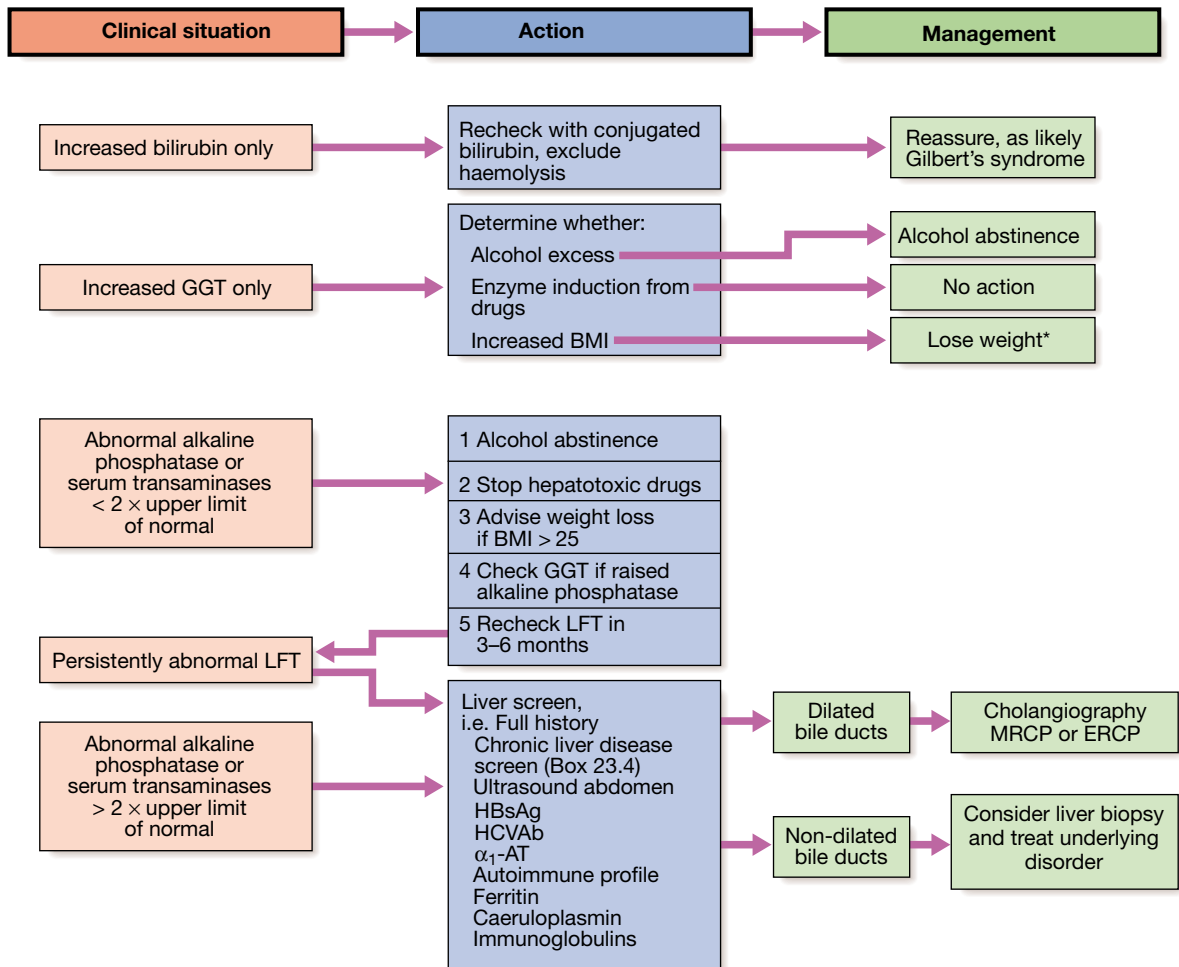

Fig. 23.13 Suggested management of abnormal LFTs in asymptomatic patients. *No further investigation needed.

23

23.9 Causes of cholestatic jaundice

Intrahepatic

- Primary biliary cirrhosis
- Primary sclerosing cholangitis
- Alcohol
- Drugs
- Cystic fibrosis
- Severe bacterial infections
- Hepatic infiltrations (lymphoma, granuloma, amyloid, metastases)
- Pregnancy (p. 975)
- Inherited cholestatic liver disease, e.g. benign recurrent intrahepatic cholestasis
- Chronic right heart failure

Extrahepatic

- Carcinoma
 - Ampullary
 - Pancreatic
 - Bile duct (cholangiocarcinoma)
 - Liver metastases
- Cholelithiasis
- Parasitic infection
- Traumatic biliary strictures
- Chronic pancreatitis

Pre-hepatic jaundice

This is caused either by haemolysis or by congenital hyperbilirubinaemia, and is characterised by an isolated raised bilirubin level.

- In haemolysis, destruction of red blood cells or their precursors in the marrow causes increased bilirubin production. Jaundice due to haemolysis is usually mild because a healthy liver can excrete a bilirubin load six times greater than normal before unconjugated bilirubin accumulates in the plasma. This does not apply to the newborn, who have a reduced capacity to metabolise bilirubin.
- The most common form of non-haemolytic hyperbilirubinaemia is Gilbert's syndrome, an inherited disorder of bilirubin metabolism (Box 23.10). Other inherited disorders of bilirubin metabolism also exist but they are very rare.

Hepatocellular jaundice

Hepatocellular jaundice results from an inability of the liver to transport bilirubin across the hepatocyte into

23.10 Congenital non-haemolytic hyperbilirubinaemia

Syndrome	Inheritance	Abnormality	Clinical features/treatment
Unconjugated hyperbilirubinaemia			
Gilbert's	Autosomal dominant	↓ Glucuronyl transferase ↓ Bilirubin uptake	Mild jaundice, especially with fasting No treatment necessary
Crigler–Najjar			
Type I	Autosomal recessive	Absent glucuronyl transferase	Rapid death in neonate (kernicterus)
Type II	Autosomal dominant	↓ ↓ Glucuronyl transferase	Presents in neonate Phenobarbital, ultraviolet light or liver transplant as treatment
Conjugated hyperbilirubinaemia			
Dubin–Johnson	Autosomal recessive	↓ Canalicular excretion of organic anions, including bilirubin	Mild No treatment necessary
Rotor's	Autosomal recessive	↓ Bilirubin uptake ↓ Intrahepatic binding	Mild No treatment necessary

the bile, occurring as a consequence of parenchymal liver disease. Bilirubin transport across the hepatocytes may be impaired at any point between uptake of unconjugated bilirubin into the cells and transport of conjugated bilirubin into the canaliculi. In addition, swelling of cells and oedema resulting from the disease itself may cause obstruction of the biliary canaliculi. In hepatocellular jaundice the concentrations of both unconjugated and conjugated bilirubin in the blood increase. Hepatocellular jaundice can be due to acute or chronic liver injury (see Fig. 23.12), and clinical features of acute or chronic liver disease may be detected clinically (see Box 23.7, p. 930).

Characteristically, jaundice due to parenchymal liver disease is associated with increases in transaminases (AST, ALT), but increases in other LFTs, including cholestatic enzymes (GGT, ALP) may occur, and suggest specific aetiologies (see below). Acute jaundice in the presence of AST > 1000 U/L is highly suggestive of an infectious cause (e.g. hepatitis A, B), drugs (e.g. paracetamol) or hepatic ischaemia. Imaging is essential, in particular to identify features suggestive of cirrhosis (e.g. irregular liver outline, splenomegaly), to define the patency of hepatic arteries and veins, and of the portal vein, and to obtain evidence of portal hypertension. Liver biopsy has an important role in defining the aetiology of hepatocellular jaundice and the extent of established liver injury.

Obstructive (cholestatic) jaundice

Cholestatic jaundice may be caused by:

- failure of hepatocytes to initiate bile flow
- obstruction of bile flow in the bile ducts or portal tracts
- obstruction of bile flow in the extrahepatic bile ducts between the porta hepatis and the papilla of Vater.

In the absence of treatment, cholestatic jaundice tends to become progressively more severe because conjugated bilirubin is unable to enter the bile canaliculi and passes back into the blood, and also because there is a failure of clearance of unconjugated bilirubin arriving at the liver cells. The causes of cholestatic jaundice are listed in Box 23.9. Cholestasis may result from defects at more than one of these levels. Those confined to the extrahepatic bile ducts may be amenable to surgical correction.

Clinical features in cholestatic jaundice (Box 23.11) comprise those due to cholestasis itself, those due to secondary infection (cholangitis) and those of the underlying condition (Box 23.12). Obstruction of the bile duct drainage due to blockage of the extrahepatic biliary tree is characteristically associated with pale stools and dark urine. Pruritus may be a dominant feature, and can be accompanied by skin excoriations. Peripheral stigmata of chronic liver disease are absent. If the gallbladder is palpable, the jaundice is unlikely to be caused by biliary obstruction due to gallstones, probably because a chronically inflamed stone-containing gallbladder cannot readily dilate. This is Courvoisier's Law, and suggests that jaundice is due to a malignant biliary obstruction (e.g. pancreatic cancer). Cholangitis is characterised by 'Charcot's triad' of jaundice, right upper quadrant pain and fever. Cholestatic jaundice is characterised by a relatively greater elevation of ALP and GGT than the aminotransferases.

Ultrasound evaluation is indicated in all cases to determine whether there is evidence of mechanical obstruction and dilatation of the biliary tree (Fig. 23.14). Management of cholestatic jaundice depends on the

23.11 Clinical features and complications of cholestatic jaundice

Cholestasis

Early features

- Jaundice
- Dark urine
- Pale stools
- Pruritus

Late features

- Malabsorption (vitamins A, D, E and K)
- Xanthelasma and xanthomas
- Weight loss
- Steatorrhoea
- Osteomalacia
- Bleeding tendency

Cholangitis

- Fever
- Rigors
- Pain (if gallstones are present)

23.12 Clinical features suggesting an underlying cause of cholestatic jaundice*	
Clinical feature	Causes
Jaundice	
Static or increasing	Carcinoma Primary biliary cirrhosis Primary sclerosing cholangitis
Fluctuating	Choledocholithiasis Stricture Pancreatitis Choledochal cyst Primary sclerosing cholangitis
Abdominal pain	Choledocholithiasis Pancreatitis Choledochal cyst
Cholangitis	Stone Stricture Choledochal cyst
Abdominal scar	Stone Stricture
Irregular hepatomegaly Palpable gallbladder	Hepatic carcinoma Carcinoma below cystic duct (usually pancreas)
Abdominal mass	Carcinoma Pancreatitis (cyst) Choledochal cyst
Occult blood in stools	Ampullary tumour
*Each of the diseases listed here can give rise to almost any of the clinical features shown, but the box indicates the most likely cause of the clinical features listed.	

underlying cause of the cholestasis and is discussed in detail in the relevant sections below.

Acute liver failure

Acute liver failure is an uncommon but serious syndrome. The presentation is with mental changes progressing from confusion to stupor and coma, and a progressive deterioration in liver function. The syndrome was originally defined further as occurring within 8 weeks of onset of the precipitating illness, in the absence of evidence of pre-existing liver disease. This distinguishes it from instances in which hepatic encephalopathy represents a deterioration in chronic liver disease. More recently, newer classifications have been developed to reflect differences in presentation and outcome of acute liver failure. One such classification divides acute liver failure into hyperacute, acute and subacute according to the interval between onset of jaundice and encephalopathy (Box 23.13).

Pathophysiology

Any cause of liver damage can produce acute liver failure, provided it is sufficiently severe (Fig. 23.15). Acute viral hepatitis is the most common cause world-wide, whereas paracetamol toxicity (p. 209) is the most frequent cause in the UK. Acute liver failure occurs occasionally with other drugs, or from *Amanita phalloides* (mushroom) poisoning,

in pregnancy, in Wilson's disease, following shock (p. 186) and, rarely, in extensive malignant disease of the liver. In 10% of cases the cause of acute liver failure remains unknown and these patients are often labelled as having non-A-E viral hepatitis or cryptogenic acute liver failure.

Clinical assessment

Cerebral disturbance (hepatic encephalopathy) is the cardinal manifestation of acute liver failure, but in the early stages this can be mild and episodic. The initial clinical features are often subtle and include reduced alertness and poor concentration, progressing through behavioural abnormalities such as restlessness and aggressive outbursts, to drowsiness and coma (Box 23.14). Cerebral oedema may occur due to increased intracranial pressure causing unequal or abnormally reacting pupils, fixed pupils, hypertensive episodes, bradycardia, hyperventilation, profuse sweating, local or general myoclonus, focal fits or decerebrate posturing. Papilloedema occurs rarely and is a late sign. More general symptoms include weakness, nausea and vomiting. Right hypochondrial discomfort is an occasional feature.

The patient is usually jaundiced, except in Reye's syndrome when jaundice is rare. Occasionally, death may occur in fulminant cases of acute liver failure before jaundice develops. Feto hepaticus can be present. The liver is usually of normal size but later becomes smaller. Hepatomegaly is unusual and, in the presence of a sudden onset of ascites, suggests venous outflow obstruction as the cause (Budd-Chiari syndrome). Splenomegaly is uncommon and never prominent. Ascites and oedema are late developments and may be a consequence of fluid therapy. Other features are related to the development of complications, which are considered below.

23.13 Classification of acute liver failure			
Type	Time: jaundice to encephalopathy	Cerebral oedema	Common causes
Hyperacute	< 7 days	Common	Viral, paracetamol
Acute	8–28 days	Common	Cryptogenic, drugs
Subacute	29 days–12 weeks	Uncommon	Cryptogenic, drugs

23.14 How to grade hepatic encephalopathy clinically	
Clinical grade	Clinical signs
Grade 1	Poor concentration, slurred speech, slow mentation, disordered sleep rhythm
Grade 2	Drowsy but easily rousable, occasional aggressive behaviour, lethargic
Grade 3	Marked confusion, drowsy, sleepy but responds to pain and voice, gross disorientation
Grade 4	Unresponsive to voice, may or may not respond to painful stimuli, unconscious

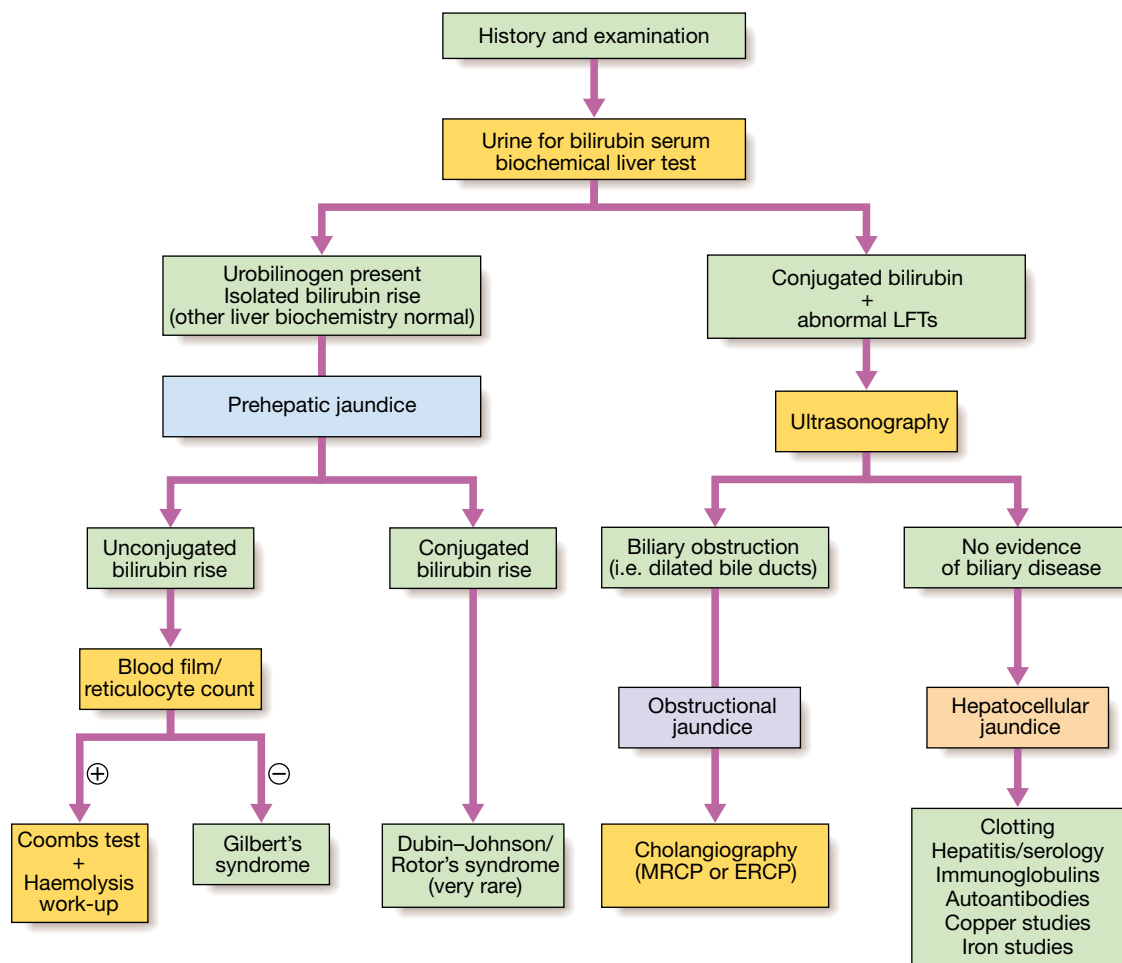

Fig. 23.14 Investigation of jaundice.

Fig. 23.15 Causes of acute liver failure in the UK. The relative frequency of the different causes varies according to geographical area.

Investigations

The patient should be investigated to determine the cause of the liver failure and the prognosis (Boxes 23.15 and 23.16). Hepatitis B core IgM antibody is the best screening test for acute hepatitis B infection, as liver damage is due to the immunological response to the virus which has often been eliminated and the test for HBsAg may be negative. The prothrombin time rapidly becomes prolonged as coagulation factor synthesis fails; this is the laboratory test of greatest prognostic value and should be carried out at least twice daily. Its prognostic importance emphasises the necessity of avoiding the use of fresh frozen plasma to correct raised prothrombin time in acute liver failure, except in the setting of frank bleeding. Factor V levels can be used instead of the prothrombin time to assess the degree of liver impairment. The plasma bilirubin reflects the degree of jaundice. Plasma aminotransferase activity is particularly high after paracetamol overdose, reaching 100–500 times normal, but falls as liver damage progresses and is not helpful in determining prognosis. Plasma albumin remains normal unless the course

is prolonged. Percutaneous liver biopsy is contraindicated because of the severe coagulopathy, but biopsy can be undertaken using the transjugular route.

Management

Patients with acute liver failure should be treated in a high-dependency or intensive care unit as soon as progressive prolongation of the prothrombin time occurs or hepatic encephalopathy is identified (Box 23.17), so that prompt treatment of complications can be initiated (Box 23.18). Conservative treatment aims to maintain life in the hope that hepatic regeneration will occur, but early transfer to a specialised transplant unit should always be considered. *N*-acetylcysteine therapy may improve outcome, particularly in patients with acute liver failure due to paracetamol poisoning. Liver transplantation is an increasingly important treatment option for acute liver failure, and criteria have been developed to identify patients unlikely to survive without a transplant (see Box 23.16). Patients should, wherever possible, be transferred to a transplant centre before these criteria are met to allow time for assessment and to maximise the time for a donor liver to become available. Survival following liver transplantation for acute liver failure is improving, and 1-year survival rates of about 60% can be expected.

23.15 Investigations to determine the cause of acute liver failure

- Toxicology screen of blood and urine
- HBsAg, IgM anti-HBc
- IgM anti-HAV
- Anti-HEV, HCV, cytomegalovirus, herpes simplex, Epstein–Barr virus
- Ceruloplasmin, serum copper, urinary copper, slit-lamp eye examination
- Autoantibodies: ANF, ASMA, LKM
- Immunoglobulins
- Ultrasound of liver and Doppler of hepatic veins

(ANF = antinuclear factor; ASMA = anti-smooth muscle antibody; LKM = liver-kidney microsomal antibody)

23.16 Adverse prognostic criteria in acute liver failure*

- H^+ > 50 nmol/L (pH < 7.3) at or beyond 24 hours following the overdose
- Serum creatinine > 300 μ mol/L (\approx 3.38 mg/dL) *plus* prothrombin time > 100 seconds *plus* encephalopathy grade 3 or 4

Non-paracetamol cases

- Prothrombin time > 100 seconds
- *or*
- Any three of the following:
 - Jaundice to encephalopathy time > 7 days
 - Age < 10 or > 40 years
 - Indeterminate or drug-induced causes
 - Bilirubin > 300 μ mol/L (\approx 17.6 mg/dL)
 - Prothrombin time > 50 seconds
- *or*
- Factor V level < 15% and encephalopathy grade 3 or 4

*Predict a mortality rate of \geq 90% and are an indication for referral for possible liver transplantation.

23.17 Monitoring in acute liver failure

Neurological

- Intracranial pressure monitoring (specialist units, p. 199)
- Conscious level

Cardiorespiratory

- Pulse
- Blood pressure
- Central venous pressure
- Respiratory rate

Fluid balance

- Hourly output (urine, vomiting, diarrhoea)
- Input: oral, intravenous

Blood analyses

- Arterial blood gases
- Peripheral blood count (including platelets)
- Sodium, potassium, HCO_3^- , calcium, magnesium
- Creatinine, urea
- Glucose (2-hourly in acute phase)
- Prothrombin time

Infection surveillance

- Cultures: blood, urine, throat, sputum, cannula
- Chest X-ray
- Temperature sites

23.18 Complications of acute liver failure

- Encephalopathy and cerebral oedema
- Hypoglycaemia
- Metabolic acidosis
- Infection (bacterial, fungal)
- Renal failure
- Multi-organ failure (hypotension and respiratory failure)

Hepatomegaly

Hepatomegaly may occur as the result of a general enlargement of the liver or because of primary or secondary liver tumour. The most common liver tumour in the West is liver metastasis, whereas primary liver cancer complicating chronic viral hepatitis is more common in the Far East. Unlike metastases, neuro-endocrine tumours typically cause massive hepatomegaly but without significant weight loss. Cirrhosis often presents with hepatomegaly, although in end-stage disease the liver may be reduced in size. Although all causes of cirrhosis can involve hepatomegaly, it is much more common in alcoholic liver disease and haemochromatosis. Hepatomegaly may resolve in patients with alcoholic cirrhosis when they stop drinking.

Ascites

Ascites is present when there is accumulation of free fluid in the peritoneal cavity. Small amounts of ascites are asymptomatic, but with larger accumulations of fluid (> 1 L) there is abdominal distension, fullness in the flanks, shifting dullness on percussion and, when the ascites is marked, a fluid thrill. In obese patients, much larger volumes of ascites may accumulate before they are detectable clinically. Other features include distortion or eversion of the umbilicus, herniae, abdominal striae, divarication of the recti and scrotal oedema. Dilated superficial abdominal veins may be seen if the ascites is due to portal hypertension.

Pathophysiology

Ascites may result from several different causes, the most common of which are malignant disease, cirrhosis or heart failure. Many primary disorders of the peritoneum and visceral organs can also cause ascites, and these need to be considered even in a patient with chronic liver disease (Box 23.19). Splanchnic vasodilata-

tion is thought to be the main factor leading to ascites in cirrhosis. This is mediated by vasodilators (mainly nitric oxide) that are released when portal hypertension causes shunting of blood into the systemic circulation. Systemic arterial pressure falls due to pronounced splanchnic vasodilatation as cirrhosis advances. This leads to activation of the renin-angiotensin system with secondary aldosteronism, increased sympathetic nervous activity, increased atrial natriuretic hormone secretion and altered activity of the kallikrein-kinin system (Fig. 23.16). These systems tend to normalise arterial pressure but produce salt and water retention. In this setting, the combination of splanchnic arterial vasodilatation and portal hypertension alters intestinal capillary permeability, promoting accumulation of fluid within the peritoneum.

Investigations

Ultrasonography is the best means of detecting ascites, particularly in the obese and those with small volumes of fluid. Paracentesis (if necessary under ultrasonic guidance) can also be used to confirm the presence of ascites but is most useful for obtaining ascitic fluid for analysis. The appearance of ascitic fluid may point to the underlying cause (Box 23.20). Pleural effusions are found in about 10% of patients, usually on the right side (hepatic hydrothorax); most are small and only identified on chest X-ray, but occasionally a massive hydrothorax occurs. Pleural effusions, particularly those on the left side, should not be assumed to be due to the ascites.

Measurement of the protein concentration and the serum-ascites albumin gradient (SAAG) are used to
